was described; the process gave only moderately satisfactory yields, owing to the fact that a varying but always a relatively considerable amount of the acid,  $CO_2H \cdot [CH_2]_n \cdot CO_2H$ , was recovered. Underlying this problem, the factors influencing the direction of fission of  $\beta$ -diketones are of fundamental importance, since it is clear that the recovery of the dibasic acid is due to hydrolysis initiated by the stage  $CH_3 \cdot [CH_2]_m \cdot C(CO \cdot CH_3)(CO_2Et) \cdot CO \cdot [CH_2]_n \cdot CO_2Et \rightarrow CH_3 \cdot [CH_2]_m \cdot CH(CO \cdot CH_3) \cdot CO_2Et + CO_2H \cdot [CH_2]_n \cdot CO_2Et$ , which competes with the desired direction of change in which the acetyl group is removed as acetic acid.

An example of such competition of acyl groups in the hydrolysis of  $\beta$ -diketones has been quantitatively studied by Bradley and Robinson (J., 1926, 2356), who found in a series of substituted dibenzoylmethanes,  $R \cdot CO \cdot CH_2 \cdot CO \cdot R'$ , that hydrolysis by alkalis

occurred with production of the stronger of the acids,  $R \cdot CO_2H$  and  $R' \cdot CO_2H$ , in preponderating amount.

This suggested two methods for the improvement of the yields in the keto-acid syntheses, namely, (a) the use of a  $\beta$ -ketonic ester,  $R \cdot CO \cdot CH_2 \cdot CO_2Et$ , such that  $R \cdot CO_2H$  is a stronger acid than acetic acid, and (b) the acylation of a substituted ethyl acetoacetate by the group related to the weakest possible acid; this could clearly be achieved by removing the terminal carboxyl group from the acyl group and introducing it at the end of the alkyl chain. Thus, an acid  $CH_3 \cdot [CH_2]_m \cdot CH_2 \cdot CO \cdot [CH_2]_n \cdot CO_2H$  can be obtained by the hydrolysis of the complexes

$CH_3 \cdot [CH_2]_m \cdot C(CO \cdot CH_3)(CO_2Et) \cdot CO \cdot [CH_2]_n \cdot CO_2Et$   
or  $CO_2Et \cdot [CH_2]_{n-1} \cdot C(CO \cdot CH_3)(CO_2Et) \cdot CO \cdot [CH_2]_{m+1} \cdot CH_3$ , and it was anticipated that the latter method would give the better yield because the dibasic acids are stronger than the fatty acids. In view of the accessibility of ethyl acetoacetate, practical effect has been given to the proposal (b) only, and actually the new process constitutes a great improvement and is applicable to the transformation of an acid  $R \cdot CO_2H$  into  $R \cdot CO \cdot CH_2 \cdot [CH_2]_n \cdot CO_2H$ , the accessory starting points being ethyl acetoacetate and  $Br \cdot [CH_2]_n \cdot CO_2Et$ . It is known (Le Sueur and Withers, J., 1915, 107, 738) that Clemmensen's method (*Ber.*, 1913, 46, 1837) can be advantageously used for the reduction of long-chain keto-acids, so we may proceed from  $R \cdot CO_2H$  to  $R \cdot [CH_2]_{n+2} \cdot CO_2H$  in a few simple stages, and can then repeat the process. The number of carbon atoms added in each stage of extension is limited only by the relative inaccessibility of the required  $\omega$ -bromo-acids, but ethyl  $\omega$ -bromodecoate can be obtained from sebacic acid and ethyl  $\omega$ -bromoundecoate from undecenic acid (Walker and Lumsden, J., 1901, 79, 1191), so an extension of 11 or 12 carbon atoms in each cycle of operations is quite feasible.

It is hoped that this development will be described in subsequent communications, and in the present memoir the conversion of certain acids,  $R \cdot CO_2H$ , into  $\gamma$ -keto-acids,  $R \cdot CO \cdot CH_2 \cdot CH_2 \cdot CO_2H$ , and the related alkylbutyrolactones is recorded.

Undecoic, undecenic and elaidic acids were converted into the chlorides and condensed with the sodium derivative of ethyl aceto-succinate in ethereal solution; the products were hydrolysed by means of dilute aqueous potassium hydroxide, at first in the cold and later on the steam-bath, and good yields of the keto-acids resulted.

By using benzoyl chloride,  $\beta$ -benzoylpropionic acid was obtained in about 41% yield, but  $\beta$ -o-nitrobenzoylpropionic acid could not be prepared by this method. This is in accord with anticipation

based on the theory already mentioned, and, from the same point of view, the failure to prepare a keto-dibasic acid by hydrolysing the ester  $\text{CO}_2\text{Et}\cdot\text{CH}_2\cdot\text{C}(\text{CO}\cdot\text{CH}_3)(\text{CO}_2\text{Et})\cdot\text{CO}\cdot[\text{CH}_2]_8\cdot\text{CO}_2\text{Et}$  is explicable. There is no further reference to these negative results in the experimental section.

The preparation of a diketo-acid succeeded, but, again, the keto-acids are stronger than the fatty acids and, as expected, the yield was poor. For this example, 10-*ketotridecoic acid* was synthesised by an application of the method of Parts I and II; its chloride and ethyl sodioacetosuccinate afforded an ester,

$\text{CH}_3\cdot[\text{CH}_2]_2\cdot\text{CO}\cdot[\text{CH}_2]_8\cdot\text{CO}\cdot\text{C}(\text{CO}\cdot\text{CH}_3)(\text{CO}_2\text{Et})\cdot\text{CH}_2\cdot\text{CO}_2\text{Et}$ , which on hydrolysis gave 4 : 13-*diketopalmitic acid*. This acid is of interest in that, on reduction and dehydration, it should furnish an unsaturated palmitolactone,

which, according to a recent patent (E.P. 292,962 of 1929), has been isolated from female secretory organs, and is claimed to be the physiologically active ovarian hormone.

These statements, in view of the recent remarkable work of Butenandt (compare *Chem.-Ztg.*, 1929, 938) on progynon, must await further confirmation; several authorities have, however, expressed the view that there exists more than one ovarian hormone.

5-*Ketopalmitic acid* has been obtained from lauryl chloride and ethyl sodio- $\alpha$ -acetoglutarate, followed by hydrolysis of the product; the opportunity is taken to describe the 7- and 8-*ketopalmitic acids*, which were obtained by applications of the method of Part I. These substances are the conceivable hydration products of palmitolic acid and have been prepared in connexion with an investigation of the course of that reaction.

#### EXPERIMENTAL.

4-*Ketomyristic Acid*,  $\text{CH}_3\cdot[\text{CH}_2]_9\cdot\text{CO}\cdot[\text{CH}_2]_2\cdot\text{CO}_2\text{H}$ .—Sodium (2.3 g.) was granulated under toluene, washed with ether, and suspended in anhydrous ether (120 c.c.), and ethyl acetosuccinate (21.6 g.) gradually added, the solution of the sodium being completed by heating on the steam-bath for 10 minutes. A solution of undecoyl chloride (obtained from 17.6 g. of the acid by the action of pure thionyl chloride and removal of the excess of the reagent in a vacuum) in ether (20 c.c.) was slowly added to the cooled mixture, which was kept for 12 hours and then refluxed for 10 minutes. The product was isolated and agitated for  $4\frac{1}{2}$  hours with aqueous potassium hydroxide (1200 c.c. of 4%). After acidification with acetic acid and isolation by means of ether, it was submitted to the action of boiling 5% sulphuric acid for 4 hours, and the hydrolysis

was completed by boiling with 8% sodium hydroxide solution for 1 hour. The product crystallised from light petroleum (b. p. 60—80°) in colourless plates (once crystallised; yield, 8.5 g. or 72%), m. p. 87° (Found: C, 69.7; H, 10.7. Calc. for  $C_{14}H_{26}O_3$ : C, 69.4; H, 10.7%) alone or mixed with the specimen previously prepared by another method (Robinson and Robinson, J., 1926, 2204).

$$\begin{array}{c} \text{O} \text{---} \text{CO} \\ | \\ \gamma\text{-n-Decylbutyrolactone, } CH_3 \cdot [CH_2]_9 \cdot CH \cdot CH_2 \cdot CH_2 \end{array}$$

A solution of 4-ketomyristic acid (4 g.) in anhydrous ethyl alcohol (90 g.) was gradually added to sodium (7.5 g.) contained in a flask heated at 150—160°. After 1½ hours, the alcohol was evaporated, and the residue mixed with dilute hydrochloric acid. The product was collected by means of ether, boiled for 30 minutes with 15% hydrochloric acid (120 c.c.) in order to ensure the formation of the lactone from the hydroxy-acid, washed in ethereal solution with aqueous sodium carbonate, freed from the solvent, and crystallised from light petroleum and later from methyl alcohol; it formed long slender needles, m. p. 30—31° (yield, 2.7 g. or 71%) (Found: C, 74.3; H, 11.3.  $C_{14}H_{26}O_2$  requires C, 74.3; H, 11.5%).

5-Ketopalmitic Acid,  $CH_3 \cdot [CH_2]_{10} \cdot CO \cdot [CH_2]_3 \cdot CO_2H$ .—Ethyl sodio-acetosuccinate dissolved in ether when prepared as described above, but ethyl sodio- $\alpha$ -acetylglutarate separated as a colourless powder and the solution of the sodium was thereby hindered.

The reaction in the present case was carried out in the usual manner, sodium (1.4 g.), ether (140 c.c.), ethyl  $\alpha$ -acetylglutarate (13.9 g.), and lauryl chloride (13.0 g.) being used; finally, the mixture was refluxed for 1 hour and the product isolated and shaken with 3% sodium hydroxide solution (850 c.c.) for 12 hours. The mixture was then concentrated on the steam-bath for 1 hour and the acid obtained by addition to ice and hydrochloric acid was crystallised from light petroleum, methyl alcohol and benzene, forming colourless plates, m. p. 88° (Found: C, 71.2; H, 11.2.  $C_{16}H_{30}O_3$  requires C, 71.1; H, 11.1%). On reduction by means of sodium and absolute ethyl alcohol, and treatment of the product with boiling 15% hydrochloric acid, 5-ketopalmitic acid furnished 8-undecylvalerolactone, which crystallised from light petroleum in plates, m. p. 29.5—30.0° (Found: C, 75.5; H, 11.8.  $C_{16}H_{30}O_2$  requires C, 75.6; H, 11.8%).

7-Ketopalmitic Acid,  $CH_3 \cdot [CH_2]_3 \cdot CO \cdot [CH_2]_5 \cdot CO_2H$ .—The condensation product from ethyl sodio- $\alpha$ -acetodecoate (16.5 g. of the ester) and 6-carbethoxyhexoyl chloride (13 g.), prepared in ethereal solution, was isolated and hydrolysed successively by agitation for 5 hours with 3% potassium hydroxide solution (700 c.c.), by boiling with 5% sulphuric acid (500 c.c.) for 24 hours, and, after steam-

distillation for the separation of methyl *n*-nonyl ketone, by boiling with 3½% potassium hydroxide solution for 6 hours. The acid, purified through its sparingly soluble sodium salt (4 g., or 22%) and then by crystallisation from light petroleum and from methyl alcohol, formed colourless plates, m. p. 78° (Found: C, 71·2; H, 11·0.  $C_{16}H_{30}O_3$  requires C, 71·1; H, 11·1%).

*8-Ketopalmitic Acid*,  $CH_3 \cdot [CH_2]_7 \cdot CO \cdot [CH_2]_6 \cdot CO_2H$ .—By an application of the method of Grün and Wirth (*Ber.*, 1922, 55, 2207) for the preparation of ethyl hydrogen sebacate, ethyl suberate (96 g.) gave ethyl hydrogen suberate (49 g.), which furnished 7-carbethoxyheptoyl chloride, b. p. 182°/69 mm. (yield, 85%).

The product from the interaction of ethyl sodio-2-acetononoate (22·8 g. of the ester) and 7-carbethoxyheptoyl chloride (22·2 g.) in dry ether was hydrolysed successively by shaking with 5% potassium hydroxide solution (400 c.c.) for 20 hours, by boiling with 5% sulphuric acid (400 c.c.) for 24 hours, and, after steam distillation, by boiling with 5% sodium hydroxide solution (250 c.c.) for 24 hours. The sodium salt, which separated on cooling, was decomposed; the acid crystallised from methyl alcohol (yield, 5 g. or 18%) in plates, m. p. 77—78° (Found: C, 70·8; H, 11·2.  $C_{16}H_{30}O_3$  requires C, 71·1; H, 11·1%). The oily oxime was converted by sulphuric acid into an amide, m. p. 58°.

The hydration of palmitic acid should yield a mixture of 7- and 8-ketopalmitic acids in which the latter should preponderate, for the reasons explained in Part II (*J.*, 1926, 2205).

The action of sulphuric acid, followed by that of water, on palmitic acid has been studied by Bodenstein (*Ber.*, 1894, 27, 3400), who obtained a ketopalmitic acid, m. p. 74°, the oily oxime of which yielded, on transposition, an amide, m. p. 57·5—58°.

The freezing points of mixtures of 8-ketopalmitic acid and 7-ketopalmitic acid have been determined, and will be published in detail in connexion with a record of experiments on the hydration of palmitic acid. It may be mentioned, however, that the freezing point of a mixture containing 30% of 7-ketopalmitic acid is about 6° lower than that of pure 8-ketopalmitic acid. Since it is certain that the 8-ketopalmitic acid is the major product of the hydration of palmitic acid, it is apparent that the acid obtained by Bodenstein contained at most 30%, and may have contained as little as 10—20%, of the isomeride.

*4-Keto- $\Delta^{13}$ -tetradecenoic Acid*,  $CH_3 \cdot CH \cdot [CH_2]_8 \cdot CO \cdot [CH_2]_2 \cdot CO_2H$ .—The condensation product from ethyl sodioacetosuccinate (21 g. of the ester) and undecenoyl chloride (19·2 g.) was isolated and hydrolysed successively by agitation with 5% potassium hydroxide solution (1000 c.c.) for 8 hours, by boiling with 5% sulphuric acid

(700 c.c.) for 7 hours, and by boiling with 4½% potassium hydroxide solution for 4 hours. The mixture was acidified and steam-distilled in order to remove a little unchanged undecenoic acid; the residual *acid* crystallised from light petroleum in colourless plates, m. p. 79.5° (yield, 14.8 g. or 55%) (Found: C, 69.6; H, 9.7.  $C_{14}H_{24}O_3$  requires C, 70.0; H, 10.0%).

$\gamma$ - $\Delta^9$ -Decenylbutyrolactone was obtained in 89% yield by reducing the acid (6 g.) in anhydrous alcohol (150 g.) with sodium (10 g.) under the usual conditions and subsequent treatment with boiling 15% hydrochloric acid. The lactone crystallised from light petroleum in needles, m. p. 26–27° (Found: C, 74.8; H, 10.7.  $C_{14}H_{24}O_2$  requires C, 75.0; H, 10.7%). A solution in chloroform absorbed bromine, and this lactone is quite different from the decylbutyrolactone previously described.

*trans*-4-Keto- $\Delta^{12}$ -heneicosenoic Acid,

Elaidyl chloride (30.2 g.) and ethyl sodioacetosuccinate (from 21.6 g. of the ester) were brought into reaction in ethereal solution (200 c.c.) in the usual manner and after 12 hours the mixture was boiled for 20 minutes. The product was agitated with 3% potassium hydroxide solution (1000 c.c.) for 8 hours and, after the addition of 30% aqueous potassium hydroxide (25 c.c.), the mixture was boiled for 2 hours. The solid obtained on acidification was crystallised from light petroleum (b. p. 40–60°); after further purification through the sparingly soluble sodium salt and by crystallisation from light petroleum and then from methyl alcohol, the *acid* formed lustrous plates, m. p. 82.5° (yield, 49%) (Found: C, 74.4; H, 11.1.  $C_{21}H_{38}O_3$  requires C, 74.6; H, 11.2%).

$\gamma$ - $\Delta^8$ -Heptadecenylbutyrolactone,

The foregoing acid (9.8 g.), dissolved in absolute alcohol (200 g.), was added in the course of 15 minutes to sodium (15 g.) heated in an oil-bath at 140–150°. The sodium disappeared after 1 hour, and the product was isolated and boiled for 1 hour with 15% hydrochloric acid (180 c.c.). After being washed in ethereal solution with aqueous sodium carbonate, the crude *lactone* was washed with a little light petroleum; it then crystallised from this solvent (b. p. 40–60°) in colourless plates, m. p. 42° (yield, 6.1 g. or 65%) (Found: C, 78.4; H, 11.9.  $C_{21}H_{38}O_2$  requires C, 78.3; H, 11.8%). The unsaturated nature of this substance was confirmed by noting its absorption of bromine in chloroform solution.

10-Ketotridecoic Acid,  $CH_3 \cdot [CH_2]_2 \cdot CO \cdot [CH_2]_8 \cdot CO_2H$ .—Ethyl sodio-2-acetobutyrate (from 31.6 g. of the ester) was prepared in dry ether

(250 c.c.), and 9-carbethoxynonyl chloride (46 g.) gradually added to the solution, which was kept for 12 hours and then refluxed for 20 minutes. The product was hydrolysed in the usual manner with cold 4% potassium hydroxide solution, boiling 6% sulphuric acid, and finally boiling 4% potassium hydroxide solution. The *keto-acid* was separated from sebacic acid by crystallisation from light petroleum, but this was a tedious operation and the yield was poor. The white plates had m. p. 63° (Found: C, 68.6; H, 10.4.  $C_{13}H_{24}O_3$  requires C, 68.4; H, 10.5%).

4 : 13-Diketopalmitic Acid,

10-Ketotridecoic acid (4 g.) was converted into its chloride by the action of thionyl chloride at 60°; decomposition occurred if the temperature was raised; the excess of reagent was removed in a vacuum. The interaction of the chloride with ethyl sodioacetosuccinate (4 g. of the ester) was carried out in the usual manner in dry ethereal solution, and the product was hydrolysed by shaking it for 12 hours with 3% aqueous potassium hydroxide (400 c.c.) and then concentrating the solution on the steam-bath for 1 hour. The *acid* precipitated on acidification crystallised from light petroleum, and then from ethyl acetate, in plates, m. p. 101° (Found: C, 67.7; H, 9.8.  $C_{16}H_{28}O_4$  requires C, 67.6; H, 9.9%).

*β-Benzoylpropionic Acid.*—The applicability of the general method was further confirmed by the preparation of this acid by the usual procedure. The product from ethyl sodioacetosuccinate (12.5 g. of the ester) and benzoyl chloride (8.8 g.) was hydrolysed by cold 1½% aqueous potassium hydroxide (1200 c.c.) for 24 hours, and the solution concentrated on the steam-bath to about 100 c.c. The mixed acids were regenerated and collected and benzoic acid was removed by sublimation at 100°. The residue (4 g.), crystallised from benzene, had m. p. 116°, alone or mixed with a specimen prepared by the action of aluminium chloride on a mixture of benzene and succinic anhydride.

The author wishes to thank Professor R. Robinson for his interest in this investigation.

UNIVERSITY COLLEGE, LONDON.

[Received, February 18th, 1930.]

CII.—*The Constitution of Carthamin. Part I.*

By (Miss) CHIKA KURODA.

CARTHAMIN, the red colouring matter of safflower, was formerly an important dye, and although the demand for it has declined considerably since the advent of artificial colouring matters, the safflower is still cultivated on a large scale, especially in India and China. Notwithstanding its high cost, carthamin is much appreciated in Japan for certain purposes : it is believed to have remarkable medicinal properties.

Malin (*Annalen*, 1840, 36, 117), Preiser (*J. pr. Chem.*, 1844, 32, 142), Schlieper (*Annalen*, 1846, 58, 357), Radcliffe (*J. Soc. Dyers and Col.*, 1897, 13, 158), and Kametaka (*J. Chem. Soc. Tokyo*, 1906, 27, 1202) investigated carthamin, but Kametaka and Perkin (*J.*, 1910, 97, 1415) were the first to isolate it in a pure crystalline condition. Both Preiser and Radcliffe, the latter using methyl alcohol as solvent, claimed to have isolated carthamin in a crystalline form; their descriptions, however, are somewhat contradictory. Kametaka and Perkin found methyl alcohol unsatisfactory as a solvent and obtained crystalline carthamin by using pyridine : they gave it the provisional formula  $C_{25}H_{24}O_{12}$  and obtained *p*-hydroxybenzoic acid (this was first isolated by Malin), *p*-coumaric acid, *p*-hydroxybenzaldehyde, and picric acid from it by various means, but were unable to prepare crystalline derivatives by methylation, benzylation, or acetylation; carthamin, however, gave crystalline additive compounds with aniline and with  $\beta$ -naphthylamine.

The author began an investigation of carthamin in 1924, but owing to the outbreak of civil war in China the supply of the raw material failed. During the last two years, supplies have again been available, and the author is also deeply indebted to Dr. Kametaka, who provided her with material collected in China by Dr. Momoji Yamazaki.

The initial substance used in the present work was a paste (sold as carthamin paste) prepared from the raw material by the traditional method of Japanese manufacturers. The paste was submitted to filtration, and the residue quickly dried on porous tile. The product, when crystallised, with great loss, from pure pyridine by a modification of Kametaka and Perkin's method (*loc. cit.*), gave carthamin, although not in a pure condition. When, however, the dried product was digested with cold dilute hydrochloric acid and again dried, it was converted into a crystalline substance which could be recrystallised from dilute methyl alcohol in good yield,

giving fine, yellow, hydrated needles, m. p. about 228° (decomp.; colour change at about 168°) (Schlieper, *loc. cit.*, obtained from a methyl-alcoholic extract of commercial carthamin a yellow substance, though not in a crystalline form, m. p. about 168°). When the yellow needles were recrystallised from pyridine, a substance separated in red needles with a green iridescence, like those of carthamin obtained by Kametaka and Perkin. Many facts indicate that the red and the yellow substance are isomeric. The latter, named *isocarthamin*, gave analytical results corresponding to the formula  $C_{21}H_{22}O_{11} \cdot 2H_2O$  when freshly prepared and quickly dried, to  $C_{21}H_{22}O_{11}$  after being dried at 60° under reduced pressure, and to  $C_{21}H_{20}O_{10}$  ( $C_{21}H_{22}O_{11} - H_2O$ ) after being dried at 100° under reduced pressure. The last formula also agrees with the analytical data recorded by Kametaka and Perkin (*loc. cit.*, p. 1418).

Carthamin and *isocarthamin* are glucosides. They can be hydrolysed by dilute sulphuric or hydrochloric acid or by emulsin, yielding glucose (1 mol.), but only when the hydrolysis is effected with dilute phosphoric acid can the other components of the glucosides, namely, *carthamidin* and *isocarthamidin*, be ultimately obtained in the crystalline condition. These two substances are separable by means of moist chloroform, in which *isocarthamidin* is insoluble and *carthamidin* is slightly soluble. The latter separates from the solution in pale yellow, hydrated needles,  $C_{15}H_{12}O_6 \cdot H_2O$ , m. p. 218°. *isoCarthamidin* separates from dilute methyl alcohol in yellow, hydrated, rhombic crystals, m. p. 240°, which lose water at 100° under reduced pressure.

Carthamidin and *isocarthamidin* have phenolic properties: they can be acetylated, but are inert towards methyl iodide, methyl sulphate, and diazomethane. When they are reduced in methyl-alcoholic solution with magnesium and hydrochloric acid, they give a magenta coloration, resembling in this respect a flavonol such as quercetin. Their absorption spectra, however, differ from those of the flavonols, and also, on decomposition by alkali, they behave somewhat differently from quercetin in that they easily yield *p*-hydroxybenzaldehyde and *p*-coumaric acid, whereas quercetin under the same conditions gives, not the corresponding aldehyde, but protocatechuic acid. It is interesting that naringin (the glucoside of naringenin), until recently considered to be a hydroxychalcone derivative, develops a red coloration on treatment in methyl-alcoholic solution with magnesium and hydrochloric acid (Tsujimura, *Bull. Inst. Phys. Chem. Res. Tokyo*, Vol. VI, 12, 1111). On the other hand, phloretin, which is closely related to naringenin, gives on treatment with alkali the products mentioned below (Will, *Ber.*, 1885, 18, 1322; Michael, *Ber.*, 1894, 27, 2687;

Sonn, *Ber.*, 1913, 46, 4050; Franck, *Centr.*, 1914, II, 253). Dihydrocarthamin (IX), obtained from carthamin by catalytic reduction, gives phloretic acid when treated with hydrogen peroxide in alkali-carbonate solution. These relationships are shown in the following scheme:

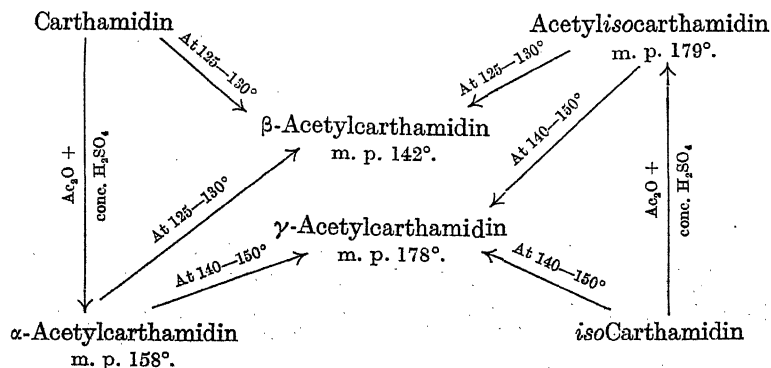

The author has so far been unable to prepare a polyhydroxybenzene from carthamin and its derivatives: only monohydric phenols such as *p*-hydroxybenzaldehyde, tribromophenol, and *p*-hydroxybenzoic, *p*-coumaric, phloretic, and picric acids—and these in poor yield—have been obtained. The following reactions of carthamidin and isocarthamidin, however, indicate, not only the presence of a polyhydroxybenzene nucleus, but also, when compared with similar reactions of di- and tri-hydric phenols of known constitutions (see table on p. 761), the relative positions of the hydroxyl groups. (1) Ferric chloride in methyl-alcoholic solution produces a transient bluish-green coloration, changing to purple-brown, and finally a brown precipitate (compare quinol). (2) An aqueous solution of barium hydroxide gives a bright indigo-blue colour (a precipitate from concentrated solutions) and then a reddish-brown precipitate: this is a very delicate test. (3) Lead acetate in methyl-alcoholic solution produces a yellow precipitate which becomes brown and then bluish-green or dark green. (4) When carthamidin is rubbed on a watch-glass with a rod moistened with 2*N*-sodium hydroxide, it becomes blue and then reddish-brown (isocarthamidin does not give this test).

When the tests (1), (2), and (3) were applied to the di- and tri-hydric phenols of known constitutions, the relative positions of the hydroxyl groups were distinguishable in the following manner: (1) if two hydroxyls are in the ortho-position with respect to each other, precipitation occurs in all three tests; (2) if there are two hydroxyls in the para-position with respect to each other, the substance gives a delicate colour change. Quinol and 2:4-dihydroxy-1:3-dimethoxybenzene resemble carthamidin in their colour reactions in test (4).

In view of these results, it is concluded that reactions (1), (2), and (3) show that hydroxyl groups in carthamidin must be arranged as those in hydroxyquinol, *viz.*, one pair in the ortho relation, and another pair in the para relation, to each other. These two sub-

stances are also alike in their instability towards boiling water and on exposure to air. Numerous attempts were made to produce a polyhydroxybenzene from carthamin, *isocarthamin*, and carthamidin by very cautiously decomposing them with hot aqueous barium hydroxide in an atmosphere of hydrogen; however, only *p*-coumaric acid, *p*-hydroxybenzaldehyde, and an acid which appeared to be gluconic acid were isolated. The hydroxylated nucleus of carthamidin is therefore much more unstable than hydroxyquinol. Now, 1:2:3:5-tetrahydroxybenzene is so unstable that it is decomposed by boiling water, and its colour reaction with alkali given in the literature resembles reaction (4) of carthamidin. If, then, this is the hydroxylated nucleus of carthamidin, the reactions described above and also the results of acetylating carthamidin and *isocarthamidin* under various conditions (see below) become explicable.

(For the reactions where no reagent is indicated, a mixture of sodium acetate and acetic anhydride was used.)

Shortly after reaching the above conclusion regarding the constitution of carthamin the author discovered that Chapman, Perkin, and Robinson (J., 1927, 3015) had shown that carajurin gave no appreciable quantity of polyhydric phenol on decomposition with alkali—a fact which in their opinion supported rather than discredited the constitution of a tetrahydroxybenzene derivative assigned to the substance. Hence it is concluded that carthamidin and *isocarthamidin* are hydroxychalcone derivatives. It is in general difficult to distinguish hydroxychalcones from hydroxyflavanones owing to their easy interconvertibility. According to Asahina, Shinoda, and Inubuse (*J. Pharm. Soc. Japan*, 1928, 48, 208, 868) the colour reaction (2) above is negative for hydroxychalcones but positive for hydroxyflavanones, and on this ground

naringin and other similar substances were shown to be hydroxy-flavanones. Hence it follows that carthamidin also belongs to this class of substance. The colour reaction (2) is also given by *isocarthamidin*,  $\alpha$ -acetylcarthamidin, and *acetylisocarthamidin*, but not by  $\beta$ - and  $\gamma$ -acetylcarthamidin.  $\beta$ -Acetylcarthamidin is a penta-acetyl derivative and  $\alpha$ -acetylcarthamidin and *acetylisocarthamidin* are tetra-acetyl derivatives. The analytical results are in complete accord with the following formulations of carthamidin and its acetyl derivatives.

When rubbed with alkali [colour reaction (4) above], *isocarthamidin* behaves like pyrogallol in that both turn brown without previously becoming indigo-blue; 1:2:3:5-tetrahydroxybenzene behaves like carthamidin; and pyrocatechol becomes indigo-blue, the colour being fairly persistent.

The structures of *isocarthamidin* and *acetylisocarthamidin* are probably (V) and (VI) respectively.

The constitutional change from a flavanone (I, II, V, VI) into a chalcone (III) or into a coumarin derivative (IV) which accompanies the acetylation finds support in the analogies furnished by naringenin (Asahina, Shinoda, and Inubuse, *loc. cit.*) for the former change and by phloretin and maulurin (Ber., 1895, 28, 1393) for the latter change. Moreover, the absorption spectrum of  $\beta$ -acetylcarthamidin (III) resembles that of chalcone (phenyl styryl ketone)

itself very closely, whereas the spectra of carthaminidin and *iso*-carthaminidin resemble the spectrum of naringin.

The glucosides carthamin and *isocarthamin* are considered to have the formulæ (VII) and (VIII) respectively (they may also be *cis*- and *trans*- isomerides), because by means of reactions (2) and (3) it can be shown that neither contains two hydroxyls in the ortho-relation and hence it is probable that the glucose residue is in the position indicated. Moreover, the glucosides yield *p*-hydroxybenzaldehyde very easily, whereas the components carthaminidin and *isocarthaminidin* do not under the same conditions. The difficulty of obtaining carthaminidin from dihydrocarthamin may be explained by representing the latter by the formula (IX).

The investigation is being continued.

#### EXPERIMENTAL.

*Preparation of Carthamin.*—The filtered dried product (20–25 g.) obtained from commercial carthamin paste (1 kg.) was in quantities of 5 g. extracted several times with pyridine (200 c.c. in all) on a water-bath; the insoluble material was 25–30% of the whole. The extracts were concentrated under reduced pressure to small bulk, water was added, and the fine red needles that slowly formed were collected and washed with acetone (yield, 2–3 g.). The sample for analysis was submitted to the above purification at least three times and was then warmed with acetone and ether and dried at 100° under reduced pressure. The analytical results, the melting point, and other properties agreed with those recorded by Kametaka and Perkin (*loc. cit.*) and the substance was identical with a specimen of carthamin kindly supplied by Dr. Kametaka (Found: C, 58.8, 57.8; H, 4.9, 4.8; ash, trace. Calc. for  $C_{21}H_{20}O_{10}$ : C, 58.2; H, 4.6%).

Each crystallisation from pyridine caused the loss of almost half of the carthamin; some of this was recovered by acidifying the fresh mother-liquor with sulphuric acid at  $0^{\circ}$ .

*Preparation of isoCarthamin.*—Crude carthamin (5 g.) was digested with water (100 c.c.) and 12% hydrochloric acid (15 c.c.) and after several hours the solid was collected, washed with water and dried on tile (yield, about 4.5 g. There was no loss when purified carthamin was used in the digestion). When a little water was added to a hot methyl-alcoholic solution of the product, *iso-carthamin* gradually separated in yellow needles (yield, about 50%); these were collected and dried quickly by washing with methyl alcohol and then with ether; m. p.  $228^{\circ}$  (reddening at about  $168^{\circ}$ ) (Found: C, 52.1, 52.0; H, 5.1, 5.2.  $C_{21}H_{22}O_{11} \cdot 2H_2O$  requires C, 51.9; H, 5.3%. Found in material dried at  $60^{\circ}$  under reduced pressure: C, 55.7; H, 4.9.  $C_{21}H_{22}O_{11}$  requires C, 56.0; H, 4.9%). When *isocarthamin* was heated at  $100^{\circ}$  under reduced pressure, it changed into a brown substance resembling that obtained from carthamin under the same conditions (Found: C, 57.9; H, 4.8. Calc. for  $C_{21}H_{20}O_{10}$ : C, 58.2; H, 4.6%).

*isoCarthamin* could not be obtained crystalline from ethyl-alcoholic solution, nor from methyl alcohol if the solution was concentrated by distillation, even under reduced pressure: in order to recover *isocarthamin* from such spoiled solutions, repetition of the treatment with hydrochloric acid is necessary. The yellow crystals of *isocarthamin* are stable in a sealed tube, but change to a red powder on exposure to air. *isoCarthamin* is soluble in water, but the yellow solution, on standing or when boiled, becomes pink in the same way as an aqueous solution of carthamin.

*Decomposition of Carthamin or isoCarthamin with Hot Dilute Hydrochloric Acid.*—When either substance was heated with 7% hydrochloric acid for 20 minutes, it changed into a black amorphous powder. The aqueous solution (1) yielded nothing crystalline to ether, (2) reduced Fehling's solution, (3) gave no immediate precipitate when treated with phenylhydrazine, the absence of mannose thus being indicated, (4) gave no results when tested for gluconic acid and pentoses by means of naphtharesorcinol and phloroglucinol respectively.

*Glucosazone from Carthamin or isoCarthamin.*—A mixture of 12% hydrochloric acid (5 c.c.), *isocarthamin* (or carthamin) (0.55 g.), and water (5 c.c.) was heated on a water-bath for 1 hour, and the black product was washed with water. The filtrate and washings were neutralised with sodium carbonate, concentrated on a water-bath, and warmed with sodium acetate (0.57 g.) and phenylhydrazine hydrochloride (0.38 g.). Glucosazone, which separated

very slowly, after being washed and dried (yield, 0.055 g.), melted at  $206^{\circ}$ , alone or mixed with an authentic specimen (Found: C, 60.2; H, 6.1. Calc.: C, 60.3; H, 6.2%).

*Determination of glucose.* In a similar experiment (*isocarthamin*, 0.2043 g.; water, 4 c.c.; 12% hydrochloric acid, 6 c.c.) the neutralised filtrate and washings were diluted to 100 c.c. with 10% aqueous ammonia and the glucose in the solution was estimated by Pavy's volumetric method (Found:  $C_6H_{12}O_6$ , 37.0, 36.9.  $C_{21}H_{22}O_{11} \cdot 2H_2O$  requires  $C_6H_{12}O_6$ , 37.0%). The same result was obtained with carthamin.

*Optical rotation of the sugar solution.* *isoCarthamin* (0.6 g.), water (6 c.c.), and 12% hydrochloric acid (9 c.c.) were heated together as before, the aqueous solution was made up to 20 c.c. (it was assumed to be a 1.1% glucose solution), and the rotation was observed:  $[\alpha]_D^{25} + 53^{\circ}$  (calc.,  $+ 52.6^{\circ}$ ). The author wishes to thank Mrs. Okada and Miss Yamaguchi for their help in this experiment.

*Catalytic Reduction of Carthamin.*—Carthamin (0.2 g.), suspended in ethyl alcohol (25 c.c.), was treated with hydrogen in the presence of palladium-black. The volume of the gas diminished during the first 10 minutes, then increased fairly rapidly to the original value, and thereafter remained almost constant. The carthamin gradually dissolved, giving a yellow solution. After 4–5 hours, the solvent was evaporated at the ordinary temperature and the residue, freed from the palladium, was kept in contact with a little water in an open vessel: fine yellow needles (probably hydrated) separated; they were insoluble in benzene and chloroform, fairly readily soluble in acetone, and very soluble in methyl alcohol (yield, about 70%). The crystals became red on drying in a desiccator, but yellow again on exposure to the air. The combustion of the substance was sluggish, requiring 2 hours for completion even on the micro-scale (Found in material dried at  $90^{\circ}$  under reduced pressure: C, 55.0; H, 5.5.  $C_{21}H_{24}O_{11}$  requires C, 55.6; H, 5.3%), but the behaviour of the product on decomposition with alkali and hydrogen peroxide (see p. 763) convinced the author that it was actually *dihydro-carthamin*.

*Decomposition of Carthamin or isoCarthamin with Phosphoric Acid.*—The powdered material (5 g.) was heated with a 9% aqueous solution of phosphoric acid (100 c.c.) on a water-bath for 40 minutes in a closed vessel, carbon dioxide being passed during the whole time. The liquid was filtered hot, cooled, extracted repeatedly with ether, and used again to decompose more of the residual solid: after four repetitions, only a small quantity of a black solid remained. The combined ethereal extracts were evaporated, leaving a residue which, after addition of a very little aqueous

acetone, slowly solidified to a yellow crystalline cake (yield, about 30%). Subsequently it was found that the dry raw material obtained directly from the original carthamin paste may be used for the preparation of the same substance in good yield (about 15% of the raw material).

*Isolation of carthamidin (I).* The crystalline cake (above) was warmed with successive quantities of moist chloroform for a few minutes, until nothing crystallised from the rapidly filtered extract on cooling. *Carthamidin* was thus obtained in pale yellow needles containing one molecule of water (yield, 30% of the crude product), and sometimes also in long needles on repetition of the purification; m. p. 218° (Found: C, 58.8, 58.9; H, 4.8, 4.4.  $C_{15}H_{12}O_6 \cdot H_2O$  requires C, 58.8; H, 4.6%. Found in material heated at 100° under reduced pressure: C, 62.7; H, 4.4; *M*, ebullioscopic in acetone, 298, 286, 270.\*  $C_{15}H_{12}O_6$  requires C, 62.5; H, 4.2%; *M*, 288).

*Carthamidin* is very soluble in acetone, methyl alcohol, acetic acid, and ethyl acetate, but sparingly soluble in light petroleum, benzene, dry chloroform, and cold water. It crystallises from hot aqueous solution in the hydrated form, but is decomposed by prolonged boiling: even at the ordinary temperature it seems to decompose slowly in aqueous solution.

When carthamin or *isocarthamin* was heated with 1% sulphuric or hydrochloric acid, no trace of *carthamidin* or *isocarthamidin* was produced.

*isocarthamidin (V).* The residue left after the extraction of the *carthamidin* with moist chloroform was dissolved in the minimum quantity of acetone: on addition of chloroform (3—4 vols.), *isocarthamidin* remained in solution but a dark resinous substance was precipitated. The latter was repeatedly dissolved in acetone and reprecipitated with chloroform. When the combined filtrates were allowed to evaporate to dryness, somewhat rounded crystals were produced; these were washed with ether and recrystallised twice from dilute methyl alcohol, *isocarthamidin* being obtained in yellow hydrated prisms, m. p. 240° (Found in material dried at 100° under reduced pressure: C, 62.5; H, 4.3.  $C_{15}H_{12}O_6$  requires C, 62.5; H, 4.2%).

When dihydrocarthamin was treated with dilute phosphoric acid under the same conditions as carthamin, no crystalline product was obtained.

*Carthamidin* and *isocarthamidin* resemble each other very closely in many of their properties. The former seems to be converted into the latter under certain conditions; for instance, when it is

\* The author is indebted to Mr. Shiba for carrying out these determinations of molecular weight.

heated with water in air or in a sealed tube at 100° or higher or with animal charcoal at 100° in aqueous solution.

*Reactions of Phenols* (see p. 754).—A = ferric chloride in methyl-alcoholic solution; B = lead acetate in methyl-alcoholic solution; C = barium hydroxide in aqueous solution.

*α-Acetylcarthamidin* (II).—When carthamidin (0.1 g.), suspended in acetic anhydride (1 c.c.), was cooled and treated with a trace of concentrated sulphuric acid, reaction started immediately with evolution of heat. After several hours, water was added and the precipitate, which separated slowly, was collected, washed with water, and dried (yield, almost theoretical). This *acetyl* compound crystallised from methyl alcohol in colourless prisms, m. p. 158° [Found: C, 60.5, 60.3; H, 4.5, 4.4;  $\text{CH}_3\cdot\text{CO}$ , determined by Freudenberg's method (*Annalen*, 1923, **433**, 230), 36.4, 36.6; *M*, ebullioscopic in benzene, 425, 445, 470.  $\text{C}_{15}\text{H}_8\text{O}_6(\text{CH}_3\cdot\text{CO})_4$  requires C, 60.5; H, 4.4;  $\text{CH}_3\cdot\text{CO}$ , 37.7%; *M*, 456]. It was very easily soluble in chloroform, benzene and acetone, fairly readily soluble in ether and methyl alcohol, and difficultly soluble in water. A methyl-alcoholic solution gave (1) no colour with ferric chloride, (2) a magenta colour (slowly) on reduction with magnesium and hydrochloric acid. When heated with hydrochloric acid in methyl-alcoholic solution, the acetyl derivative gave carthamidin, which was identified by its m. p. after being washed with ether to remove a red impurity. Acetylcarthamidin was optically inactive in benzene solution.

*Acetylisocarthamidin* (VI).—This was prepared in almost theoretical yield in the same way as *α-acetylcarthamidin*. It is easily soluble in benzene, chloroform, and acetone, sparingly soluble in

methyl alcohol, and almost insoluble in ether. When ether or methyl alcohol is added to its chloroform solution, *acetylisocarthamidin* separates in fine, colourless, silky needles, m. p. 179° [Found: C, 60.5, 60.4; H, 4.5, 4.4;  $\text{CH}_3\cdot\text{CO}$ , 37.4; *M*, ebullioscopic in benzene, 430, 442.  $\text{C}_{15}\text{H}_8\text{O}_6(\text{CH}_3\cdot\text{CO})_4$  requires C, 60.5; H, 4.4;  $\text{CH}_3\cdot\text{CO}$ , 37.7%; *M*, 456].

The absorption spectrum of *acetylisocarthamidin* and its behaviour towards ferric chloride and towards magnesium and hydrochloric acid are the same as those of  $\alpha$ -*acetylcarthamidin*.

The differences in melting point, crystalline form, and solubility in methyl alcohol and in ether of these two acetyl compounds are important as means of identifying *carthamidin* and *isocarthamidin*, which are otherwise difficult to distinguish from each other.

$\beta$ -*Acetylcarthamidin* (III).—A mixture of *carthamidin* (0.1 g.), anhydrous sodium acetate (0.5 g.), and acetic anhydride (1.5 c.c.) was heated at 125–130° for 5 hours; the product was then cooled and mixed with water. After the excess of acetic anhydride had been decomposed, the precipitate was collected, washed with water, and dried (yield, nearly 0.14 g.). It crystallised from methyl alcohol in large rhombs, m. p. 142° [Found: C, 60.3, 60.3; H, 4.5, 4.5;  $\text{CH}_3\cdot\text{CO}$ , 42.7, 42.1.  $\text{C}_{15}\text{H}_7\text{O}_6(\text{CH}_3\cdot\text{CO})_5$  requires C, 60.2; H, 4.4;  $\text{CH}_3\cdot\text{CO}$ , 43.2%].

$\beta$ -*Acetylcarthamidin* in methyl-alcoholic solution gives a colour reaction neither with ferric chloride nor with magnesium and hydrochloric acid. It is very easily soluble in chloroform and acetone and sparingly soluble in cold methyl alcohol and ether. It may also be obtained in almost theoretical yield from *isocarthamidin*,  $\alpha$ -*acetylcarthamidin* and *acetylisocarthamidin* by the same method.

$\gamma$ -*Acetylcarthamidin* (IV).—A mixture of *carthamidin* (0.1 g.), anhydrous sodium acetate (0.5 g.), and acetic anhydride (1.5 c.c.) was heated in an oil-bath at 140–150° for 5 hours: the procedure was then as described above, but a further quantity of the product was obtained from the aqueous filtrate by extraction with ether.  $\gamma$ -*Acetylcarthamidin* separated from methyl alcohol in minute colourless crystals, m. p. 178°. The yield was poor (about 25%), because  $\beta$ -*acetylcarthamidin* and a decomposition product were also formed: these rendered the purification rather tedious (Found: C, 62.5, 62.6; H, 4.3, 4.3.  $\text{C}_{25}\text{H}_{20}\text{O}_{10}$  requires C, 62.5; H, 4.2%). The compound may also be obtained from *isocarthamidin*,  $\alpha$ -*acetylcarthamidin*, and *acetylisocarthamidin* by the above method, though in poor yield.

$\gamma$ -*Acetylcarthamidin* resembles *acetylisocarthamidin* in appearance and their melting points are almost the same. The two sub-

stances, however, differ in solubility in many solvents, particularly methyl alcohol and ether, in each of which the former is the more soluble and dissolves fairly readily. Its methyl-alcoholic solution gives a colour reaction neither with ferric chloride nor with magnesium and hydrochloric acid.

*Action of Hydrogen Peroxide on Carthamin* (compare Kametaka and Perkin, *loc. cit.*).—A solution of carthamin (1 g.) in 1% aqueous sodium carbonate (60 c.c.) and 3% aqueous hydrogen peroxide (40 c.c.) was kept at the ordinary temperature until it became yellow; it was then acidified with dilute sulphuric acid and extracted with ether. The residue after evaporation of the ether was dried, extracted with hot benzene to remove a trace of *p*-hydroxybenzaldehyde, dissolved in hot water, and decolorised with animal charcoal; on cooling, *p*-coumaric acid crystallised (yield, about 10%), m. p. 210° (Found: C, 65.9; H, 4.8. Calc.: C, 65.9; H, 4.9%).

*Action of Hydrogen Peroxide on Quercetin*.—The above operation was applied to quercetin, protocathechuic acid, m. p. 199°, being obtained in theoretical yield (Found: C, 54.3; H, 3.9. Calc.: C, 54.6; H, 3.9%).

*Action of Hydrogen Peroxide on Dihydrocarthamin and on Phloretin*.—Dihydrocarthamin (0.2 g.) was treated in the same way as carthamin (one-fifth quantities). The product obtained after evaporation of the ether was pressed on a tile; the crystalline residue (about 0.03 g.), m. p. about 125°, separated from hot concentrated aqueous solution (animal charcoal) in prisms, m. p. 129° (Found: C, 65.1; H, 6.1. Calc. for  $C_9H_{10}O_3$ : C, 65.1; H, 6.0%).

In a similar way phloretin gave phloretic acid (Found: C, 65.1; H, 5.9%) which, alone or mixed with the specimen obtained from dihydrocarthamin, melted at 129°.

*Action of Bromine Water on Carthamin*.—When digested with bromine water (100 c.c.), carthamin (0.5 g.) yielded a yellow precipitate (about 0.6 g.), decomp. about 146° (Found: C, 26.7; H, 2.5; Br, 53.0%). This substance slowly changed into a brown resin and a small quantity of tribromophenol sublimed. When the substance was heated with 5% aqueous alkali and the acidified product distilled with steam, tribromophenol was obtained.

*Action of Alkali on Carthamin and its Decomposition Products*.—The black amorphous powder produced by the decomposition of carthamin with dilute hydrochloric acid (see p. 758) (4.5 g.) was heated with potassium hydroxide (5 g.) and water (2 c.c.) at 160° for 30 minutes. The bluish-green product, when dissolved in water, became violet and then brown. The solution was acidified with dilute sulphuric acid, the precipitate (0.15 g.) removed, and the

filtrate extracted with ether. From the extract, a substance (0.2 g.) was obtained which gave *p*-hydroxybenzoic acid, m. p. and mixed m. p.  $210^{\circ}$ , on purification (Found : C, 60.8; H, 4.2. Calc. : C, 60.9; H, 4.4%).

Carthamin was heated with 5% aqueous caustic alkali and the solution was then acidified and extracted with ether : *p*-hydroxybenzaldehyde and *p*-coumaric acid were isolated from the extract. When concentrated caustic alkali (about 20%) was used, only *p*-hydroxybenzaldehyde was obtained (compare Kametaka and Perkin, *loc. cit.*). When carthamin was fused with potassium hydroxide and a little water at  $140^{\circ}$ , a bluish-green mass was obtained from which *p*-hydroxybenzoic acid, m. p.  $210^{\circ}$ , was isolated in a yield of nearly 10%. Various concentrations of caustic alkali produced only *p*-hydroxybenzaldehyde from carthamidin or isocarthamidin (even from 0.02 g.).

*Action of Hot Baryta Water on Carthamin.*—Carthamin (3 g.) and hot saturated aqueous baryta (60 c.c.) were heated together on a water-bath for 5 hours in an atmosphere of hydrogen. Carbon dioxide was passed through the cooled liquid, the precipitate removed, and the filtrate extracted with ether : from the extract, *p*-hydroxybenzaldehyde (0.33 g.) was isolated. Dilute sulphuric acid was added to the aqueous liquid, the barium sulphate removed, and the filtrate extracted with ether : from this extract, *p*-coumaric acid (0.24 g.) was isolated. The aqueous liquid was now treated with basic lead acetate and, after filtration, with hydrogen sulphide. After further filtration it was concentrated by distillation under reduced pressure, a colourless, acidic, syrupy residue (about 0.5 g.) being obtained. This substance did not reduce Fehling's solution and gave no colour reaction with ferric chloride. When it was heated, it swelled and charred, emitting an odour resembling that of burning tartaric acid or sugar. The substance, which appeared to be gluconic acid, was neutralised with potassium carbonate and the concentrated aqueous solution was treated with alcohol; the white crystals produced were washed with ether and dried in a desiccator (Found : K, 16.0. Calc. for  $C_6H_{11}O_7K$  : K, 16.7%).

The same process applied to isocarthamin gave the same products, but its application to carthamidin was not successful owing to the insolubility of the barium salt in water.

*Absorption Spectra of Carthamidin, isoCarthamidin,  $\alpha$ -Acetylcarthamidin, Acetylisocarthamidin,  $\gamma$ -Acetylcarthamidin, Chalkone, and Naringin.*—The spectra were photographed through the kindness of Mr. Sakurai. In each case the substance was dissolved in ethyl alcohol and concentrations of  $N/5000$ — $N/10000$  were employed, the iron arc being used as the light source. Carthamidin

and isocarthamidin resemble each other closely and have bands with centres at about  $\lambda$  2900 Å. Both substances cut off the violet end of the visible spectrum to nearly equal extents in  $N/5000$ -solutions. The absorption spectrum of naringin has a general resemblance to that of carthamidin in  $N/10000$ -solution.  $\alpha$ -Acetylcarthamidin and acetylisocarthamidin give similar absorptions, both having shallow bands with centres at about  $\lambda$  2600 Å and transmitting the light rather more freely in the ultra-violet region. The absorption spectra of these two substances differ from that of  $\beta$ -acetylcarthamidin, which, however, resembles that of chalkone to some extent, since it has a band with centre at about  $\lambda$  3000 Å. All the absorption spectra seem to have some sharp narrow bands in the near ultra-violet region, but these are difficult to fix with certainty owing to the strong iron lines in their neighbourhood.

The author desires to thank the Keimeikai Society and the Department of Education for grants and to express her appreciation of the helpful interest shown by Prof. Majima and of the assistance of Miss Inouye and Miss Matsuguma. She also has pleasure in acknowledging her indebtedness to Prof. W. H. Perkin for his valuable assistance in publication, and to Prof. A. G. Perkin for his kind criticism.

### CIII.—*The Constitution of Carthamin. Part II.* *$\beta$ -Carthamidin Pentamethyl Ether and its Synthesis.*

By (Miss) CHIKA KURODA.

ONE of the chief hindrances to the study of carthamin and carthamidin, namely, their resistance to methylation, has now been removed.  $\beta$ -Acetylcarthamidin (I) has been methylated by Freudenberg's method (*Annalen*, 1923, **433**, 236): the product,  $\beta$ -carthamidin pentamethyl ether (II), is identical with synthetic 2:3:4:6-tetramethoxyphenyl 4-methoxystyryl ketone.

Carthamin, therefore, which has long been considered a specially complex colouring matter, is a member of a typical class, the hydroxychalkones: it may, however, assume the quinonoid (see formula VII of the preceding paper) or quinhydrone form.

2:3:4:6-Tetramethoxyacetophenone (III) is produced in almost theoretical yield from 1:2:3:5-tetramethoxybenzene and acetyl chloride in the presence of aluminium chloride but in the absence of a solvent (compare Bargellini and Bini, *Atti R. Accad.*

*Lincoi*, 1910, **19**, 595; Bargellini, *Gazzetta*, 1914, **49**, 47; Chapman, Perkin, and Robinson, *J.*, 1927, 3020).

#### EXPERIMENTAL.

**Methylation of  $\beta$ -Acetylcarthamidin.**—50% Potassium hydroxide solution (7 c.c.) was added with great caution to a solution of methyl sulphate (3 c.c.) and  $\beta$ -acetylcarthamidin (0.2 g.) in methyl alcohol (15 c.c.) in an atmosphere of hydrogen: to complete the reaction, a little heat was supplied. When water was added to the product,  $\beta$ -carthamidin pentamethyl ether (II) separated as a fine precipitate (0.05–0.06 g.). A chloroform solution of the products of several preparations was evaporated and the methyl ether, obtained in prisms, was washed with ether and recrystallised from methyl alcohol; m. p.  $112^\circ$  (Found: C, 66.8; H, 6.0.  $\text{C}_{20}\text{H}_{22}\text{O}_6$  requires C, 67.0; H, 6.1%).

$\beta$ -Carthamidin pentamethyl ether is almost colourless (very pale yellow) and is readily soluble in chloroform and benzene and fairly readily soluble in ether and alcohol; it gives a red solution in concentrated sulphuric acid, and is coloured red by concentrated hydrochloric acid, showing distinct halochromy.

**Synthesis of  $\beta$ -Carthamidin Pentamethyl Ether (2:3:4:6-Tetramethoxyphenyl 4-Methoxystyryl Ketone).**—Pyrogallol trimethyl ether was obtained by Chapman, Perkin, and Robinson's method (*J.*, 1927; 3028), the yield being much improved (26.3 g.; m. p.  $47^\circ$ ) when the following quantities were used: pyrogallol 20 g., methyl alcohol 50 c.c., methyl sulphate 45 c.c., 40% sodium hydroxide solution 90 c.c. It was converted by Graebe and Hess's method (*Annalen*, 1905, **340**, 237) into 2:6-dimethoxybenzoquinone, which gave 2:6-dimethoxyquinol on reduction with sulphurous acid. The product was treated with benzene, which removed a nitrated impurity.

When a crystal of 2:6-dimethoxyquinol is touched with 2*N*-caustic alkali on a watch-glass, an intense indigo-blue colour is produced which immediately changes to brown.

1 : 2 : 3 : 5-Tetramethoxybenzene (2.1 g.; m. p.  $47^{\circ}$ ) was obtained when a mixture of 2 : 6-dimethoxyquinol (2 g.), methyl alcohol (5 c.c.), and methyl sulphate (5.2 c.c.) was treated with 40% sodium hydroxide solution (15 c.c.) in an atmosphere of hydrogen, a little heat being finally supplied.

A mixture of the tetramethoxybenzene (2 g.) and acetyl chloride (4 c.c.), cooled in water, was gradually treated with powdered aluminium chloride (2 g.). When the product became semi-solid (after 20 minutes), ice was added; 2 : 3 : 4 : 6-tetramethoxyacetophenone (2.2 g.) then crystallised in colourless needles. These were collected, digested with aqueous caustic alkali (which removed only a trace of demethylated material), and washed with water (yield, 2.1—2.2 g.). When much water was added to its concentrated methyl-alcoholic solution, the ketone separated in long fine needles (Found: C, 60.1; H, 6.4; OMe, 51.1. Calc.: C, 60.0; H, 6.6; OMe, 51.7%). The *oxime*, prepared by heating a mixture of the ketone (0.3 g.), sodium acetate (0.25 g.), hydroxylamine hydrochloride (0.25 g.), and ethyl alcohol (4 c.c.) on a water-bath for 3 hours, crystallised from dilute methyl alcohol in colourless hydrated needles, m. p.  $53-54^{\circ}$  (Found: C, 53.1; H, 7.0.  $C_{12}H_{17}O_6N, H_2O$  requires C, 52.8; H, 7.0%).

When a solution of the tetramethoxyacetophenone (1 g.) and anisaldehyde (0.7 g.) in methyl alcohol (6 c.c.) was warmed at  $50-60^{\circ}$  with 50% potassium hydroxide solution (4 g.), the methoxy-chalkone gradually crystallised. After several hours, water was added and the crystals were collected and washed with water (yield, 1.4 g.). The 2 : 3 : 4 : 6-tetramethoxyphenyl 4-methoxystyryl ketone was recrystallised from methyl alcohol (Found: C, 66.6; H, 6.0%). It then melted, alone or mixed with  $\beta$ -carthamidin pentamethyl ether, at  $112^{\circ}$  and agreed with this substance in all its properties. The absorption spectra of the two substances in  $N/5000$ -alcoholic solution, kindly photographed by Mr. Sakurai, the iron arc being used as a light source, were identical in every respect. Both showed a very wide band with its centre at about  $\lambda$  3300 Å. and another smaller band at about  $\lambda$  2700 Å. Indications of sharp narrow bands were observed in both cases in the region about  $\lambda$  3800 Å.

The author desires to thank the Keimeikai Society and the Department of Education for grants. She also wishes to express her appreciation of the helpful interest shown by Prof. Majima and the kind assistance of Miss Matsuguma.

CIV.—*Syntheses of Cyclic Compounds. Part VI.*  
3- and 4-Methylcyclohexanones.

By ARTHUR ISRAEL VOGEL and MARIAM P. OOMMEN.

THE principal object of the present investigation was to determine the influence of the substitution of a methyl group for hydrogen in the 3- and 4-positions upon the character and the configuration of the *cyclohexane* ring. The only previous work on this subject appears to be that of Birch and Thorpe (J., 1922, **121**, 1821), who found that the bridged *spiro*-compounds (I), where  $R_1R_2C$  is 3-

and 4-methylcyclohexane, decomposed completely into the open-chain compound (III) on treatment with alkali under standard conditions, a result in contrast with that obtained with the unsubstituted *cyclohexane* ring ( $R_1R_2C = \text{cyclohexane}$ ), where the *spiro*-compound (II) was produced (Birch, Gough, and Kon, J., 1921, **119**, 1315). It is doubtful whether this method of comparing stabilities of ring systems, in its present state, is of any great value, since all the compounds (I) with substituents,  $R_1R_2C$ , other than *cyclohexane* are converted into the open-chain compounds (III) under the conditions employed and no means have yet been found for distinguishing between the rates of fission of individual members of the series. The method adopted in the present research is that described by one of us (Vogel, J., 1928, 2010) for the comparison of substituent groups and ring systems. The cyano-esters (IV)

were prepared by the condensation of the ketones with ethyl cyanoacetate in the presence of piperidine and reduced in ethereal solution with moist aluminium amalgam; the relative yields of the unimolecular (V) and the bimolecular products (VI) are shown in Table I,

TABLE I.

$CR_1R_2 \cdot C(CN) \cdot CO_2Et$	Yield % (V).	Yield % (VI).
$CR_1R_2 = \text{cyclopentane}$ .....	79	13
$= \text{cyclohexane}$ .....	84	6
$= 3\text{-methylcyclohexane}$ .....	83	6
$= 4\text{-methylcyclohexane}$ .....	87	4

the values for the *cyclopentane* and *cyclohexane* compounds being included for purposes of comparison: in so far as the yields of the

bimolecular compounds—which owing to their relatively slight volatility are employed for comparative purposes—are concerned, there seems to be no essential difference in behaviour between the unsubstituted and the methyl-substituted *cyclohexane* rings.

The unsaturated cyano-esters have the  $\alpha\beta$ -structure: the  $\beta\gamma$ -isomeride is present, if at all, in very small quantity. The  $\beta\gamma$ -structures assigned to the cyano-esters derived from 3- and 4-methyl-*cyclohexanones* by Harding, Haworth, and Perkin (J., 1908, 93, 1943) and by Harding and Haworth (J., 1910, 97, 486) require correction: the esters are completely reduced by moist aluminium amalgam and no definite evidence has been obtained of the presence of any appreciable quantity of unsaturated isomerides in the reduction products.

Prolonged hydrolysis of the reduced cyano-esters (V) with alcoholic potassium hydroxide afforded the corresponding malonic acids, the constitution and saturated character of which were proved by their synthesis from the iodides and ethyl sodiomalonate (compare Zelinski and Alexandrow, *Ber.*, 1901, 34, 3885).

Some physical properties of the pure ketones\* are recorded in Table II (compare Schoorl, *Rec. trav. chim.*, 1929, 48, 935). The

refractive indices were measured at about 20°; the exact temperatures are given in the Experimental section. The surface tensions and the densities were determined over a range of temperatures and have been reduced to 20°, a linear variation with temperature being assumed. The parachors,  $[P]$  (obs.), were calculated by the usual formula. The parachors,  $[P_1]$ , for the corresponding cyclic hydrocarbons can be evaluated from the observed values for the cyclic ketones by substituting Sugden's values of 2H for :O. If, now, from these the parachor for the simple *cyclohexane* ring be found by replacing the value for CH<sub>3</sub> by that for H, the contribution per

\* The results for 2-methyl-*cyclohexanone* have been included for the sake of completeness.

$\text{CH}_2$  group,  $[P'_1/n]$ , which is an important criterion of the configuration of the ring (Vogel, J., 1928, 2018), can be calculated : the results (Table III, which includes the previous results for the

unsubstituted 6-ring) are in close agreement with that obtained from the observed parachor for the simple *cyclohexane* ring and thus provide further support for the view that there is no essential difference in configuration between the unsubstituted *cyclohexane* ring and that present in 3- and 4-methyl*cyclohexanones*.

## EXPERIMENTAL.

The 3- and 4-methyl*cyclohexanones* used were the pure products supplied by the Deutsche Hydrierwerke Aktiengesellschaft.

4-Methyl*cyclohexane* Series.

Ethyl 4-methyl*cyclohexylidene*-1-cyanoacetate was prepared by the condensation of 4-methyl*cyclohexanone* and ethyl cyanoacetate in the presence of piperidine (Harding, Haworth, and Perkin, *loc. cit.*) in ca. 60% yield. It had b. p.  $172^\circ/21$  mm. (Harding, Haworth, and Perkin give b. p.  $165$ – $168^\circ/14$  mm.),  $d_{40}^{21.2}$  1.0227,  $n_D^{21.2}$  1.4882,  $[R_L]_D$  58.38 (calc., 56.42).

*Ethyl* 4-methyl*cyclohexyl*-1-cyanoacetate (as V).—The preceding ester (100 g.) was reduced with 150 g. of moist aluminium amalgam in ether (Vogel, J., 1927, 594; 1928, 2010) : there was a period of induction of about 1.5 hours and the reaction was complete after 7 hours. The product was worked up in the usual manner and distilled, *ethyl* 4-methyl*cyclohexyl*-1-cyanoacetate (87 g.) passing over at  $160$ – $169^\circ/21$  mm. (more than 90% at  $163^\circ/21$  mm.). The viscid residue, having been washed several times with light petroleum (b. p.  $40$ – $60^\circ$ ), crystallised when left over-night in a vacuum over concentrated sulphuric acid (yield, 4 g.); it melted at  $75^\circ$  (softening at  $65^\circ$ ) and was the bimolecular *cyano-ester* (Found : *M*, in camphor, 421.  $\text{C}_{24}\text{H}_{36}\text{O}_4\text{N}_2$  requires *M*, 418). The liquid reduction product after redistillation had b. p.  $162^\circ/20$  mm.,  $d_{40}^{22.2}$  1.0018,  $n_D^{22.2}$  1.4585, whence  $[R_L]_D$  57.03 (calc., 56.89) (Found : C, 68.6; H, 9.1.  $\text{C}_{12}\text{H}_{19}\text{O}_2\text{N}$  requires C, 68.8; H, 9.2%).

4-Methyl*cyclohexyl*-1-malonic Acid.—Solutions of ethyl 4-methyl*cyclohexyl*-1-cyanoacetate (30 g.) in rectified spirit (160 g.) and of potassium hydroxide (100 g.) in water (100 g.) were mixed, heated on the steam-bath for 24 hours (the evolution of ammonia had then

ceased), and evaporated to dryness. The residue was triturated several times with ether to remove any unchanged ester and acidified with dilute sulphuric acid; 4-methylcyclohexyl-1-malonic acid, m. p.  $172^{\circ}$ , precipitated in almost quantitative yield, had m. p.  $182$ — $183^{\circ}$  after several crystallisations from formic acid (*d* 1.2) (Hope and Perkin, J., 1909, 95, 1367, give m. p.  $177$ — $178^{\circ}$ ) (Found: equiv., by titration with baryta, 101. Calc., 100). An additional small quantity was extracted by ether from the filtrate after saturation with ammonium sulphate.

*Synthesis of 4-Methylcyclohexyl-1-malonic Acid from 4-Methylcyclohexyl Iodide and Ethyl Sodiomalonnate.*—4-Methylcyclohexanone was reduced with sodium and moist ether (compare Bentley, J., 1895, 67, 264) to the alcohol, b. p.  $174^{\circ}/760$  mm. This (116 g.) was treated with red phosphorus (9.5 g.) and iodine (90 g.), rise of temperature being prevented, and after 12 hours the whole was heated on the steam-bath for 2 hours, and 4-methylcyclohexyl iodide isolated in the usual manner (compare Bentley, *loc. cit.*). It had b. p.  $63^{\circ}/3.5$  mm.,  $d_{4}^{20.9^{\circ}}$  1.5086,  $n_D^{20.9^{\circ}}$  1.5325, whence  $[R_L]_D$  46.04 (calc., 45.13) (Found: I, 56.6.  $C_7H_{13}I$  requires I, 56.7%). When freshly distilled, the iodide is a colourless mobile liquid with a characteristic odour.

The reaction between 4-methylcyclohexyl iodide (127 g.; 1 mol.) and ethyl sodiomalonate (2 mols.: \* compare Zelinski and Alexandrow, *loc. cit.*; prepared from 90.7 g. of ethyl malonate, 13.05 g. of sodium, and 200 c.c. of dry alcohol) was carried out in the way described by Hope and Perkin (J., 1909, 95, 1363). The product on distillation gave first ethyl malonate and 4-methylcyclohexyl iodide; ethyl 4-methylcyclohexyl-1-malonate then passed over at  $164$ — $168^{\circ}/29$  mm. On redistillation, it boiled at  $161$ — $163^{\circ}/18$  mm. (Hope and Perkin give b. p.  $163$ — $165^{\circ}/20$  mm.); yield, 75 g. or 55%.

The acid obtained by the hydrolysis of the ester with alcoholic potassium hydroxide on the steam-bath melted, after three crystallisations from formic acid, at  $182$ — $183^{\circ}$  (decomp.) (Found: equiv., by titration, 100.5) and was identical (mixed m. p.) with 4-methylcyclohexyl-1-malonic acid prepared as described above. From the filtrate from the precipitated acid, saturated with ammonium sulphate, ether extracted about 2 g. of an acid, m. p.  $100$ — $110^{\circ}$ , and  $110^{\circ}$  after recrystallisation from benzene: this was probably impure *r*-3-methylcyclohexyl-1-malonic acid (m. p.  $120$ — $121^{\circ}$ ; mixed m. p.  $116$ — $117^{\circ}$ ) (Found: equiv., 101), but the quantity was too small for identification.

\* A slightly smaller yield was obtained with equimolecular quantities.

### 3-Methylcyclohexane Series.

Ethyl 3-methylcyclohexylidene-1-cyanoacetate was prepared in *ca.* 60% yield by the condensation of the ketone with ethyl cyanoacetate in the presence of piperidine (Harding and Haworth, *loc. cit.*) and had b. p. 160—163°/15 mm. A middle fraction prepared for analysis had b. p. 163°/16 mm.,  $d_4^{20}$  1.0288,  $n_D^{20}$  1.4914, whence  $[R_L]_D$  58.36 (calc., 56.42) (Found: C, 69.2; H, 8.2. Calc.: C, 69.5; H, 8.3%).

*Ethyl r-3-Methylcyclohexyl-1-cyanoacetate.*—The preceding ester (100 g.) was reduced with 150 g. of moist aluminium amalgam in ether (7 hours). The product gave on distillation *ethyl r-3-methylcyclohexyl-1-cyanoacetate* (83 g.), which passed over at 150—153°/15 mm., mainly at 152°/15 mm. The residue crystallised after being treated with light petroleum (b. p. 40—60°) in the manner detailed for the 4-methyl compound; yield, 6 g. It had m. p. 76° (softening at 65°) and was probably a mixture of isomeric bimolecular cyano-esters (Found: *M*, in camphor, 416.  $C_{24}H_{36}O_4N_2$  requires *M*, 418). The liquid reduction product after redistillation had b. p. 152°/15 mm.,  $d_4^{20}$  1.0022,  $n_D^{20}$  1.4586, whence  $[R_L]_D$  57.02 (calc., 56.89) (Found: C, 68.4; H, 9.1.  $C_{12}H_{19}O_2N$  requires C, 68.8; H, 9.2%).

*r-3-Methylcyclohexyl-1-malonic Acid.*—The hydrolysis of ethyl 3-methylcyclohexyl-1-cyanoacetate was effected (36 hours) as described under the 4-methyl compound. The resultant oily acid, crystallised twice from benzene, formed needles, m. p. 115—116° (rapidly heated), 120—121° (slowly heated) (Found: C, 60.3; H, 8.1; equiv., 99.  $C_{10}H_{16}O_4$  requires C, 60.0; H, 8.1%; equiv., 100). *r-3-Methylcyclohexyl-1-malonic acid* is soluble in water, chloroform, ether, and formic acid; it is sparingly soluble in dilute hydrochloric acid and in benzene when cold but dissolves readily on warming (the corresponding 4-methyl compound is very soluble in ether, but dissolves readily in water, chloroform, and formic acid only when warm). The presence of an isomeric acid could not be detected.

*Synthesis of r-3-Methylcyclohexyl-1-malonic Acid from 3-Methylcyclohexyl Iodide and Ethyl Sodiomalonate.*—In the ways already indicated, 3-methylcyclohexanone was converted through the alcohol, b. p. 174°/760 mm., into 3-methylcyclohexyl iodide,\* b. p. 61—63°/3 mm. (Knoevenagel, *Annalen*, 1897, 297, 154, gives b. p. 82—83°/10 mm.) (yield, almost quantitative), a colourless mobile liquid with a characteristic odour when freshly distilled.

The condensation with ethyl sodiomalonate was carried out, in

\* This probably contained some of the 4-methyl iodide (see p. 773).

the manner already described, with 97 g. of the iodide, 10 g. of sodium, 200 c.c. of dry alcohol, and 138 g. of ethyl malonate. The product, b. p. 159—163°/19 mm. (45 g.), hydrolysed with twice the calculated quantity of alcoholic potassium hydroxide, gave an almost quantitative yield of oily acids, which solidified on trituration with benzene. The acids were treated with cold formic acid: the insoluble portion, recrystallised three times from hot formic acid, melted at 182—183° and its identity with 4-methylcyclohexyl-1-malonic acid was confirmed by direct comparison and by a mixed m. p. determination (Found: equiv., 99); the soluble portion was evaporated to dryness on the steam-bath, the resultant oil triturated with a small quantity of benzene, and the solid thus obtained treated with cold formic acid. The residue obtained on evaporation of the filtrate melted at 110—111° after several crystallisations from benzene (Found: C, 60.1; H, 8.1%; equiv., 99.5). This acid resembles *r*-3-methylcyclohexyl-1-malonic acid, prepared from the cyano-ester, very closely in properties (solubility, crystalline form, etc.) and is probably identical with it; a mixture of the two melted at 117—118°. There appeared to be a very small quantity of an isomeric acid present which could not be removed by fractional crystallisation from common organic solvents.

In order to put the surprising nature of the above result, *viz.*, the formation of approximately equal quantities of 3- and 4-methylcyclohexylmalonic acids in the condensation of 3-methylcyclohexyl iodide and ethyl sodiomalonate, beyond all question, the whole experiment was repeated with pure 3-methylcyclohexanone prepared from the semicarbazone, m. p. 189—190°. (The ketone employed for the above experiments gave a quantitative yield of a semicarbazone, m. p. 186°, and 189—190° after two crystallisations from dilute methyl alcohol.) The pure ketone was successively converted into the alcohol, b. p. 173°/760 mm., the iodide, b. p. 61—62°/3 mm., and ethyl methylcyclohexylmalonate, b. p. 158—162°/22 mm., mainly 160°/22 mm. (47 g. of the iodide furnished 23 g. of the malonic ester). The ester on hydrolysis gave the same mixture of acids as before. This remarkable reaction will be more fully investigated: possibly, during the conversion of 3-methylcyclohexanol into the iodide and under the influence of the phosphorus iodides present, dehydration occurs, followed by addition of hydrogen iodide in the two positions leading to the formation of 3- and 4-methylcyclohexyl iodides.

*Determination of Surface Tensions and of Densities over a Range of Temperatures. Calculation of the Parachor.*

The apparatus and procedure employed in these determinations were those already described (Vogel, J., 1928, 2027). The correction

for the meniscus was 0.24 mm., and the mean constant  $K$  1.8746. The symbols in the tables have already been defined (Vogel, *loc. cit.*).

All the ketones were regenerated, by means of oxalic acid, from the semicarbazones, which had been recrystallised from rectified spirit until the m. p.'s were constant.

2-Methylcyclohexanone,  $M = 112.10$ , b. p.  $165^\circ/757$  mm.,  $n_D^{19.4^\circ}$  1.4484,  $d_4^{19.4^\circ}$  0.9255, whence  $[R_L]_D$  32.45 (calc., 32.34). Semicarbazone, m. p.  $195-196^\circ$ .

Densities determined:  $d_4^{18.9^\circ}$  0.9270;  $d_4^{61.4^\circ}$  0.8927;  $d_4^{81.4^\circ}$  0.8756.

In conclusion, the authors wish to express their thanks to Professor J. F. Thorpe, F.R.S., and to Dr. M. A. Whiteley for their kind interest in this investigation, and to the Chemical Society for a grant which has helped to defray its cost.

CV.—*The Chemistry of the Three-carbon System.*  
 Part XXIV. *The Regeneration of Esters from*  
*their Sodio-derivatives.*

By WILFRED EYNON HUGH and GEORGE ARMAND ROBERT KON.

It has already been suggested that the function of activating groups in enhancing the mobility of a three-carbon system is connected with the capacity of the mobile hydrogen to enter such groups (compare Kon and Speight, J., 1926, 2727). For instance, the rapid interconversion of  $\alpha\beta$ - and  $\beta\gamma$ -unsaturated ketones in presence of sodium ethoxide is no doubt due to the formation of the sodio-derivatives of the enolic form of the ketone; or, in terms of the ionic hypothesis of tautomerism, the change proceeds through the establishment of an equilibrium between the ions of the two keto-forms and the common enol ion (Ingold, Shoppee, and Thorpe, J., 1926, 2477; Linstead, J., 1929, 2498). There are thus two equilibria—one involving only the keto-enol system of the activating group, the other the three-carbon system as well.

One of the chief differences between keto-enol and three-carbon systems is the greater mobility of the former; it should, therefore, be possible to realise conditions under which only the keto-enol change can proceed to completion, without causing mobility of the adjacent three-carbon system and thus giving rise to a "false equilibrium." This would be expected in systems sufficiently acidic to form stable enols and in the absence of polar catalysts. For instance, if the  $\alpha\beta$ -unsaturated ethyl *cyclopentylidenemalonate* (I) were converted into the sodio-derivative, which is necessarily derived from the  $\beta\gamma$ -form, and hydrogen could be introduced in place of sodium under conditions precluding complete equilibration, the enol produced should be converted into its own keto-form, which is the hitherto unknown  $\beta\gamma$ -isomeride (II).

The ester (I) and ethyl  $\alpha$ -cyanocyclohexylideneacetate (III) were chosen for the investigation; in addition, ethyl  $\alpha$ -cyano- $\beta$ -ethylcinnamate (IV) and ethyl  $\alpha$ -cyano- and  $\alpha$ -carbethoxy- $\gamma$ -phenyl- $\beta$ -methylbutenoates (V) and (VI) were prepared:

Although the results so far obtained are of a preliminary character, they show that it is possible to arrest three-carbon tautomerism to some extent whilst allowing keto-enol equilibrium to be established in the manner suggested. The method adopted consists in forming the sodio-derivative of the ester, preferably in a neutral solvent, and decomposing it by the addition of a weak organic acid such as benzoic acid, at a low temperature; after removal of the sodium benzoate, the ester is isolated by evaporation of the solvent, somewhat on the lines of Knorr's classical work on ethyl acetoacetate.

Negative results were always obtained with the cyano-ester (III), but the ester (I) gave definite indications of a change. The ester obtained from the sodio-derivative not only had a lower boiling point, density, and refractive index, but showed a considerable increase in additive power towards iodine chloride: all these properties are consistent with the  $\beta\gamma$ -unsaturated structure. Oxidation with ozone led to a substance having the properties both of an aldehyde and of a  $\beta$ -ketonic ester, as would be expected from such a structure.

Even careful hydrolysis of the new ester gave the original acid and no isomeride has yet been obtained.

Although esterification of the pure acid by way of its silver salt (Kon and Speight, *loc. cit.*) leads to the pure  $\alpha\beta$ -ester (I), esterification in presence of a strong mineral acid gives an ester containing a considerable quantity of the  $\beta\gamma$ -form, in some cases as much as is present in the ester prepared by regeneration from the sodio-derivative. The esters obtained by different processes differ considerably in properties; that obtained by the direct condensation of cyclopentanone with ethyl malonate is mainly the  $\alpha\beta$ -ester, whereas acidification of the sodio-derivative in alcoholic solution without special precautions yields an ester containing a considerable proportion of the  $\beta\gamma$ -form: this "equilibrium ester" appears to have a fairly constant composition; it is difficult to estimate the proportion of the two isomerides in it by the iodometric method, as the pure  $\beta\gamma$ -ester has in all probability not been obtained.

It was hoped to gain a means of comparison by determining the iodine addition of the pure  $\beta\gamma$ -ester of the cyclohexane series (ethyl cyclohexenylmalonate). This ester was prepared by the silver-salt process from the pure acid, which had a very high affinity for iodine (91.4%), in contrast with that of the cyclopentane acid (0.35%); but the ester had a low iodine value and therefore was valueless for our purpose.

Cyano-esters with a phenyl group in the  $\beta$ - and especially in the  $\gamma$ -position appeared likely to pass readily into the  $\beta\gamma$ -forms (compare Linstead and Williams, J., 1926, 2735; Johnson and Kon,

*ibid.*, p. 2748), and for this reason the esters (IV) and (V) were synthesised: they were found to have the  $\alpha\beta$ -unsaturated structure, unlike Linstead and Williams's cyano-ester, but although they yielded  $\beta\gamma$ -unsaturated alkylation products, the  $\beta\gamma$ -isomerides could not be obtained from them. The condensation product of benzyl methyl ketone and ethyl malonate was abnormal in structure, and the acid obtained from it on hydrolysis had lost the elements of water (compare Linstead and Williams, *loc. cit.*); in addition, the double bond was already in the  $\beta\gamma$ -position, because the acid yielded benzaldehyde on oxidation: it has not yet been fully investigated.

#### EXPERIMENTAL.

*Ethyl  $\alpha$ -Cyanocyclohexylideneacetate* (III).—The ester was prepared by the method of Harding, Haworth, and Perkin (J., 1908, 93, 1949) and had the properties recorded by Birch, Kon, and Norris (J., 1923, 123, 1361): the value 53.94 given there for  $[R_L]_D$  is a misprint for 53.594.

The  $\alpha\beta$ -structure of the ester was confirmed by oxidation: 5 g. of the ester were treated with the required amount of ice-cold neutral 3% aqueous potassium permanganate and the solution was kept for an hour; cyclohexanone, isolated by steam-distillation and extraction with ether, was identified in the form of semicarbazone (m. p. and mixed m. p. 165–166°).

The ester (1/10 g.-mol.) was slowly added to 2.3 g. of "molecular" sodium covered with dry ether. The reaction was vigorous, but it was difficult to induce all the sodium to react. Finally, light petroleum was added and the precipitated sodio-derivative was collected rapidly, suspended in dry ether, and treated with 1/10 mol. of benzoic acid in dry ether. When the yellow colour had disappeared, the ethereal solution was washed with aqueous sodium carbonate and with water, dried over calcium chloride, and evaporated, finally in a vacuum. The properties of the ester obtained,  $d_4^{16.5}$  1.0616,  $n_D^{18.5}$  1.48327, changed but little after distillation (b. p. 160–164°/18 mm.). In another experiment the preparation of the sodio-derivative was carried out in benzene solution, which was preferable to ether, with a similar result. In a third experiment the regeneration was carried out at  $-20^\circ$  by means of dry hydrogen chloride or by means of less than the calculated amount of glacial acetic acid (containing a little acetic anhydride to ensure the absence of water) and the washing was omitted. In all cases the ester had the same iodine addition (about 5% in one hour) as that of the pure  $\alpha\beta$ -ester, and this did not change on treatment with sodium ethoxide. The change in physical properties was therefore clearly due to a certain amount of reduction of the cyano-ester during the formation

of the sodio-derivative. In order to obviate this, sodium ethoxide, freed from excess of alcohol, was used to form the sodio-derivative, which was then precipitated with a large volume of light petroleum and treated with benzoic acid; no indication of the existence of a  $\beta\gamma$ -ester was obtained.

*Ethyl cyclopentylidenemalonate* (I).—The ester was prepared by the method of Kon and Speight (*loc. cit.*), but it was found convenient to modify the process of isolation as follows. The almost black reaction product of cyclopentanone and ethyl malonate was mixed with 3–4 volumes of light petroleum and well shaken; the acetanilide and the tarry matter formed were precipitated and the very troublesome and wasteful process of washing was thus obviated. The almost clear petroleum solution was filtered, washed with water and alkali, and dried; on evaporation it gave a fair yield of the required ester,  $d_4^{23.5}$  1.0613,  $n_D^{23.5}$  1.4696, iodine addition in 1 hour (in chloroform solution by the method of Linstead and May; J., 1927, 2565) 11.1%.

The ester on hydrolysis gave the acid already described by Kon and Speight; the iodine addition of the pure acid in sodium bicarbonate solution was only 0.35% in 1 hour. This was esterified through the silver salt and the ester produced had b. p.  $160^\circ/20$  mm.,  $d_4^{23.0}$  1.0618,  $n_D^{23.0}$  1.47301,  $[R_L]_D$  59.75 (compare Kon and Speight, *loc. cit.*), iodine addition in 1 hour 1.5%.

The first experiments on the regeneration of the ester from its sodio-derivative were carried out with "molecular" sodium in benzene in the manner described on p. 777; a definite indication of change was obtained. In later experiments, sodium ethoxide was prepared from specially dehydrated alcohol, the excess of alcohol carefully removed in a vacuum at  $100^\circ$ , and the ester added together with some petroleum (b. p.  $40$ – $60^\circ$ ); when the sodio-derivatives had formed, more petroleum was added and the solid allowed to settle. The petroleum solution was decanted, the residue again washed with petroleum (the sodio-derivative can also be filtered off), and benzoic acid in dry ether added to the sodio-derivative with shaking, more petroleum then being added. The gelatinous sodium benzoate was filtered off, and the petroleum solution washed with dilute aqueous sodium carbonate, washed, dried, and evaporated. The ester, obtained in 30–50% yield, varied but little in properties; the best specimen had b. p.  $147$ – $148^\circ/19$  mm.,  $d_4^{24.5}$  1.0511,  $n_D^{24.5}$  1.45743,  $[R_L]_D$  58.37 (calc., 58.02), and an iodine addition of 38.4%; it consisted, therefore, mainly of *ethyl  $\Delta^1$ -cyclopentenylmalonate* (II) (Found: C, 64.0; H, 8.0.  $C_{12}H_{18}O_4$  requires C, 63.7; H, 8.0%). The molecular refraction shows an exaltation of only 0.35 unit (comparable with that found by Kon and Speight

for the  $\alpha$ -methyl derivative and for cyclohexenylmalonic ester), due, no doubt, to the conjugation of the two carbethoxy-groups. The ester did not give a colour with ferric chloride.

The petroleum solution decanted from the sodio-derivative was acidified with hydrochloric acid, washed with sodium carbonate solution, and evaporated, yielding a further quantity of ester; this had a lower iodine addition—about 30%—and presumably was the "equilibrium ester."

A specimen of the  $\beta\gamma$ -ester, prepared by direct esterification as described below, was treated with alcoholic sodium ethoxide, and the product isolated without special precautions; it had b. p. 142—150°/20 mm.,  $d_4^{20}$  1.0551,  $n_D^{20}$  1.46191,  $[R_L]_D$  58.91, and an iodine addition of 28.0%, and was thus very similar to the preceding ester.

When sodium methoxide was used in place of the ethoxide in the above preparation, the product obtained was *methyl ethyl cyclopentenylmalonate*; after redistillation it boiled at 137—138°/18 mm. and had  $d_4^{20}$  1.09776,  $n_D^{20}$  1.46380, iodine addition about 37% (Found: C, 62.0; H, 7.3.  $C_{11}H_{16}O_4$  requires C, 62.2; H, 7.6%).

The  $\beta\gamma$ -ester was also produced when the solid  $\alpha\beta$ -acid was kept in contact with 1% alcoholic hydrogen chloride (8 vols.) at room temperature; the acid slowly dissolved in the course of 10 days and the ester was then isolated and the considerable unesterified portion again treated with alcoholic hydrogen chloride. The ester had b. p. 146—148°/20 mm.,  $d_4^{20}$  1.0546,  $n_D^{20}$  1.45923,  $[R_L]_D$  58.65; the iodine addition was 37.5%, so the ester was evidently mainly the  $\beta\gamma$ -form. In another instance, the acid was boiled with a saturated solution of hydrogen chloride in absolute alcohol for a short time; the ester produced was mainly the  $\alpha\beta$ -form.

The  $\beta\gamma$ -ester, dissolved in ethyl acetate, was treated with ozonised oxygen at 0°, the ozonide was freed from the solvent and decomposed by warm water, and the product isolated by means of ether and distilled. Much decomposition (elimination of alcohol?) took place and a definite fraction was not obtained, the greater part boiling between 140° and 150°/11 mm. This gave an intense blue colour, slowly changing to red, with ferric chloride, and Schiff's test, and was thus an aldehyde and a  $\beta$ -ketonic ester, presumably  $CHO \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot CO \cdot CH(CO_2Et)_2$ ; the carbon content, however, agrees better with the formula  $CHO \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot CO \cdot CH_2 \cdot CO_2Et$  (Found: C, 59.1; H, 7.2.  $C_{12}H_{18}O_6$  requires C, 55.8; H, 7.0%.  $C_9H_{14}O_4$  requires C, 58.0; H, 7.6%); crystalline derivatives could not be obtained from it.

The  $\beta\gamma$ -ester was hydrolysed by means of cold 5% alcoholic sodium hydroxide, and the acid isolated in the usual manner. The

$\alpha\beta$ -acid, m. p.  $171^\circ$ , was isolated in quantity; a more soluble constituent was also present, but it could not be obtained pure. An attempt to prepare the pure  $\beta\gamma$ -ester by partial esterification of the crude acid obtained above (compare Eccott and Linstead, J., 1929, 2153) was unsuccessful; the ester produced had a slightly lower iodine addition than the specimen from which it was derived.

*Ethyl cycloHexenylmalonate*.—The pure acid, m. p.  $150^\circ$  (Kon and Speight), was found to have an iodine addition of 91.4% in 1 hour. It was esterified through the silver salt, giving an ester, b. p.  $160^\circ/20$  mm.,  $d_4^{20.9^\circ}$  1.0504,  $n_D^{20.9^\circ}$  1.4646, iodine addition 7.5%. Another specimen of the ester was separated into two portions by distillation, but both had practically identical properties and iodine additions (7.4 and 8.1%). After treatment of the ester with sodium ethoxide without special precautions, the iodine addition rose somewhat (9.6%). The ozonisation of the ester was repeated, Kon and Speight's results being confirmed.

*Ethyl  $\alpha$ -Cyano- $\beta$ -ethylcinnamate* (IV).—Ethyl cyanoacetate (57 g.) and propiophenone (67 g.) were mixed with 1 c.c. of piperidine and heated on the steam-bath for 3 days. The product was dissolved in ether, washed with dilute hydrochloric acid and with water, dried, and distilled. Most of the initial material was recovered, but some 12 g. of an oil, b. p.  $182$ — $188^\circ/17$  mm., were collected. The yield of this oil could be increased to about 28 g. by adding anhydrous sodium sulphate to the reaction mixture to facilitate the separation of the water formed in the reaction. Condensation also took place in the presence of sodium ethoxide in alcohol (11.5 g. of sodium in 150 c.c. of alcohol), the mixture being heated until the whole of the solid ethyl sodiocyanoacetate had disappeared (about 2 hours); the yield of high fraction contained in the neutral reaction product was about 20 g. The recovered material could be used again. The fraction of b. p.  $182$ — $188^\circ/17$  mm. gave on careful redistillation a large fraction, b. p.  $185^\circ/15$  mm., consisting of *ethyl  $\alpha$ -cyano- $\beta$ -ethylcinnamate*,  $d_4^{19.3^\circ}$  1.0695,  $n_D^{19.3^\circ}$  1.53803,  $[R_L]_D$  67.01 (calc., 64.26) (Found: C, 73.2; H, 6.5.  $C_{14}H_{15}O_2N$  requires C, 73.4; H, 6.6%). The structure of the ester was confirmed by oxidation with permanganate exactly as described on p. 777; propiophenone was obtained in good yield and identified in the form of its semicarbazone.

All attempts to obtain the  $\beta\gamma$ -isomeride from the sodio-derivative were unsuccessful.

The ester was readily ethylated through its sodio-derivative, prepared with the aid of "molecular" sodium in benzene. The new ester, *ethyl  $\alpha$ -cyano- $\beta$ -phenyl- $\alpha$ -ethyl- $\Delta^8$ -penteenoate*,

had b. p. 182—186°/16 mm.,  $d_4^{17.2}$  1.0545,  $n_D^{17.2}$  1.52175,  $[R_L]_D$  74.33 (calc., 73.50) (Found: C, 74.9; H, 7.3.  $C_{16}H_{19}O_2N$  requires C, 74.7; H, 7.4%). Like other similar compounds, the ethylated cyano-ester readily lost carbethoxyl in the form of ethyl carbonate on being kept with an equivalent of sodium ethoxide at 35° for 24 hours, giving  $\beta$ -phenyl- $\alpha$ -ethyl- $\Delta^a$ -pentenonitrile, b. p. 142—146°/14 mm.,  $d_4^{19.0}$  0.9856,  $n_D^{19.0}$  1.54052,  $[R_L]_D$  58.97 (calc., 57.98) (Found: C, 83.6; H, 7.7.  $C_{13}H_{15}N$  requires C, 84.3; H, 8.2%).

*Attempted Condensation of Propiophenone and Ethyl Malonate.*—It was not found possible to obtain a condensation product from these substances under any of the conditions tried.

*Ethyl  $\alpha$ -Cyano- $\gamma$ -phenyl- $\beta$ -methyl- $\Delta^a$ -butenoate (V).*—Benzyl methyl ketone (134 g.), ethyl cyanoacetate (113 g.), and piperidine (2.5 c.c.) were kept at room temperature for 3 days with occasional shaking. Water began to separate after about 3 hours. The mixture was worked up as described on p. 780, and the product distilled under reduced pressure; after unchanged materials had passed over, an oil was obtained which on redistillation gave 46 g. of the ester (V): a small quantity was also obtained from the lower fractions, and there was hardly any high-boiling fraction. The ester had b. p. 182—184°/11 mm.,  $d_4^{18.9}$  1.0790,  $n_D^{18.9}$  1.53401,  $[R_L]_D$  66.00 (calc., 64.26) (Found: C, 73.5; H, 6.6.  $C_{14}H_{15}O_2N$  requires C, 73.4; H, 6.6%). It gave benzyl methyl ketone in good yield (semi-carbazone, m. p. 189—190°) on oxidation with neutral permanganate, its structure thus being confirmed.

Attempts to obtain the  $\beta\gamma$ -isomeride were unsuccessful. From the sodio-derivative prepared with the aid of sodium ethoxide by the method described on p. 778, the ester was regenerated unchanged, the iodine addition being the same before and after the experiment (3.8% in 1 hour). When "molecular" sodium was used, some change in the physical properties of the ester took place, but this was due to reduction; no rise in iodine addition was observed.

The ester was ethylated as described on p. 780. The product did not boil uniformly, doubtless owing to the presence of a small amount of reduced material, but a considerable fraction, b. p. 190—192°/13 mm., was obtained consisting of ethyl  $\alpha$ -cyano- $\gamma$ -phenyl- $\beta$ -methyl- $\alpha$ -ethyl- $\Delta^b$ -butenoate,  $d_4^{18.2}$  1.0452,  $n_D^{18.2}$  1.51986,  $[R_L]_D$  74.76 (calc., 74.50) (Found: C, 74.4; H, 7.4.  $C_{16}H_{19}O_2N$  requires C, 74.7; H, 7.4%). When this ester was treated with sodium ethoxide, ethyl carbonate and  $\gamma$ -phenyl- $\beta$ -methyl- $\alpha$ -ethyl- $\Delta^a$ -butenonitrile,  $CH_2Ph \cdot CMe \cdot CEt \cdot CN$ , were produced. The latter on redistillation boiled at 159—161°/16 mm. and had  $d_4^{18.4}$  0.97806,  $n_D^{18.4}$  1.52469,  $[R_L]_D$  57.97 (calc., 57.98) (Found: C, 83.9; H, 8.3.  $C_{13}H_{15}N$  requires C, 84.3; H, 8.2%).

*Condensation of Benzyl Methyl Ketone with Ethyl Malonate.*—The condensation was carried out by the method of Kon and Speight (*loc. cit.*). From 1 g.-mol. of the ketone, about 10 g. of a fraction, b. p. 180—188°/14 mm., presumably consisting of the ester (VI), were obtained. On hydrolysis with alkali, the ester gave an acid,  $C_{12}H_{10}O_3$  (Found: C, 71.4; H, 5.1. *M*, by titration, 196.5.  $C_{12}H_{10}O_3$  requires C, 71.3; H, 5.0%; *M*, 202.  $C_{12}H_{12}O_4$  requires C, 65.5; H, 5.4%). On oxidation with alkaline permanganate the acid yielded benzaldehyde, which was identified by means of its semicarbazone.

The authors' thanks are due to the Royal Society for grants which have defrayed the cost of this investigation.

## CVI.—*The Properties of the Chlorides of Sulphur.* *Part III. Dielectric Constants.*

By THOMAS MARTIN LOWRY and GILBERT JESSOP.

IN the two preceding papers of this series (J., 1927, 746; 1929, 1421), it has been shown (i) that sulphur dichloride,  $SCl_2$ , crystallises as a stable phase from a liquid chloride of sulphur containing from 59 to 65 atoms % of chlorine, and a new chloride,  $S_3Cl_4$ , separates in the range 57—59 atoms %; (ii) that sulphur dichloride in the liquid state is dissociated at atmospheric temperatures to the extent of about 16% according to the equation  $2SCl_2 \rightleftharpoons S_2Cl_2 + Cl_2$ ; (iii) that sulphur tetrachloride,  $SCl_4$ , which is the stable solid phase over a wide range of compositions above 65 atoms % of chlorine, cannot be detected in the liquid phase; and (iv) that a liquid chloride of sulphur therefore behaves as a ternary mixture of mono- and di-chlorides and chlorine only. In the present paper these results have been confirmed by measurements of the dielectric constants of a series of samples ranging from sulphur monochloride to pure chlorine, which show that sulphur tetrachloride is stable in the solid phase, but cannot be detected in the liquid phase.

### EXPERIMENTAL.

*Methods.*—The apparatus used for the measurement of dielectric constants (compare Sayce and Briscoe, J., 1925, 127, 315) is shown in Fig. 1. It employs a valve generating circuit, but does not appear to be open to the objections which have been raised by many authors to such circuits. The stress applied to the dielectric must

be small and of sine-wave form, without the harmonics of considerable amplitude which are found in most valve-operated circuits; and the apparent value of the capacity must not vary when the liquid shows a small conductivity. In the present apparatus these conditions are fulfilled in view of the fact that the circuit which contains the dielectric is not coupled directly to the valve;

FIG. 1.

*Apparatus for measuring dielectric constants.*

and experimental tests have shown that the introduction of a high resistance in parallel with the condenser merely reduces the accuracy of the measurement, without altering the absolute value of the constant. The main difficulties were (i) to construct a condenser of large capacity (150 cm.) which could be adjusted with great accuracy (within 0.01 cm.), and (ii) to construct a cell, which would hold only a small volume (5–10 c.c.) of a corrosive liquid, but could with-

FIG. 2.

*Variable condenser.*

stand an internal pressure of 1–2 atm., and be used at any temperature from  $-100^{\circ}$  to  $25^{\circ}$ .

(a) *Condensers.* The condenser of variable capacity and wide range included four fixed condensers,  $C_a$  to  $C_d$ , having capacities of about 10, 20, 40, and 80 cm. respectively, and a variable condenser,  $C_b$ , with a capacity of about 15 cm. The fixed condensers were made from air-spaced aluminium plates mounted on ebonite. One set of plates was connected to the earthed lining of the box containing the apparatus, and the other to small mercury cups which could be connected to the "live" side of the circuit by means of wire bridges operated from the outside of this box. The variable condenser,  $C_b$ , was cylindrical, as shown in Fig. 2, whereas Sayce and

Briscoe used a rotating-plate condenser. The "live" side was a fixed brass tube, A, mounted on ebonite blocks. The earthed plate was formed by an accurately turned brass cylinder, B, attached to a rod F, and was mounted on two rigid bearings, C and C', the latter, carrying the tube B, being V-shaped. The air gap between A and B was about 1 mm. The capacity of the condenser was varied with the help of a fine screw, D, against the point of which the end of the inner cylinder was pressed by a spring, which is not shown in the diagram. "End effects" were prevented by means of earthed guards, E. The condenser, which was used over a small range only,

FIG. 3.

*Dielectric-constant cell.*

FIG. 4.

*Conductivity cell.*

as shown by the dotted lines, was calibrated against a small fixed condenser, and it was found that the variation of capacity was proportional to the rotation of the divided head of the screw D over the entire working range.

(b) *Cell.* The type generally used is shown in Fig. 3. The inner plate of the condenser consisted of a cylinder, A, of platinum foil, which was kept in shape by being mounted on a short closed glass tube. Surrounding this, and separated from it by a gap of about 1 mm., was a stout platinum cylinder, B, which formed the outer plate of the condenser. The inner tube and outer cylinder were held rigidly apart by means of small glass bridges, C. The condenser fitted loosely into a glass tube, closed at the bottom and provided at the top with a delivery tube, which could be sealed. Platinum

wires from the condenser plates were led out near the top of the wide tube. Connexion with the "live" side of the circuit was made by means of a small wire bridge in mercury cups. The outer cylinder was permanently earthed.

The lower part of the cell was surrounded by a stout copper cylinder, which was earthed, and round which a Dewar flask containing liquid air could be placed. This served to hold the cell, to act as an earthed sheath, and to maintain a uniform temperature in the liquid. Temperature was measured by means of a single-junction copper-constantan thermocouple, with one junction inside the copper sheath and the other in a Dewar flask containing ice and water. The current from it was measured on a microgalvanometer which could be switched out of the valve circuit into the thermocouple circuit.

(c) *Arrangement of circuits.* Oscillatory currents were maintained in circuit  $L_1C_1$  by means of the valve  $V$ , connected as shown. The magnitude of the direct component of the current in the anode circuit is a function of the oscillating currents in  $L_1C_1$ . If a second circuit,  $L_3C_3$ , is now coupled loosely to this, energy is withdrawn when the natural frequency of  $L_3C_3$  is very nearly the same as that in  $L_1C_1$ . If the coupling is adjusted correctly, and the value of  $L_3C_3$  is then altered, the anode current first falls gradually to a well-defined minimum and afterwards rises gradually again; this minimum is very sensitive to change of capacity in  $L_3C_3$ , and could be determined within about 0.02 cm. variation in the capacity of  $C_3$ .

The whole assembly of the apparatus is shown diagrammatically in Fig. 1. The cell and the battery of condensers, denoted by  $C_3$ , were connected in parallel with the inductance,  $L_3$ , which consisted of 12 well-spaced turns of No. 20 copper wire wound on an ebonite former, giving a wave-length of about 200 m.  $L_1$  and  $L_2$  were ordinary wireless inductances, No. 30. The variable condenser,  $C_1$ , had a maximum value of 0.0025 microfarad, and the by-pass condenser,  $C_2$ , had a value of 0.01 microfarad.  $G$  was a microgalvanometer of sensitivity about 0.5 microamp. per scale division.  $R_1$  was a 300-ohm potentiometer, and  $R_2$  a resistance of about 100 ohms.  $R_1$  and  $R_2$  were adjusted so as to neutralise the greater part of the anode current through the galvanometer. A galvanometer shunt,  $R_3$ , was added for convenience of working. The fixed condensers,  $C_{a-d}$ , were calibrated in terms of scale readings on the divided head of  $C_v$ . All the "live" parts of the apparatus, except the experimental cell, were housed in a wooden box with an earthed lining of sheet metal. In order to prevent sudden fluctuations of anode current the valve was wrapped in cotton wool, and a 6-microfarad condenser put across the terminals of the high-tension battery.

Before any measurements were made,  $C_1$  was adjusted so that, with  $C_{a-d}$  in circuit, resonance was obtained with  $C_v$  at about the middle of its range. It then remained unaltered throughout the series of experiments. In an experiment, the resonance point was determined roughly with shunt  $R_3$  partly in, and  $R_1$  adjusted so that the galvanometer needle was about in the centre of the scale at the minimum point.  $R_3$  was then taken out and the minimum found by altering  $C_v$  in each direction three times. The mean of these six readings gave the true resonance point. The experimental cell was then put in circuit and capacity removed from  $C_3$  until resonance was again obtained as before. The capacity of the cell was equal to the capacity removed from  $C_3$ . Another set of readings was then taken to see that the zero had not altered. The change in zero was not usually more than 0.02 unit, whereas the capacity of the cell in air was of the order of 20 units.

(d) *Calibration.* Since the air between the live plate and earth is not replaced completely by liquid, the dielectric constant could not be obtained directly by measuring the ratio of the capacity of the cell when filled and when empty. The cell was therefore calibrated with carbon tetrachloride and chloroform. These liquids were carefully purified and dried; their respective dielectric constants at 25° were taken as 2.20 and 4.79 (Sayce and Briscoe, J., 1926, 2623). The observed capacities were: Air, 30.19;  $CCl_4$ , 57.62;  $CHCl_3$ , 120.31. These were made the basis of a calibration curve for the cell over the range of dielectric constants covered by the experiments.

### Results.

The dielectric constants of sulphur chloride mixtures were measured over the range of compositions from sulphur monochloride to pure chlorine, and at temperatures from that of the room down to that at which solidification was complete. Samples containing less chlorine than the dichloride were put into the cell as equilibrium mixtures; mixtures containing more chlorine were made in the cell and left over-night to reach equilibrium. The observed values for the dielectric constants of 13 different samples at different temperatures are recorded in Table I.

### Discussion of Dielectric Constants.

(a) The dielectric constants of the liquids, which are plotted for 5 typical compositions in Fig. 5, fall as the temperature rises, the relationship being linear in each case. The temperature coefficient, as well as the magnitude of the dielectric constant, rises progressively from chlorine to sulphur monochloride. In accordance with Debye's analysis, this implies that there is a progressive increase in

the dipole moments as well as in the polarisability of the molecule as atoms of sulphur are inserted between the chlorine atoms in the series  $Cl_2$ ,  $SCl_2$ ,  $S_2Cl_2$ . The curves obtained by plotting the dielectric constants against composition at three temperatures (Fig. 6) are approximately linear, but with a sharp bend at the composition of the dichloride; the absence of a complete discontinuity can be attributed, as in the case of other properties, to the dissociation of the dichloride into a ternary mixture containing also the monochloride and free chlorine. No indication was obtained, however,

FIG. 5.

FIG. 6.

of any discontinuity or change of curvature at the composition of the tetrachloride.

(b) The dielectric constants of the solid, which are practically independent of the temperature, have been plotted in Fig. 6 and joined by an arbitrary curve. Three types of behaviour can be recognised.

(i) Solid chlorine, of which the dielectric constant is now recorded, apparently for the first time, has almost exactly the same dielectric constant as liquid chlorine, the average values above and below the m. p. being 2.17 and 2.10. This is interpreted as meaning that, whilst the molecules are polarisable, they have only a very small permanent dipole moment, a result in harmony with the small temperature coefficient recorded above and with other methods of estimating this quantity.

(ii) Sulphur monochloride, on the other hand, after a progressive rise from 4.7 to 5.8 as the liquid is cooled from 15° to -50°, shows an abrupt fall from 6.4 to 3.2 when it finally solidifies. This behaviour is characteristic of liquids with a large permanent dipole moment, since water ( $\epsilon = 81$ ), alcohol ( $\epsilon = 62.7$ ), and nitrobenzene ( $\epsilon = 43.3$ ) show an abrupt fall on solidification to values (3.1, 2.7, and 4.1 respectively) which are comparable with those observed in non-polar liquids such as benzene (2.2) or carbon tetrachloride (2.2).

(iii) An entirely different and novel behaviour was observed in solids of intermediate composition, where a large *increase* of dielectric constant was recorded on solidification. This striking abnormality is shown clearly in the broken curve of Fig. 5, where the dielectric constant is seen to turn sharply upwards as the liquid becomes solid, and to droop again as the solid gradually melts. If we were obliged to admit that the solid had the same chemical constitution as the liquid, we should conclude that the molecules had a negative dipole moment, which is absurd. It is, however, easy to see that this anomaly reaches a maximum *at or near the composition of sulphur tetrachloride*, and must therefore be attributed to the presence of this compound in the solid phase. The proportions in which it would be present in each case cannot yet be stated, and might vary widely with the conditions of crystallisation, but the position of the maximum fixes beyond question the chemical composition of the abnormal component of the mixture. Moreover, the complete dissociation of the tetrachloride on fusion is demonstrated once more by these observations, since, if it survived in any appreciable proportion, it could scarcely fail to reproduce in the curve for the *liquid* the maximum which is so conspicuous a feature of the curve for the *solid* sulphur chlorides. Finally, it may be pointed out that the high dielectric constant (6.2) of solid sulphur

tetrachloride brings it into line with salts such as rock-salt (6.3), sylvine (4.9), fluorspar (6.9), and ammonium chloride (7.0), whereas the solid monochloride (3.2) resembles sulphur (3.9) and chlorine (2.1) in showing the low dielectric constants usually observed in solid molecular compounds.

Since no case appears to have been established previously of a large increase in the dielectric constant of a liquid on solidification,\* it is of interest to record that we have discovered an analogous case in phosphorus pentachloride, m. p. 148°, where our own observations show an increase in the dielectric constant from 2.7 for the liquid at 165° to 4.1 for the solid at 130°. As is well known, Langmuir has attributed to both compounds a salt-like structure, which would explain the high dielectric constant of the solids, but at this stage we are content merely to point out that the abnormality to which we have directed attention suggests a change of structure during the passage from the liquid to the solid state, the precise nature of which awaits investigation with the help of X-ray analysis.

(c) The dielectric polarisation, in terms of the molecular weights ( $M_1$  and  $M_2$ ) and mole-fractions ( $n_1$  and  $n_2$ ) of a mixture, can be deduced from the formula

$$p = \frac{\epsilon - 1}{\epsilon + 2} \frac{M_1 n_1 + M_2 n_2}{d}$$

We have therefore calculated the values of this function in the first instance for mixtures of sulphur dichloride (i) with monochloride and (ii) with chlorine, in such large excess that the dissociation of the dichloride would be quite insignificant. Since, however, the formula is not restricted to gases or dilute solutions, we have extended the calculations to solutions containing much larger proportions of the dichloride, and obtained results which are entirely concordant with those given by the more dilute solutions. For this purpose, the dielectric constants were first reduced by interpolation to a temperature of 0°, and were then combined with the densities at this temperature to give the dielectric polarisation of the mixtures. When these numbers are plotted against the mole-fraction of sulphur (Fig. 7), two straight lines are obtained, which intersect accurately on the boundary of the diagram. These liquids therefore obey a simple mixture rule with  $p = 12$ , 27, and 46 for chlorine, dichloride, and monochloride, respectively.

This result might, perhaps, have been predicted if we were certain in advance that we were dealing with a simple ternary (pseudo-binary) system containing only the components shown in the

\* Schmundt, *J. Physical Chem.*, 1904, 8, 122, gives phosphorus (solid) 4.1, (supercooled liquid) 3.85 at 20°; Pirani, *Diss.*, Berlin, 1903, gives sulphur (at f. p.) 3.98, solid (room temperature) 4.22.

equation  $\text{Cl}_2 + \text{S}_2\text{Cl}_2 \rightleftharpoons 2\text{SCl}_2$ . If, however, we were to postulate, with Trautz (*Z. Elektrochem.*, 1929, **35**, 110), a series of equilibria in which the tetrachloride plays an essential part, no such simple relationship could be expected. The data plotted in Fig. 7 are therefore of real importance, since they prove that the compound formed by adding a small excess of chlorine to sulphur monochloride (which might have been  $\text{S}_3\text{Cl}_4$ ) and the compound formed by adding a small amount of sulphur to pure liquid chlorine (generally supposed hitherto to be  $\text{SCl}_4$ ) have in fact the same constant of dielectric polarisation, and in this respect, as in others, are identical.

FIG. 7.

#### Conductivities.

It is generally agreed that sulphur mono- and di-chlorides and chlorine are covalent compounds, as represented by the formulæ  $\text{Cl-S-S-Cl}$ ,  $\text{Cl-S-Cl}$ , and  $\text{Cl-Cl}$ ; and this formulation is confirmed by the gradation in the dielectric polarisation of the three substances. Langmuir, however, has attributed to sulphur tetrachloride a polar formula  $[\text{SCl}_3]^+\text{Cl}^-$ , and the electronic theory of valency suggests that a similar polar formula should be assigned to trisulphur tetrachloride,

which may be formulated as  $[\text{ClS-}\overset{+}{\text{S}}\text{Cl-S-Cl}]\text{Cl}^-$ . Evidence of the presence of sulphur tetrachloride and justification of Langmuir's polar formula would therefore be provided simultaneously if solutions could be prepared showing a substantial electrolytic conductivity. The apparatus used to test this is shown in Fig. 4. It had a cell constant of 0.17 and was specially designed for use at low temperatures with corrosive substances easily decomposed by water.

(i) A solution of sulphur tetrachloride (*sic*) in liquid chlorine was prepared by weighing the liquid dichloride into the cell, cooling it over liquid air, and passing in an excess of chlorine. When the

liquid was cooled to a temperature at which solid sulphur tetrachloride was beginning to separate, the conductivity of the saturated solution was found to be only  $0.18 \times 10^{-6}$  mho, i.e., of the same order as that of liquid chlorine.

(ii) A solution of sulphur dichloride in liquid hydrogen chloride was prepared by weighing the liquid dichloride into the cell and condensing hydrogen chloride by cooling over liquid air. The conductivity of the solution just below its boiling point was  $0.7 \times 10^{-6}$  mho. Chlorine was then passed in until the red colour of the dichloride had disappeared completely by precipitation of the tetrachloride as a colourless solid. The conductivity of the saturated solution was then  $0.65 \times 10^{-6}$ .

These observations show that no electrolytic conductivity is developed on attempting to prepare solutions of sulphur tetrachloride in chlorine or in hydrogen chloride. This result could be interpreted as showing either (i) that the tetrachloride is a non-electrolyte in these two solvents, or (ii) that it is insoluble in, or completely dissociated by, these two solvents and is therefore precipitated quantitatively as fast as it is formed. There is no method available for distinguishing sharply between these possibilities, although the first deduction is obviously unproven in view of the failure of all attempts to detect the presence of the tetrachloride in solution. The completeness with which the tetrachloride is removed from the solutions is, however, itself an indication of a wide difference in polarity from chlorine and the mono- and di-chloride, with which it should otherwise be freely miscible, as in the case of the non-polar chlorides of carbon. A similar argument can be applied to trisulphur tetrachloride which, at temperatures below  $-100^{\circ}$ , forms two liquid layers with its products of dissociation. We can therefore only return a negative reply to any questions as to the conductivity or other similar properties of sulphur tetrachloride, since we have been unable to find any evidence of the existence of this compound in the liquid state.

#### *Summary.*

(a) The dielectric constants of sulphur chloride mixtures have been measured over the range of composition from monochloride to chlorine and from room temperature down to the freezing points.

(b) The isothermals for the liquids confirm the existence of sulphur dichloride, but do not show any inflexion corresponding with the tetrachloride, even at  $-50^{\circ}$ .

(c) The dielectric constant of the solids shows a pronounced maximum at the composition of the tetrachloride.

CVII.—*A Synthesis of Pyrylium Salts of Anthocyanidin Type. Part XIX. A Synthesis of Delphinidin Chloride not involving a Demethylation Process, and Syntheses of Hirsutidin Chloride and of Delphinidin Chloride 3'-Methyl Ether, possibly identical with Petunidin Chloride.*

By WILLIAM BRADLEY, ROBERT ROBINSON, and GEROLD SCHWARZENBACH.

THE recognition that the purest specimens of cyanidin chloride can most readily be obtained if demethylation of methyl ethers is entirely avoided (Robertson and Robinson, Part XV, J., 1928, 1526; Willstätter and Robinson, *Ber.*, 1928, 61, 2504) made it desirable that the improved synthetical method already applied to the cases of pelargonidin chloride (Robertson, Robinson, and Sugiura, Part XVI, J., 1928, 1533) and cyanidin chloride (Part XV, *loc. cit.*) should be extended to include the preparation of delphinidin chloride.

This has now been carried out, and the resulting hexahydroxy-flavylium chloride compared with a specimen of delphinidin chloride from a natural source, no divergences of behaviour of the specimens being detected.

*O*-Triacetylgalloyl chloride and diazomethane furnished  $\omega$ -*diaz*-3:4:5-*triacetoxyacetophenone*,  $(\text{AcO})_3\text{C}_6\text{H}_2\cdot\text{CO}\cdot\text{CHN}_2$  (I), and  $\omega$ :3:4:5-*tetra-acetoxyacetophenone* (II) was readily obtained from the *diaz*-derivative by the action of acetic acid.

The tetra-acetate (II) condensed with 2-*O*-benzoylphloroglucin-aldehyde (III) (Robertson and Robinson, J., 1927, 1710) in alcohol-ethyl acetate solution under the influence of hydrogen chloride, with production of 5-*O*-benzoyldelphinidin chloride (IV), the acetyl groups being all removed in the course of the reaction. The final stage, namely, the elimination of the benzoyl group, gave trouble owing to the oxidisability of the substance in alkaline solution, but this difficulty was not insuperable. The debenzoylated product of the action of aqueous-alcoholic sodium hydroxide on (IV) was changed

to delphinidin chloride by treatment with hydrochloric acid under special conditions which it was found necessary to observe closely.

*Synthesis of Hirsutidin Chloride.*—In 1927, Karrer and Widmer (*Helv. Chim. Acta*, 1927, **10**, 758) isolated a new anthocyanin, hirsutin chloride, from the *Primula hirsuta*, and found that, on hydrolysis in the usual manner, *hirsutidin chloride*,  $C_{18}H_{17}O_7Cl$ , was obtained.

This anthocyanidin contained three methoxyl groups, gave syringic acid on oxidation and delphinidin salts on demethylation, and was therefore recognised as a methyl ether of syringidin chloride (*O*-methylmalvidin chloride). The methyl groups might be in the 3:3':5', 5:3':5', or 7:3':5'-positions, and, of these, Karrer and his collaborators preferred the last two. The synthesis of *O*-3:3':5'-trimethyldelphinidin chloride has already been effected (Bradley and Robinson, J., 1928, 1541), and, since the properties of this salt were different from those of hirsutidin chloride, concurrence with Karrer's view was expressed.

5:3':5'-*O*-Trimethyldelphinidin chloride (V) was obtained by condensing 2-*O*-methylphloroglucinaldehyde with  $\omega$ -acetoxy-4-benzoyloxy-3:5-dimethoxyacetophenone,

(Bradley and Robinson, *loc. cit.*), in formic acid solution in presence of hydrogen chloride. As in the synthesis of malvidin chloride, the benzyl group is eliminated.

7:3':5'-*O*-Trimethyldelphinidin chloride (VI) was obtained by hydrolysing its 5-*O*-benzoyl derivative derived from the use of

2-*O*-benzoyl-4-*O*-methylphloroglucinaldehyde (VII) in a similar process. This salt proved to be identical with hirsutidin chloride. The aldehyde (VII) was obtained on methylating 2-*O*-benzoylphloroglucinaldehyde by means of silver oxide and methyl iodide; its constitution follows from the occurrence of the flavylum salt synthesis and from relations represented in the subjoined scheme.

*Synthesis of Delphinidin Chloride 3'-Methyl Ether.*—This substance, which may be identical with petunidin chloride (Willstätter and Burdick, *Annalen*, 1916, **412**, 217), has been synthesised by an application of the *O*-benzoylphloroglucinaldehyde method; the chief difficulties were encountered in obtaining the required ketonic component.

(1) Karrer and Bloch, *Helv. Chim. Acta*, 1927, 10, 374; (2) Karrer and Helfenstein, *ibid.*, p. 789; (3) Robertson and Robinson, J., 1927, 1710; (4) Robertson, Robinson, and Struthers, J., 1928, 1455; (5) this paper.

The first step was to devise a more convenient method for the preparation of 3-*O*-methylgallic acid than those recorded by Vogl (*Monatsh.*, 1899, **20**, 397) and Fischer (*Ber.*, 1913, **46**, 1123). In this, we were successful, and the new method of protection of vicinal hydroxyl groups in polyhydric phenols that was adopted is one that should find numerous applications in other directions. Methyl gallate and diphenyldichloromethane in acetone solution in presence of pyridine, with subsequent addition of sodium hydroxide, afforded methyl 3-hydroxy-4:5-diphenylmethylenedioxybenzoate (VIII). This ester was methylated by means of methyl iodide and sodium ethoxide, and, on hydrolysis by alkaline solutions, 3-methoxy-4:5-diphenylmethylenedioxybenzoic acid (IX) was obtained; 3-*O*-methylgallic acid (X) resulted when the methylated ester was treated with boiling concentrated hydrochloric acid.

3-*O*-Methylgallic acid had m. p. 220° (diacetyl derivative, m. p. 170—171°) in agreement with the description of Fischer (*loc. cit.*) (Vogl, *loc. cit.*, gives the m. p. 199—200°).

Shriner and McCutchan, however, in a recent paper (*J. Amer. Chem. Soc.*, 1929, **51**, 2193), have stated that the acid has m. p. 132° (diacetyl derivative, m. p. 102—103°), and it was therefore necessary to explain this discrepancy. We find that the action of 8% aqueous sodium hydroxide at 200° on bromovanillin in the presence of copper actually yields 3-*O*-methylgallaldehyde (XI) and not the corresponding acid, as Shriner and McCutchan supposed.

Starting with the diphenylmethyle ether or the diacetyl derivative of 3-*O*-methylgallic acid and passing through the stages  $R\cdot CO_2H$ ,  $R\cdot COCl$  and  $R\cdot CO\cdot CHN_2$  to  $R\cdot CO\cdot CH_2\cdot OAc$ , we obtained the  $\omega$ -acetoxygallacetophenone derivatives (XII) and (XIII), respectively, and either of these, on condensation with 2-*O*-benzoyl-

phloroglucinaldehyde in the usual way, gave rise to 5-*O*-benzoyl-3'-*O*-methyldephinidin chloride (XIV). The 3'-*O*-methyldephinidin chloride (XV) obtained on hydrolysis very closely resembles petunidin chloride, but we are unable to express any opinion at this stage on the question of its identity with that anthocyanidin.

#### EXPERIMENTAL.

$\omega$ -Diazo-3:4:5-triacetoxyacetophenone (I).—Triacetylgalloyl chloride was prepared by the method of Fischer, Bergmann, and Lipschitz (*Ber.*, 1918, 51, 55). A solution of the chloride (18 g.) in chloroform (50 c.c.) was added during 10 minutes to ethereal diazomethane (140 c.c., from 25 c.c. of nitrosomethylurethane) cooled to  $-10^{\circ}$ . Evolution of nitrogen accompanied the rapid separation of pale yellow crystals of the diazo-ketone, and these were collected after 30 minutes and washed with ether (yield, 17.6 g.; m. p.  $120-122^{\circ}$ ). For analysis, the diazo-ketone was crystallised twice from benzene; it was obtained in stout lemon-yellow plates or tables, m. p.  $125-126^{\circ}$  with evolution of nitrogen (Found: C, 52.7; H, 3.7; N, 8.7, 8.8.  $C_{14}H_{12}O_7N_2$  requires C, 52.5; H, 3.8; N, 8.7%).

$\omega$ -Diazo-3:4:5-triacetoxyacetophenone is easily soluble in alcohol and benzene, more sparingly soluble in ether, and almost insoluble in light petroleum. It possesses the usual properties of diazomethylketones. Nitrogen is eliminated by heating, by the addition of iodine or aqueous mineral acids to an alcoholic solution, or by warming with glacial acetic acid. A drop of aqueous sodium hydroxide added to the cold dilute alcoholic solution causes the development of a yellow colour; from more concentrated solutions, a green amorphous solid, soluble in water, is precipitated, and, when gently heated, these solutions become reddish-brown.

$\omega$ :3:4:5-Tetra-acetoxyacetophenone (II).—A solution of the diazo-ketone (12 g.) in pure glacial acetic acid (25 c.c.) was warmed at  $60-80^{\circ}$  until the vigorous evolution of nitrogen had ceased (about 30 mins.). The cooled solution was diluted with ether (300 c.c.), and the crystalline precipitate of  $\omega$ :3:4:5-tetra-acetoxyacetophenone collected (yield, 9.3 g.; m. p.  $118-121^{\circ}$ ). The ethereal mother-liquor was washed with potassium bicarbonate solution, filtered, dried, and evaporated; an oil (2 g.) remained which gave a bluish-green coloration with ferric chloride, and from which only a small amount of the crystalline ketone could be isolated. The proportion of the oily fraction was greater when less pure acetic acid was employed and was increased, also, by more prolonged heating during the decomposition of the diazo-ketone. When the ketone was isolated by pouring the cooled acetic acid solution into water, the oily product could not be employed directly, and, after recrystallisation, the

yield was considerably smaller than that obtained by the above procedure. The ketone crystallised from ethyl alcohol (charcoal) in tables or colourless thick plates having a characteristic spearhead form, m. p. 122—123° (Found: C, 54.9; H, 4.8.  $C_{16}H_{16}O_9$  requires C, 54.6; H, 4.6%).

$\omega : 3 : 4 : 5$ -Tetra-acetoxyacetophenone is readily soluble in alcohol, benzene and acetic acid, but more sparingly soluble in ether. It is insoluble in aqueous sodium carbonate, although rapidly dissolved by cold dilute sodium hydroxide solution. An alcoholic solution gives no reaction with ferric chloride, and the ketone reduces Fehling's solution in the cold.

*Benzoyldelphinidin Chloride* (IV) (First preparation).—Finely powdered  $\omega : 3 : 4 : 5$ -tetra-acetoxyacetophenone (5.2 g.) and benzoylphloroglucinaldehyde (4.0 g.) were added to a mixture of ethyl alcohol (80 c.c.) and ethyl acetate (80 c.c.), and the solution cooled to 0°. Dry hydrogen chloride was admitted and, saturation having been attained, the mixture was allowed to reach the room temperature. At first, a portion of the aldehyde was precipitated, but later redissolved completely. After being kept over-night, the dark green flavylum salt was collected and washed with ether (yield, 2 g.). The use of ethyl alcohol alone gave an amorphous product; ethyl acetate alone furnished a crystalline substance which gave no coloration with ferric chloride in alcoholic solution. The product was obtained in short prisms, having in mass a dark olive-green appearance. It was recrystallised from hot methyl alcohol (20 vols.) containing concentrated hydrochloric acid (1 vol.), in which it was only very sparingly soluble. The recrystallised material was dull greyish-violet in appearance and consisted of slender, dark red prisms.

Benzoyldelphinidin chloride is easily soluble in alcohol to a violet-red solution; the violet shade increases on keeping or on dilution with more alcohol; the very dilute solution in methyl alcohol is pure blue. When an equal volume of water is added to the violet-red methyl-alcoholic solution, the colour fades instantly to pale blue, and the red colour is immediately restored on the addition of acid. Heated with 0.5% hydrochloric acid, the salt dissolves to a pale red solution which rapidly fades even while in contact with the undissolved substance. A pale blue colour results when a drop of aqueous sodium carbonate is added to a freshly prepared alcoholic solution of the salt; on dilution with water, the solution becomes green and then rapidly fades to yellow. A drop of 5% aqueous potassium hydroxide added to the alcoholic solution gives a bluish-green colour which fades slowly to green; on the other hand, a drop of 0.5% potassium hydroxide gives a fairly stable, pure blue colour

which is still weakly blue after one hour. Similarly, solid sodium acetate added to the freshly prepared methyl-alcoholic solution gives a fairly stable, pure blue colour. The salt dissolves in aqueous sodium carbonate, but the blue colour initially produced fades almost immediately to violet.

*Delphinidin Chloride* (First preparation).—Finely powdered, crude benzoyldelphinidin chloride (2 g.) was added to 10% aqueous sodium hydroxide (16 c.c.) from which air had been displaced by a stream of hydrogen, and the solution kept 4 hours after the salt had dissolved completely. The deep blue solution formed initially changed through green to orange. Ethyl alcohol (10 c.c.) and concentrated hydrochloric acid (10 c.c.) were then added, and the deep red solution was kept in the cold during 3—4 days until a portion dissolved in aqueous sodium carbonate with a pure blue colour. Attempts to hasten the re-synthesis of the flavylum salt by warming the solution or by increasing the concentration of acid gave oily products from which crystalline material could not be obtained. Concentrated hydrochloric acid (30 c.c.) was then added in several small portions, and, next day, almost the whole of the product had separated in a microcrystalline condition. Washed with hydrochloric acid and dried in the air, it formed a dense, dark brownish-red powder, having a greenish lustre.

Preliminary purification was effected by solution in a small volume of ethyl alcohol and precipitation of the salt from the filtered solution by means of concentrated hydrochloric acid. The flocculent material was collected, dried, and washed with ether (Specimen A). The product was obtained in an oily condition when precipitation was effected from an alcoholic hydrogen chloride solution by the addition of ether.

Specimen A separated completely from solution in 15% hydrochloric acid, but several repetitions of this treatment failed to give definitely crystalline material. When dry hydrogen chloride was admitted above the surface of a concentrated alcoholic solution of Specimen A cooled in ice-water, crystalline material was readily obtained in small yield as an olive-green lustrous substance. The mother-liquor could be almost completely precipitated by dilution with aqueous hydrochloric acid, but the material (an ethyl ether?) obtained in this way was much more sparingly soluble than delphinidin chloride. Attempts to obtain delphinidin chloride tetrahydrate from the crystalline portion under the conditions of Willstätter and Weil (*Annalen*, 1916, 412, 190) were unsuccessful.

When, however, Specimen A was heated with hydriodic acid under Zeisel conditions, as described by Willstätter and Weil (*loc. cit.*), delphinidin iodide separated in a well-crystallised condition,

although in small yield. The crystal form, pointed plates, was identical with that of the specimen from material of natural origin. Willstätter and Weil remark that the crude anthocyanidin obtained from the glucoside could not be crystallised from methyl-alcoholic hydrogen chloride, but the crystalline iodide was readily obtained and from this the crystalline chloride. The iodide was obtained in better yield by dissolving Specimen A (1.15 g.) in cold 0.5% hydrochloric acid (30 c.c.) and adding freshly distilled hydriodic acid (15 c.c., b. p. 127°) to the filtered solution. A small amount of crystalline material was precipitated rapidly, but the crystallisation was complete only after several days, during which the containing flask was filled with carbon dioxide and kept in the dark. The crystals were collected, washed with a little dilute hydriodic acid, dried in the air, and washed with ether (yield, 0.45 g.). Only a very small additional amount was obtained when the mother-liquor was concentrated. The iodide was obtained in this manner in stout prisms or tables, green in mass and having a bright yellow lustre. This salt crystallises from its solution in hot dilute hydriodic acid on the addition of concentrated hydriodic acid in well-shaped, elongated rhombic plates, often connected by their acute-angled corners so as to form rosettes. The crystals are deep red by transmitted light and exhibit a marked yellow glitter. The same crystal shape and appearance have been noted in material of natural origin (demethylation of natural malvidin).

The crude crystalline iodide (0.95 g.) was dissolved in 0.5% hydrochloric acid (30 c.c.), and the chloride precipitated by adding concentrated hydrochloric acid (30 c.c.) to the filtered solution. The amorphous chloride, which separated at once and completely, was crystallised by dissolving 0.13 g. in 5% hydrochloric acid (9 c.c.) and adding hot concentrated hydrochloric acid (18 c.c.) to the hot solution. The chloride separated on cooling in long, dark red prisms or in crystalline granules. The former were green by reflected light and had a bright yellow lustre. Two recrystallisations were effected under the same conditions (Specimen B) (Found: C, 48.3; H, 4.0; Cl, 9.2; loss at 110° in a high vacuum, 9.3. Found in anhydrous material: C, 53.4; H, 3.2; Cl, 10.1.  $C_{15}H_{11}O_7Cl \cdot 2H_2O$  requires C, 48.1; H, 4.0; Cl, 9.5;  $H_2O$ , 9.6%.  $C_{15}H_{11}O_7Cl$  requires C, 53.2; H, 3.3; Cl, 10.5%).

*Benzoyldelphinidin Chloride* (Second preparation).—Numerous further experiments on the conditions for the preparation of this salt were carried out. The product obtained by condensation of the components in ether-alcohol was not homogeneous and the yield was inferior; a very considerable improvement followed on the adoption of the following method.

2-*O*-Benzoylphloroglucinaldehyde (7.4 g.) and  $\omega$ :3:4:5-tetra-acetoxyacetophenone (9.6 g.), along with ethyl alcohol (150 c.c.), were mixed in a flask provided with an efficient stirrer, a tap funnel, inlet and outlet (calcium-chloride tube) tubes, and cooled in melting ice. The mixture was saturated with hydrogen chloride and, after 2 hours, was warmed at 30° for 1½ hours; it was then again cooled to near 0°, and acetyl chloride (167 c.c.) gradually introduced. The process was interrupted for 3 hours when about half of the acetyl chloride had been added. The product was collected (8.2 g.) after about 12 hours. Altogether, 22.6 g. of the salt were obtained from six experiments in which the conditions were slightly modified; cooling at 0° during the whole period greatly diminished the yield, but substituting the room temperature for the 30° mentioned above gave good results (1.9 g. from 2 g. of the aldehyde and 6.4 g. from 6 g.). It was now found that *benzoyldelphinidin chloride* could be crystallised, by adding concentrated hydrochloric acid to its solution in ethyl alcohol, in prisms forming a glistening green mass (Found in material dried over sulphuric acid: C, 57.6; H, 3.7.  $C_{22}H_{15}O_8Cl \cdot H_2O$  requires C, 57.4; H, 3.7%).

*Delphinidin Chloride* (Second preparation).—After a preliminary test, 20 g. of the crude benzoyl compound prepared by the acetyl chloride method were hydrolysed in five similar experiments as follows:—

The finely powdered benzoyl compound (4.0 g.) was added to 10% aqueous sodium hydroxide (30 c.c.), cooled in ice and frequently shaken until dissolution was complete (15 mins.). Air was previously displaced from the apparatus by hydrogen, and a current of the latter was passed through the alkaline solution during the hydrolysis. After 15 minutes, the solution was allowed to reach the room temperature, and, after 3½ hours, an ice-cold mixture of ethyl alcohol (20 c.c.) and concentrated hydrochloric acid (20 c.c.) was added. The clear, deep red solution was kept 10–12 days until a portion gave a pure blue coloration with a little sodium carbonate solution; the time required for the completion of this stage was considerably longer than the corresponding period for the earlier preparation. Concentrated hydrochloric acid (120 c.c.) was then added in several portions, the solution kept over-night, and the precipitated mixture of salts and benzoic acid collected, washed with 20% hydrochloric acid, and dried (Y).

The united filtrates gave, on keeping, a further crop of the flavylum salt (Z; yield, 3.15 g.), which was almost free from benzoic acid and inorganic salts and for this reason was conveniently worked up separately.

The united first fractions Y were dried in the air, finely powdered, and washed with ether; when wet with the solvent, the material

became pasty, but friable again immediately the solvent had evaporated. After being powdered again, the product was extracted with cold ethyl alcohol-concentrated hydrochloric acid (in all, EtOH, 120 c.c.; 30% HCl, 30 c.c.): there was a considerable residue (R) (see below). The filtered extracts were mixed with an equal volume of water and with concentrated hydrochloric acid (250 c.c.). The amorphous product was collected and extracted with cold 0.5% hydrochloric acid (about 500 c.c. in several portions and with mechanical stirring). Almost the whole of the substance dissolved, and it was recovered by the addition of concentrated hydrochloric acid (1300 c.c.) to the filtered solution so as to make the final hydrogen chloride concentration about 25%. When the precipitate was collected, dissolved in hot 0.5% hydrochloric acid, and freshly distilled hydriodic acid (80 c.c., *d* 1.7) added to the filtered solution, the iodide slowly separated during several days in a beautifully crystalline condition. The usual precautions—protection from light and replacement of the air of the containing flask by carbon dioxide—were observed.

The fraction Z of the crude chloride was treated in a very similar fashion, the iodides from Y and Z were united and dissolved in hot 5% hydrochloric acid (400 c.c.), and the chloride was precipitated by the addition of concentrated hydrochloric acid (600 c.c.). This product was amorphous, but crystallised by repetition of the solution in 5% hydrochloric acid and increase of the acid concentration to 25% (Specimen C) (Found in air-dried material: C, 48.5; H, 3.9; loss at 110° in a high vacuum, 9.0. Found in anhydrous material: C, 53.3; H, 3.1%).

The crystals of this specimen were deep red prisms by transmitted light and olive-green in mass; under some conditions, which it is not possible to define precisely, the material separated in ill-defined granules, and occasionally as opaque aggregates, from which well-shaped crystals appeared to protrude.

The residue R (above) crystallised directly from methyl alcohol-hydrochloric acid (9 vols. CH<sub>3</sub>OH and 1 vol. 30% hydrochloric acid) (Specimen D), and the material recovered from the mother-liquor was crystallised in the usual way from 25% hydrochloric acid (Specimen E). Subsequent to these experiments, it was found that less difficulty was experienced in crystallising the delphinidin chloride, made substantially as described, if the hydrogen used to displace air from the apparatus during the hydrolysis was freed from traces of oxygen by passage through an alkaline pyrogallol solution.

The specimens B, C, D and E exhibited identical colour reactions, and these were, further, identical with those of specimens of delphinidin chloride prepared by demethylation of malvidin

(syringidin) chloride and by the hydrolysis of vicin picrate with hydrochloric acid. We are greatly indebted to Professor P. Karrer for kindly supplying the delphinidin chloride (*ex malvidin*) and the vicin picrate. Vicin is an anthocyanin of the sweet pea (Karrer and Widmer, *Helv. Chim. Acta*, 1927, **10**, 67) and is a delphinidin glucoside.

The colours observed in a range of buffered solutions of definite  $p_H$  under the conditions prescribed by Robertson and Robinson (*Biochem. J.*, 1929, **23**, 35) were the following, the observations in parentheses referring to 5-*O*-benzoyldelphinidin chloride.

1% Hydrochloric acid, red with blue tinge (rose red, bluer than delphinidin and partly precipitated on standing), unchanged after 15 minutes; 10% hydrochloric acid, the same (similar, but all the salt was precipitated, leaving a colourless solution); (1) permanganate (purplish-red, fading to violet); (2) similar, but shade bluer [similar to (1)]; (3) similar to (2) (no change); (4) not much change, violet-red (deeper violet); (5) deeper violet-red (deeper violet); (6) similar reddish-violet (bluer violet); (7) reddish-violet (violet-blue); (8) reddish-violet, bluer in thin layers (blue); (9) blue in thin layers, violet in thick layers (blue); (10) blue (blue with no violet tinge); (11) rather dull greenish-blue (blue); (12), (13) and (14), no change [(14) and (15) are greener and duller]; (15) similar colour, quickly becoming slate blue and then very pale brown.

After 15–20 minutes, the colours observed were: (1) faded rose pink (very weak violet); (2) and (3) weak violet [(2), (3) and (4) form a series in which a reddish-violet colour increased]; (4) a little more intense reddish-violet; (5) and (6) more intense reddish-violet; (7) bluer violet; (8) weaker blue-violet; (9)–(13) inclusive, greenish-blue [(5), (6), (7), (8) and (9) form a series in which the violet colour becomes bluer; (10), (11) and (12) blue; (13) bluish-green]; (14) weak, faded green (pale green); (15) yellowish-brown (pale brownish-yellow).

After 1½ hours, the colours were: (1), (2) and (3), weak violet, increasing in (4), (5) and (6), bluer in (7) and violet-blue in (8); (9), (10), and (11) were green, tinged with blue; (12), (13), (14) and (15), yellowish-brown [all faded; (1), (2), (3) and (4), increasing weak violet; (5), (6), (7) and (8), bluer; (9), (10) and (11), blue; (12), bluish-green; (13), pale green; (14) and (15), pale brownish-yellow].

After 24 hours, (1), (2), (3), (4) and (5), practically colourless, with a small, flocculent, violet precipitate; (6) very faint violet, no flocks; (7) and (8), almost colourless; (9) very faint yellow; (10), (11), (12), (13) and (14), yellow, increasing in intensity to weak golden-yellow; (15), weaker yellow [(1), very faintly blue, a trace of violet flocculent precipitate; (2) and (3), faintly blue, a little more pre-

cipitate; (4) and (5) weak blue, maximum precipitation; (6) and (7), weak blue; (8), very pale blue, no precipitate; (9) and (10), almost colourless; (11), (12), (13), (14), (15), (16) and (17), weak lemon-yellow].

The comparisons of the different specimens of delphinidin chloride, natural and synthetic, disclosed no divergences whatever, either in regard to the shades of colour observed, the relative amounts of precipitates or the rate of change of the colours of the solutions. The specimens (B), (C), (D) and (E) had all the ordinary properties of delphinidin chloride as recorded by Willstätter and his collaborators, and specimen (D) was used for the preparation of the characteristic monohydrate under the conditions prescribed by Willstätter and Weil (*Annalen*, 1916, 442, 192). The experiment succeeded, and well-shaped, dark brownish-violet, rhombic plates, all of them elongated, as shown in some cases in Willstätter and Weil's figure, were obtained (Found: loss at 110° in a vacuum, 6.0.  $C_{15}H_{11}O_7Cl \cdot H_2O$  requires  $H_2O$ , 4.9%). The somewhat high value for the loss in weight may be due to loss of hydrogen chloride or to admixture with one of the other hydrates, but it is interesting to note that Willstätter and Weil (*loc. cit.*) found the loss in a vacuum desiccator to be 5.88% and 5.57% in two experiments.

The crystals of the monohydrate exhibited the behaviour towards 5% hydrochloric acid which was described by Willstätter and Weil in the case of the specimen of natural origin.

6-Hydroxy-2-benzoyloxy-4-methoxybenzaldehyde (VII).—The preparation of a monomethyl ether of *O*-benzoylphloroglucinaldehyde was unsuccessfully attempted in several different ways, using methyl iodide and alkali-metal salts of the hydroxy-aldehyde, but the following process gave moderately satisfactory results.

A mixture of *O*-benzoylphloroglucinaldehyde (2.5 g.), methyl iodide (4.1 g.), finely divided silver oxide (3.3 g.), and acetone (25 c.c.) was mechanically shaken for 12 hours, filtered, and the precipitate washed with acetone. The pale yellow filtrates were united and the solvent was removed under reduced pressure. The orange-yellow viscous residue was dissolved in ether (50 c.c.), filtered from a trace of insoluble flocculent material, and washed with 10% aqueous sodium carbonate. Acidified, this fraction gave only a negligible amount of a colourless crystalline substance, although *O*-benzoylphloroglucinaldehyde is readily removed from its solution in ether by this means. The ethereal solution was then twice shaken with 5% aqueous potassium hydroxide (10 c.c., 5 c.c.) and the alkaline solutions were separated and acidified with dilute acetic acid, without delay. This product was a pink crystalline precipitate and a colourless emulsion, which became resolved into a

mass of fine needles in the course of 4—5 hours; yield, 1.9 g., m. p. 95—102°. The ethereal solution was again washed with 5% potassium hydroxide solution, dilute sulphuric acid, and water; dried and evaporated, it gave an oily solid (0.23 g.) which consisted essentially of benzoyldimethylphloroglucinaldehyde (Robertson, Robinson, and Struthers, J., 1928, 1455).

In a second experiment, *O*-benzoylphloroglucinaldehyde (5.2 g.) and methyl iodide (4.6 g.) in acetone (40 c.c.) were shaken with silver oxide (3.5 g.) during 5 hours, after which methyl iodide (4.6 g.) in acetone (10 c.c.) and silver oxide (3.5 g.) were added and the shaking was continued over-night. Benzoyldimethylphloroglucinaldehyde (2.2 g., m. p. 143—145°) and benzoylmethylphloroglucinaldehyde (1.5 g.) were isolated.

*6-Hydroxy-2-benzoyloxy-4-methoxybenzaldehyde* crystallised from ethyl alcohol in colourless plates, m. p. 109° (Found: C, 66.0; H, 4.5.  $C_{15}H_{12}O_5$  requires C, 66.2; H, 4.4%), easily soluble in benzene and chloroform, very sparingly soluble in light petroleum and insoluble in water. The alcoholic solution gives a brownish-red coloration with ferric chloride. A solution of the aldehyde (1.8 g.) in cold 10% aqueous sodium hydroxide (10 c.c.) was kept in an atmosphere of hydrogen (probably unnecessary) during 4 hours. The acidified solution was extracted with ether, and the extract was washed with aqueous potassium bicarbonate, in order to remove benzoic acid, then with water, dried, and evaporated. The colourless residue crystallised from benzene in slender needles, m. p. 141—142°, unchanged by further recrystallisation from water.

This aldehyde is identical with phloroglucinaldehyde 4-methyl ether, isolated by Karrer and Bloch (*Helv. Chim. Acta*, 1927, 10, 374) from the product of methylation of phloroglucinaldehyde by diazomethane, and from the mixture of aldehydes obtained from *O*-monomethylphloroglucinol by the Gattermann reaction. We were able to confirm this by direct comparison with a specimen of the substance kindly sent to us by Professor Karrer; the m. p. of a mixture of the specimens was not depressed.

*6-Hydroxy-2-benzoyloxy-4-benzoyloxybenzaldehyde*.—A solution of *O*-benzoylphloroglucinaldehyde (5.4 g.) and benzyl chloride (7.5 g.) in acetone (40 c.c.) was shaken during 14 hours with silver oxide (7.0 g.). The silver compounds were separated, washed with acetone, and the united solutions evaporated in a vacuum. The residue was dissolved in ether and the solution washed first with aqueous sodium carbonate and then with 5% aqueous potassium hydroxide. The latter fraction was acidified without delay and the precipitated oil, which solidified in the course of a few hours, was taken up in benzene and the dried solution concentrated to 5—6 c.c. Crystals of the

benzylated aldehyde separated, and these were collected (yield, 1.5 g.; m. p. 198°) and recrystallised first from benzene containing ethyl alcohol (m. p. raised to 201–203°) and finally from light petroleum, forming thin, colourless, rhomboidal plates, m. p. 202–203° (Found: C, 72.6; H, 4.4.  $C_{21}H_{16}O_5$  requires C, 72.4; H, 4.6%). The aldehyde is easily soluble in ethyl alcohol, more sparingly soluble in benzene and very sparingly soluble in light petroleum. In alcoholic solution, it gives with ferric chloride a reddish-brown coloration which suggests that the substance is 6-hydroxy-2-benzoyloxy-4-benzyloxybenzaldehyde.

4:6-Diacetoxy-2-methoxybenzaldehyde.—2-O-Methylphloroglucin-aldehyde (Herzig and Wenzel, *Monatsh.*, 1903, 24, 860; Karrer and Glattfelder, *Helv. Chim. Acta*, 1921, 4, 724) was prepared from phloroglucinol monomethyl ether (Herzig and Aigner, *Monatsh.*, 1900, 21, 435) by the Gattermann reaction. In the final stage, it was found advisable to wash the aldimine hydrochloride with fresh ether, to dry it in a vacuum, and to hydrolyse it at 80° with about 10 times its weight of water for 25–30 minutes. The aldehyde crystallised during the process in yellow needles, which were almost pure, m. p. 200–202°, after a single recrystallisation from dilute alcohol. When hydrolysis is effected in the presence of mineral acid, the product is brown (Herzig and Wenzel, *loc. cit.*) and dissolves in aqueous sodium carbonate with a greenish fluorescence which renders it valueless for our purpose.

The aldehyde was only incompletely acetylated by ice-cold aqueous sodium hydroxide (4 mols.) and ethereal acetic anhydride (3 mols.), but readily under the conditions of Pratt and Robinson (J., 1925, 1184). Anhydrous potassium carbonate (2 g.) was added in small amounts to a mixture of acetic anhydride (5 c.c.) and finely powdered 2-O-methylphloroglucinaldehyde (1 g.) so as to maintain a vigorous evolution of carbon dioxide. The pasty mass was kept for 1 hour, water added, and the product stirred with potassium bicarbonate until the excess of acetic anhydride had been decomposed; it was then collected, washed with water, and dried. Recrystallised from benzene–light petroleum, light petroleum, and finally ligroin, the 4:6-diacetoxy-2-methoxybenzaldehyde formed colourless plates, m. p. 107° (Found: C, 56.8; H, 4.6.  $C_{12}H_{12}O_6$  requires C, 57.1; H, 4.8%). This derivative was very easily soluble in alcohol or benzene, more sparingly so in ligroin, light petroleum or ether. An alcoholic solution gave no reaction with ferric chloride, but when an aqueous-alcoholic solution was heated hydrolysis occurred and a reddish-brown ferric chloride reaction was observed.

The substance was also obtained by the methylation of O-diacetylphloroglucinaldehyde (Robertson and Robinson, J., 1927, 1712),

in the preparation of which the following quantities were employed : phloroglucinaldehyde 5 g., acetic anhydride 14 c.c., *N*-sodium hydroxide 100 c.c. The yield was about 6 g., m. p. 102—103°, from 20 g. of phloroglucinaldehyde. *O*-Diacetylphloroglucinaldehyde (1.05 g.) and methyl iodide (2.1 g.) in acetone (5 c.c.) were shaken with silver oxide (1.8 g.) during 6 hours. Isolated in the usual manner, only 0.1—0.2 g. of material, insoluble in sodium hydroxide, was obtained. *O*-Diacetylphloroglucinaldehyde (2.4 g.) and methyl iodide (4.5 g.) in acetone (15 c.c.) were shaken with silver carbonate (6 g.) during 16 hours; evolution of carbon dioxide then appeared to have ceased. The silver compounds were separated and washed with acetone, and the filtrates evaporated in a vacuum. The residue crystallised in contact with ether in colourless elongated plates (0.9 g., m. p. 106—107°). The mother-liquor furnished a small additional amount (0.5 g.) of crystalline material. Recrystallised from ligroin, the main fraction was obtained in colourless elongated plates, m. p. 107—108° alone or mixed with the acetylated 2-methylphloroglucinaldehyde.

*5-O-Benzoyl-7:3':5'-O-trimethyldelphinidin Chloride*.—In the presence of dry hydrogen chloride, a solution of 4-*O*-methylphloroglucinaldehyde in ethyl acetate or ether rapidly becomes brownish-red and deposits a brownish or reddish-brown amorphous substance (xanthylum salt?). For this reason, the benzoylated aldehyde was employed for the condensations to flavylum salts. A solution of 4-*O*-methyl-2-*O*-benzoylphloroglucinaldehyde (1.35 g.) and  $\omega$ -acetoxy-4-benzyloxy-3:5-dimethoxyacetophenone (1.72 g.) (Bradley and Robinson, J., 1928, 1560) in ethyl acetate (30 c.c.) was cooled in ice while being saturated with dry hydrogen chloride, and then kept at room temperature over-night. An intense reddish-purple solution was very rapidly formed, and the flavylum salt crystallised in fine needles, which were collected, washed with ethyl acetate, ether, and dried, forming a green spongy mass (yield, 1.98 g.). An additional amount of equally pure material (0.15 g.) separated from the mother-liquor during 48 hours. The salt was recrystallised by cooling a hot solution in methyl alcohol containing concentrated hydrochloric acid (about 7 vols. %); the fine needles obtained appeared purple by transmitted and lustrous green by reflected light (Found: C, 59.5; H, 4.6; Cl, 6.8.  $C_{25}H_{21}O_8Cl \cdot H_2O$  requires C, 59.8; H, 4.6; Cl, 7.1%).

This salt is practically insoluble in hydrochloric acid; hot 1% hydrochloric acid dissolves it to a pink solution which, when cold, gives with aqueous sodium carbonate only a yellow coloration. The violet-red alcoholic solution is readily decolorised on dilution, and the colour is restored by the addition of acid. A freshly pre-

pared solution of the salt in methyl alcohol gives, with solid sodium acetate, only a lilac coloration. Aqueous sodium carbonate, added to an acidified methyl-alcoholic solution, gives a pale blue coloration, which fades almost completely. Under the same conditions, 5% sodium hydroxide solution gives a bluish-green solution which rapidly becomes pale green and finally yellow. The solution of the salt in concentrated sulphuric acid is violet-red and not fluorescent.

7:3':5'-O-Trimethyldelphinidin Chloride (*Hirsutidin Chloride*) (VI).—Hydrolysis of the benzoyl derivative could not be conveniently effected by aqueous sodium hydroxide, since complete solution was not attained even after several hours. After several trials, the following procedure was adopted. The crude crystalline benzoyl derivative (0.7 g.) was finely powdered and suspended in methyl alcohol (7 c.c.) through which a current of hydrogen was passed. Potassium hydroxide (0.9 g.) in water (3 c.c.) was then added. Dissolution was effected in 10–15 minutes, and the blue solution initially produced changed slowly through green to deep orange. After 4 hours, concentrated hydrochloric acid (3.4 c.c.) was added, and this precipitated a voluminous colourless solid which filled the liquid. Gently warmed at 50–60° during 25–30 minutes, this dissolved to a clear, deep red solution, from which the debenzoylated flavylum salt separated during the process in a well-crystallised condition (yield, 0.26 g.), leaving the mother-liquor almost colourless.

This crude product was dried, washed with ether, and a portion (0.4 g.) added to boiling methyl alcohol (60 c.c.). After 4–5 minutes, the solution was filtered (undissolved residue, 0.06 g.) and concentrated hydrochloric acid (2 c.c.) was added to the filtrate, which was kept at 50–55° while concentrated hydrochloric acid (8 c.c.) was added in portions of 1 c.c.: each addition was accompanied by the precipitation of a quantity of the flavylum salt. After 12 hours, the crystals were collected and dried in air (yield, 0.15 g.). The salt was obtained in short, dark red, pointed prisms, which were frequently arranged in rosettes (Found: C, 56.5; H, 4.6; Cl, 9.1.  $C_{18}H_{17}O_7Cl$  requires C, 56.8; H, 4.5; Cl, 9.3%).

Heated with water, the salt dissolves to a weak red solution with a slight violet tinge, but this fades rapidly at the boiling point and becomes colourless; the red colour is restored by the addition of acid. In hot 0.5% hydrochloric acid, the salt is already sparingly soluble; it dissolves to a reddish solution, whereas a cold saturated solution in 4% hydrochloric acid is only pink. The cooled solution in hot 0.25% hydrochloric acid presumably contains much pseudo-base, since excess of aqueous sodium carbonate gives a brownish-green solution which changes to olive-green. The fresh dilute

solution in methyl alcohol is violet-red and gives with sodium carbonate solution or solid sodium acetate a pure blue coloration. On the other hand, when the solution is kept for some time previous to the test, a greenish-blue coloration is obtained. The salt dissolves in aqueous *N*/10-sodium hydroxide to a purple-blue solution which rapidly becomes crimson-blue (dichroic) and then fades to emerald-green.

*5:3':5'-O-Trimethyladelphinidin Chloride* (V).—2-*O*-Methylphloroglucinaldehyde resembles its isomeride in yielding in ethereal ethyl acetate or formic acid solution, in the presence of dry hydrogen chloride, an amorphous brownish-red substance, which is soluble in water and alcohol but insoluble in ether or benzene and dissolves in aqueous alkalis to red solutions exhibiting green fluorescence.

In many of our preliminary experiments on the aldehyde-ketone condensations, a fluorescent by-product was obtained, and the intensity of the fluorescence was apparently greater than that resulting by self-condensation of the aldehyde alone. The proportion of this by-product appeared to be smaller in formic acid than in ethyl acetate solution, and it was completely eliminated by the following procedure.

A solution of  $\omega$ -acetoxy-4-benzyloxy-3:5-dimethoxyacetophenone (2.0 g.) in formic acid (10 c.c.) was saturated with dry hydrogen chloride at room temperature, and 2-*O*-methylphloroglucinaldehyde (0.8 g.) was then added in several small portions during 5 hours. A deep crimson solution was rapidly formed (in previous experiments the medium became brownish-red) and a well-crystallised substance separated. After 12 hours this was collected, washed with formic acid and then with ethyl alcohol (8 c.c.) containing concentrated hydrochloric acid (2 c.c.), and dried in the air (0.35 g.). An additional amount of material separated during 2 days, but the solution was too viscous to permit of filtration and the salt was more conveniently isolated by diluting the product with alcohol (50 c.c.) containing concentrated hydrochloric acid (20 c.c.) and collecting the precipitate which slowly formed. This fraction was not completely crystalline (yield, 0.9 g.).

The crystalline material was recrystallised by solution in methyl alcohol containing 2.5% by volume of concentrated hydrochloric acid and addition of concentrated hydrochloric acid to the filtered solution (Found: C, 56.1; H, 4.5; Cl, 9.1%). This specimen was recrystallised by dissolving 0.1 g. of the salt in methyl alcohol (350 c.c.) containing concentrated hydrochloric acid (9 c.c.), and adding concentrated hydrochloric acid (40 c.c.) to the filtered solution. Collected and dried in air, this material was a green crystalline powder having a bright yellow lustre (Found: C, 56.1; H, 4.5;

Cl, 9.2.  $C_{18}H_{17}O_7Cl \cdot 0.25H_2O$  requires C, 56.1; H, 4.5; Cl, 9.2%). It was seen under the microscope to consist of dark red, hexagonal tables and short slender prisms, and it may have contained two hydrates, as the analyses suggested, one having been precipitated immediately on the addition of acid to the warm solution and the other having crystallised more slowly on cooling. The salt dissolves in sodium carbonate solution with a pure blue colour, and the same colour is obtained by adding sodium acetate to a freshly prepared solution in methyl alcohol.

To test the possibility of the presence of benzylated material, a portion of the specimen first analysed (0.1 g.) was finely powdered, suspended in glacial acetic acid (100 c.c.), and heated at  $80^\circ$  in a stream of dry hydrogen chloride during 3 hours. Only a very small portion of the salt dissolved, but complete debenzylation was assured under these conditions. The product was collected, washed, and dried: it gave the same qualitative reactions as the original specimen.

*Comparison of the Colour Reactions of Hirsutidin Chloride (H) with those of 7 : 3' : 5'-O-Trimethyldephinidin Chloride (S) and of 5 : 3' : 5'-O-Trimethyldephinidin Chloride (A).*—All the reactions of H were found on direct comparison to be identical with those of S and to differ from those of A. When ammonia was added to an alcoholic solution, a greenish-blue solution resulted; when derived from H or S, this was blood-red by transmitted artificial light, but under these conditions the A solution was violet or bluish-violet. By transmitted sunlight, H and S solutions were blue and violet in thick layers; A was greenish-blue. Alcoholic solutions of H and S were magenta; that of A was violet.

Under the standard procedure of Robertson and Robinson (*loc. cit.*), the colours in a range of buffered solutions from  $p_H$  3.2 to  $p_H$  11.6 were the following:—

H and S: (1) bluish-red, rapidly changing to brownish-red; (2) the same; (3) reddish-brown; (4) weak brownish-red; (5) violet tinged brownish-red; (6) fading violet; (7) bluish-violet, blue in thin layers; (8)—(15) inclusive, blue, red in shade by comparison with (A) solutions.

After  $\frac{1}{2}$  hour: (1), (2), (3) and (4), almost colourless but more coloured than (A) solutions; (5) very weak brownish-red; (6), (7) and (8), increasing violet; (9)—(12), blue, violet by transmitted artificial light; (13), (14) and (15), blue, redder violet by transmitted artificial light.

After 24 hours: (1)—(5), colourless; (6)—(8), increasing pale violet; (9)—(12), bluish-green; (13)—(15), greenish-blue.

(A) gave colours in marked contrast, on direct comparison: (1)

bluish-red; (2) same; (3) same, but fading; (4) bluer red, fading quickly; (5) reddish-violet, fading; (6) violet, fading; (7) and (8) no change; (9)—(15) inclusive, blue with green shade.

After  $\frac{1}{2}$  hour: (1)—(8), almost colourless; (9) very pale violet-blue; (10) blue, very different from (9); (11)—(15), greenish-blue.

After 24 hours: (1) and (2), colourless; (3), (4) and (5), colourless, minute flocculent precipitate (none in H and S); (6), (7), (8) and (9), very feeble yellowish-green; (11) and (12), very pale greenish-yellow; (13) weak orange-yellow; (14) and (15), pale orange.

Throughout, blue solutions of H and S were much redder by artificial light, but A gave blue solutions even when examined by artificial light.

4:5-*Dihydroxy-3-methoxybenzaldehyde* (XI).—A mixture of 5-bromovanillin (31 g.), copper bronze (12 g.), and 8% sodium hydroxide solution (600 c.c.) was heated in a rotating autoclave at 200—210° during 1 hour. The cooled product was acidified with a slight excess of dilute sulphuric acid and filtered from a small tarry precipitate; after 12 hours, crystalline material (0.98 g.) had separated and this also was removed. The dark filtrate (1400 c.c.) was concentrated under diminished pressure. The distillate (800 c.c.) gave only 0.24 g. of a red insoluble precipitate when mixed with an excess of 2:4-dinitrophenylhydrazine hydrochloride in 2*N*-hydrochloric acid. The residual solution was extracted with ether and the dark product so isolated was extracted with benzene, yielding almost pure 3-*O*-methylgallaldehyde (19.4 g.), m. p. 129—131° with slight previous softening. The aldehyde crystallised from water, benzene or light petroleum in almost colourless needles, m. p. 132—134° (Found in material dried at 100° in a vacuum: C, 57.3; H, 4.8.  $C_8H_8O_4$  requires C, 57.1; H, 4.8%).

The 2:4-dinitrophenylhydrazone was precipitated when a cold solution of the aldehyde (0.44 g.) in water was added to an excess of 2:4-dinitrophenylhydrazine in 2*N*-hydrochloric acid. The solid was collected and dried at 100° (yield, 0.83 g. Calc., 0.88 g.). The hydrazone crystallised from ethyl alcohol, in which it was sparingly soluble, in dark red, pointed prisms, which began to decompose at 230° (Found in material dried over sulphuric acid: C, 48.2; H, 3.7; N, 15.5, 15.9.  $C_{14}H_{12}O_7N_4$  requires C, 48.3; H, 3.5; N, 16.1%).

*Methylation.* Methyl sulphate (2.5 g.) and aqueous sodium hydroxide (10 c.c. of 10%) were added gradually and alternately to a suspension of the aldehyde (0.5 g.) in water (5 c.c.). The whole was mechanically shaken during 1 hour and then sodium hydroxide solution (10 c.c. of 20%) was added and the shaking continued.

During this process, the methylated aldehyde separated from the strongly alkaline solution in colourless needles (0.33 g.), m. p. 73—75°, and, after recrystallisation, m. p. 74—75° (Heffter and Capellmann give m. p. 77°, and Semmler and Mauthner, respectively, record the m. p.'s 75° and 74—75° for 3:4:5-trimethoxybenzaldehyde).

*Acetylation.* The aldehyde (1.7 g.) was acetylated by dissolving it in ether containing acetic anhydride (6 g.) and shaking the solution with water to which 5% aqueous potassium hydroxide (68 c.c.) was added in small successive amounts, the whole being cooled to 0°. The separated ethereal solution was washed with 5% aqueous potassium hydroxide, then with dilute sulphuric acid and water. The product crystallised from benzene—light petroleum in needles, m. p. 98—99° (Shriner and McCutchan record the m. p. 102—103° for the acetylation product, prepared by another method, and, on analysis, obtained data in agreement with the formula  $C_{12}H_{12}O_7$ , which indicates that the substance crystallises with  $1H_2O$ ).

*Methyl 5-Hydroxy-3:4-diphenylmethylenedioxybenzoate* (VIII).—In the course of preliminary experiments on the condensation of diphenyldichloromethane with methyl gallate, considerable quantities of a sparingly soluble, oily by-product, probably  $CPh_2[O \cdot C_6H_2(OH)_2 \cdot CO_2Me]_2$ , were obtained. A two-stage process under the following conditions gave the best results.

A solution of methyl gallate (84 g.) and pyridine (36.5 c.c.) in acetone (200 c.c.) was added to one of diphenyldichloromethane (108 g.) in acetone (100 c.c.) and kept for 12 hours. A solution of sodium hydroxide (37 g.) in water (100 c.c.) was then slowly added; the temperature rose and reached the boiling point of the mixture; after 2 hours, the whole was added to water (2000 c.c.). The brown oily material was separated and dissolved in ether, and the extract washed with aqueous sodium carbonate and then with aqueous sodium hydroxide (20 g. in 400 c.c.). The *methyl* ester precipitated from the latter extract on acidification was collected; it crystallised from benzene (yield, 60 g.; m. p. 163° after two crystallisations) in colourless needles, m. p. 165° (Found: C, 73.6; H, 5.0; loss at 110° in a vacuum, 10.1.  $C_{21}H_{16}O_5 \cdot 0.5C_6H_6$  requires C, 73.7; H, 5.1;  $C_6H_6$ , 10.1%).

The presence of benzene in this material was confirmed by means of a test devised by Professor W. Ramsden. This can be used for the detection of traces of aromatic hydrocarbons, and depends on the insoluble film (often pink) obtained by condensation with formaldehyde in the presence of concentrated sulphuric acid. It may be demonstrated by shaking one drop of benzene with half a test-tube full of water, pouring away the liquid, and adding a few

c.c. of sulphuric acid and two or three drops of 40% aqueous formaldehyde.

*Methyl 3-Methoxy-4:5-diphenylmethylenedioxybenzoate* (Methyl ester of IX).—Methyl hydroxydiphenylmethylenedioxybenzoate (68 g.) was dissolved in hot methyl alcohol (300 c.c.), the solution cooled and forthwith mixed with an alcoholic solution of sodium ethoxide (4.5 g. of sodium in 50 c.c.) and methyl iodide (20 c.c.). The mixture was gently boiled for  $\frac{1}{2}$  hour and, on cooling, short colourless prisms (61 g.), m. p.  $134.5^\circ$ , separated; the m. p. was not raised by recrystallisation (Found: C, 72.8; H, 5.2.  $C_{22}H_{18}O_5$  requires C, 72.9; H, 5.0%). The ester (20 g.) was refluxed for 2 hours with water (100 c.c.) and potassium hydroxide (6 g.); the precipitate obtained on acidification of the cooled solution crystallised from aqueous acetone in thick polyhedral plates (16 g.), m. p.  $217^\circ$  (Found: C, 72.3; H, 4.7.  $C_{21}H_{16}O_5$  requires C, 72.4; H, 4.6%).

This *3-methoxy-4:5-diphenylmethylenedioxybenzoic acid* (8 g.) was mixed with carbon tetrachloride (12 c.c.) and phosphorus pentachloride (8 g.), and the whole gently boiled until the evolution of hydrogen chloride slackened. The chloride crystallised, on the addition of light petroleum to the cooled clear liquid, in large compact prisms (1.5 g.), m. p.  $109^\circ$  (Found: Cl, 9.9.  $C_{21}H_{15}O_4Cl$  requires Cl, 9.7%).

*$\omega$ -Diazo-3-methoxy-4:5-diphenylmethylenedioxyacetophenone*,  $C_{22}H_{16}O_4(C_6H_5)_2(OMe)CO \cdot CHN_2$ .—A solution of methoxydiphenylmethylenedioxybenzoyl chloride (8.5 g.) in chloroform (20 c.c.) was slowly added to an ethereal solution of diazomethane (from 13 c.c. of nitrosomethylurethane and 75 c.c. of ether) cooled in a freezing mixture. A brisk evolution of nitrogen occurred and pale yellow needles separated (7.5 g.). The substance crystallised from benzene-light petroleum in yellow needles, which became darker at  $135^\circ$  and decomposed from  $160$ – $170^\circ$ : these temperatures, however, are not characteristic and depend on a particular rate of heating (Found: C, 70.7; H, 4.6; N, 7.2.  $C_{22}H_{16}O_4N_2$  requires C, 70.9; H, 4.4; N, 7.5%).

*$\omega$ -Acetoxy-3-methoxy-4:5-diphenylmethylenedioxyacetophenone* (XII).—The foregoing diazo-ketone (7.5 g.) was cautiously heated with acetic acid (20 c.c.) on the steam-bath for 15 minutes; the acetic acid was then distilled in a good vacuum. The residue crystallised from benzene-light petroleum in stout prisms (6.3 g.), m. p.  $126$ – $127^\circ$  (Found: C, 71.6; H, 5.2.  $C_{24}H_{20}O_6$  requires C, 71.3; H, 5.0%).

*3-O-Methylgallic Acid* (X).—A mixture of methyl 3-methoxy-4:5-diphenylmethylenedioxybenzoate (40 g.) and concentrated hydrochloric acid (150 c.c.) was refluxed for 2 hours, cooled, and neutralised with potassium bicarbonate. The undissolved benzo-

phenone was pulverised, and the filtered solution acidified with hydrochloric acid, giving 16 g. of grey needles. The acid crystallised from water (charcoal) in elongated colourless prisms, m. p. 220°, in agreement with Fischer's statement (*loc. cit.*). The air-dried product was found to contain  $\frac{1}{2}\text{H}_2\text{O}$  (Found: C, 49.6; H, 4.8; loss at 110° in a vacuum, 4.8. Calc. for  $\text{C}_8\text{H}_8\text{O}_5 \cdot \frac{1}{2}\text{H}_2\text{O}$ : C, 49.7; H, 4.7;  $\text{H}_2\text{O}$ , 4.7%). The *diacetyl* derivative was obtained by heating the acid (16 g.) with acetic anhydride (60 g.) and zinc chloride (1.5 g.) on the steam-bath for 2 hours. The product was purified by solution in aqueous potassium bicarbonate and recovery; it finally crystallised from aqueous alcohol in colourless prisms (17 g.), m. p. 170–171° (Found: C, 53.8; H, 4.7.  $\text{C}_{12}\text{H}_{12}\text{O}_7$  requires C, 53.7; H, 4.5%).

4 : 5-Diacetoxy-3-methoxybenzoyl chloride was obtained by heating a mixture of the acid (15 g.), phosphorus pentachloride (12 g.), and chloroform (17 c.c.) until solution occurred and the reaction was completed. On addition of light petroleum and cooling in a freezing mixture, the derivative separated; it crystallised from carbon tetrachloride in stout prisms, m. p. 109° (Found: Cl, 12.6.  $\text{C}_{12}\text{H}_{11}\text{O}_6\text{Cl}$  requires Cl, 12.4%).

$\omega$ -Diazo-4 : 5-diacetoxy-3-methoxyacetophenone,

was obtained by the usual method and precipitated from the reaction mixture on the addition of light petroleum as a quickly crystallising oil (7 g. from 9.5 g. of the chloride). It crystallised from benzene–light petroleum at a low temperature in pale yellow, short prisms, m. p. 90–91° (Found: C, 53.4; H, 4.4; N, 9.2.  $\text{C}_{13}\text{H}_{12}\text{O}_6\text{N}_2$  requires C, 53.4; H, 4.1; N, 9.6%).

$\omega$  : 4 : 5-Triacetoxy-3-methoxyacetophenone (XIII).—The foregoing diazo-ketone (5 g.) gave in the usual way 4.8 g. of pale yellow prisms. The substance crystallised from benzene–light petroleum in elongated prisms, m. p. 138.5°, softening at 136° (Found: C, 55.4; H, 5.0.  $\text{C}_{15}\text{H}_{16}\text{O}_8$  requires C, 55.5; H, 5.0%).

5-O-Benzoyl-3'-O-methylidelpinidin Chloride (XIV).—(A) This is much the better of the two methods for the preparation of the salt; the condensation occurs with greater facility and the yield is higher than in (B).

A solution of  $\omega$ -acetoxy-3-methoxy-4 : 5-diphenylmethylenedioxyacetophenone (1.6 g.) and 2-O-benzoylphloroglucinaldehyde (1 g.) in ethyl acetate (60 c.c.) was cooled in melting ice, saturated with hydrogen chloride, and kept for 12 hours under the pressure of the hydrogen chloride generator. The dark violet deposit of prisms, brown by transmitted light under the microscope, was collected (1 g.) and crystallised (0.9 g.) by solution in hot ethyl

alcohol (200 c.c.) containing a few drops of concentrated hydrochloric acid and addition of 7% hydrochloric acid (200 c.c.) to the filtered solution. The glistening needles (0.5 g.) that separated had a fine bronze lustre (Found: C, 55.9; H, 4.4; MeO, 6.0; Cl, 7.1.  $C_{23}H_{17}O_8Cl \cdot 2H_2O$  requires C, 56.1; H, 4.3; 1MeO, 6.3; Cl, 7.2%).

The substance is insoluble in water and acetone and very sparingly soluble in hot dilute hydrochloric acid. It gives a crimson alcoholic solution, becoming blue on the addition of ferric chloride. The alkali-colour reactions resemble those of *O*-benzoylcyanidin and *O*-benzoyldelphinidin chlorides.

(B) A mixture of  $\omega$ :4:5-triacetoxy-3-methoxyacetophenone (1.2 g.), 2-*O*-benzoylphloroglucinaldehyde (1 g.), and alcohol (25 c.c.) was cooled in melting ice and saturated with hydrogen chloride whilst being vigorously mechanically stirred. The temperature was then maintained at 35° for 2 hours, after which the dark red, homogeneous liquid was cooled in ice, and acetyl chloride (25 c.c.) slowly added during 1 hour. Next day, the violet deposit was collected (0.5 g.) and crystallised as described under (A). The colour reactions and other properties of this specimen were identical with those of the product obtained by the method A. It was apparent that the presence of the acetoxy-groups attached to the aromatic nucleus retarded the condensation, and flavylium salt was only obtained under conditions favouring the removal of the acetyl residues by hydrolysis. Herein lies the explanation of the necessity for the period of heating at 35° and the selection of a hydroxylic solvent.

3'-*O*-Methyldelphinidin Chloride (XV).—The benzoyl derivative (0.5 g.) was added to alcohol (5 c.c.) and 10% aqueous sodium hydroxide (5 c.c.), and the mixture kept for 2 hours and occasionally shaken; air was excluded by hydrogen, washed by permanganate and alkaline pyrogallol. After the addition of concentrated hydrochloric acid (3 c.c.), the whole was heated on the steam-bath for 1 hour, cooled, and more hydrochloric acid (10 c.c.) added. The dark precipitate was washed with acetone and ether and dried. The crude product was dissolved in ethyl alcohol (125 c.c.), containing a few drops of concentrated hydrochloric acid, and the filtered solution mixed with an equal volume of 7% hydrochloric acid. The chloride crystallised in yellowish-green, elongated, rhombohedral plates, yellowish-brown by transmitted light under the microscope (Found: C, 51.6; H, 4.0; Cl, 9.6; loss at 110° in a vacuum, 3.4. Found in material dried at 110°: C, 53.4; H, 3.9; Cl, 9.8.  $C_{16}H_{13}O_7Cl \cdot H_2O$  requires C, 51.9; H, 4.1; Cl, 9.6;  $\frac{1}{2}H_2O$ , 2.4%.  $C_{16}H_{13}O_7Cl \cdot \frac{1}{2}H_2O$  requires C, 53.2; H, 3.9; Cl, 9.8%). Apparently the salt loses rather more than  $\frac{1}{2}H_2O$  at 110°, but, being then very

hygroscopic, regains the composition  $C_{16}H_{13}O_7Cl \cdot \frac{1}{2}H_2O$  during the brief period of exposure preceding the analysis of the dried material by combustion.

*3'-O-Methyldelphinidin chloride* closely resembles cyanidin chloride in its general properties; the alcoholic acid solutions are a little bluer, and the precipitation of colour-base on the addition of water, so characteristic of cyanidin, does not take place to the same extent. The colour reactions in a range of buffered solutions (Robertson and Robinson, *loc. cit.*) were the following :—

(1) Deep cherry-red; (2) very slightly bluer; (3) the same; (4) a little bluer; (5) a little bluer, still cherry-red; (6) reddish-violet; (7) bluer reddish-violet; (8) bluer violet; (9) violet-blue in thin layers; (10) blue; (11), (12) and (13), greener blue; (14) greenish-blue, fading very rapidly; (15) greenish-blue, quickly changing to pale green. (3), (4) and (5) faded rapidly to brownish-red, and the presence of colour-base was confirmed by centrifuging the solution in a high-speed apparatus, a solid deposit and a colourless solution then being obtained.

After  $3\frac{1}{2}$  hours, the colours were: (1) and (2), colourless; (3), (4) and (5), colourless, brownish-red precipitate; (6) reddish-violet, a little precipitate; (7), (8) and (9), violet; (10), (11), (12) and (13), a series from greenish-blue to bluish-green; (14) and (15), orange.

After 24 hours: (1)—(8), colourless, with precipitate in (4), (5) and (6); (9)—(13), very weak orange to weak orange; (14) and (15), a little deeper orange.

These appearances (denoted as caused by S) were directly compared with those produced under the same conditions by natural petunidin chloride (P) (Willstätter and Burdick, *loc. cit.*), natural myrtilidin chloride (M) (Willstätter and Zollinger, *Annalen*, 1915, 408, 83; 1916, 412, 205), for specimens of which we are deeply indebted to Professor R. Willstätter, and with mixtures (DM) of malvidin chloride and delphinidin chloride. There was a very close resemblance between all these series when the anthocyanidin and buffered solutions were first mixed, especially between S and P, the only divergence being that P did not separate colour-base in (3), (4) and (5). S and P remained similar and, after 24 hours, were identical, but S and M diverged at several points after 10 minutes, and this divergence reached a maximum after 1 hour; after 24 hours, there were still marked differences, but, on long keeping, both S and M exhibited the deepest orange colour at (9) and (10). DM gave colours undoubtedly closer to M than to P, but there were differences between M and DM at certain points. Colorimetric observations of the blue ferric chloride and copper sulphate reactions in alcoholic solution showed that the order (stronger to

weaker) was : S, P, M, DM; the ratio of intensity S/P was about 7/5.

The only conclusion which can be legitimately drawn from these observations at the present stage is that petunidin is not perfectly pure 3'-O-methyldelphinidin, but it is still possible that the anthocyanidin has essentially this constitution. Small percentages of impurities would suffice to change the crystal form and alter the composition of the hydrate.

Further work on this unsolved problem is in progress.

The authors wish to thank the Swiss Commission of the Ramsay Memorial Fellowships Trust for a fellowship awarded to one of them.

### CVIII.—*Anthoxanthins. Part XI. A Synthesis of Diosmetin and of Luteolin 3'-Methyl Ether.*

By ALBERT LOVECY, ROBERT ROBINSON, and SHIGEHICO SUGASAWA.

THE rhamnoglucoside, diosmin, was isolated in 1925 by Oesterle and Wander (*Helv. Chim. Acta*, 8, 519) from *Scrophularia nodosa*, *Hyssopus officinalis*, as well as from species of *Conium*, *Barosma*, *Hedeoma*, *Menika*, *Toddalia*, and *Linaria*, and found to yield an aglycone, diosmetin (I), which was shown to be a methyl ether of luteolin. The isovanillin-type of orientation is so infrequently

encountered in nature that it was thought desirable to synthesise diosmetin and the isomeride (II) which, according to A. G. Perkin (J., 1900, 77, 423), stands in a close relationship to scoparin from *Cytisus scoparius* (Link).

The two flavones have been obtained by debenzoylation of the benzyl ethers produced by condensation of phloracetophenone with sodium *O*-benzylisovanillate and *O*-benzylvanillate, respectively. The methods employed are thus quite parallel with that devised for the synthesis of syringetin (Heap and Robinson, Part IX, J., 1929, 67). The synthetic diosmetin and its triacetate were directly compared with specimens of the natural product and of its triacetate

kindly sent to us by Professor O. A. Oesterle, to whom we are deeply indebted, and no divergences of behaviour were observed.

#### EXPERIMENTAL.

*isoVanillic Acid*.—This substance can be obtained by the hydrolysis of veratric acid by means of acids, the methoxyl group in the *m*-position to the carboxyl being preferentially attacked (compare 4-nitroveratrole; Cardwell and Robinson, J., 1915, 107, 255).

A mixture of veratric acid (20 g.) and hydrobromic acid (200 c.c. of 40%) was boiled under reflux; after 1–1½ hours, a clear yellowish-brown solution was obtained, but in a short time a white substance was deposited; when the voluminous precipitate had become crystalline, it was collected on a sintered-glass filter-plate. The crude material (8–9 g.), m. p. 245–247° after sintering at 235°, was pure enough for many purposes; once crystallised from water, it had m. p. 248–249° (literature, 250°). The hot acid filtrate deposited a white flocculent material on cooling and, by renewed treatment with boiling 40% hydrobromic acid, a further quantity of *isovanillic acid* (about 1 g.) was obtained (total yield, 50–55%).

*O-Benzylisovanillic Acid and Derivatives*.—The direct benzylation of *isovanillic acid* gave indifferent results, owing to separation difficulties, and accordingly we adopted the following processes :

(A) Following Shinoda (*J. Pharm. Soc. Japan*, 1928, 48, 936), we prepared *isovanillin* (25 g., m. p. 115°) by the semi-demethylation of veratraldehyde (100 g.) by means of boiling 43% hydrobromic acid (1500 g.) during 3 hours. The dark filtrate from tarry matter was extracted with chloroform, and the residue after removal of the solvent was dissolved in aqueous potassium hydroxide and freed from neutral substances by extraction with ether. The hydroxy-aldehyde was regenerated, isolated by means of chloroform, and crystallised from water (600 c.c.).

*isoVanillin* (90 g.), dissolved in a solution of potassium hydroxide (34 g.) in water (200 c.c.), was mixed with benzyl chloride (50 g.), and the whole heated (oil-bath at 110–120°) for 7 hours with frequent shaking. The product was isolated by extraction with chloroform and crystallisation from alcohol (yield, 80 g.; recrystallised, 66 g., m. p. 62–63°) in colourless needles, m. p. 63° (Found : C, 74.4; H, 5.8.  $C_{15}H_{14}O_3$  requires C, 74.5; H, 5.8%). Mixed with benzylvanillin (m. p. 63°), it melted at about 48°. Oxidation of *O-benzylisovanillin* was effected by means of potassium permanganate in acetone solution, the best results being obtained in relatively small-scale operations (less than 15 g.). The acid crystallised from alcohol and then from ethyl acetate in white, elongated, hexagonal plates, m. p. 177–178°.

(B) This is the better of the alternatives. *iso*Vanillic acid gave an equal weight of the methyl ester (crystallised from ether-light petroleum; m. p. 65–66°) on treatment in the usual way with methyl alcohol and hydrogen chloride.

Potassium hydroxide (5.5 g.) in methyl alcohol (50 c.c.) was added to a mixture of methyl *isovanillate* (17 g.), benzyl chloride (12 g.), and methyl alcohol (25 c.c.), and the whole heated on the steam-bath for 5 hours. Potassium chloride and methyl *O-benzylisovanillate* separated from the hot solution and, after cooling, the ester was collected and washed with water (yield, 21.5 g. or 82%; m. p. 121°); recrystallised from methyl alcohol-acetone, it melted at 124° (Found: C, 70.8; H, 6.1.  $C_{16}H_{14}O_4$  requires C, 70.6; H, 5.9%). A mixture of methyl *O-benzylisovanillate* (52 g.), potassium hydroxide (12 g.), and water (120 c.c.) was heated on the steam-bath for 2 hours, and the clear solution then acidified. *O-Benzylisovanillic acid*, crystallised from acetic acid, had m. p. 177° (Found: C, 69.4; H, 5.6.  $C_{15}H_{14}O_4$  requires C, 69.8; H, 5.4%).

*O-Benzylisovanillic Anhydride*.—A cold ethereal solution of pure thionyl chloride (3.7 g.) was added during 2 hours with stirring to a suspension of powdered benzylisovanillic acid (12.5 g.) in dry ether (50 c.c.) and pyridine (5.3 g.) cooled in a mixture of ice and salt. The whole was kept at 0° for several hours with occasional shaking, crushed ice was then added, and the solid was collected and triturated successively with ice-cold dilute hydrochloric acid, dilute aqueous sodium carbonate, and water, and dried in a vacuum (yield, 11 g.; a small further quantity was recovered by means of ether). The *anhydride* crystallised from benzene or ethyl acetate in glistening needles, m. p. 156° after softening at 153° (Found: C, 72.3; H, 5.3.  $C_{30}H_{26}O_7$  requires C, 72.3; H, 5.2%).

5 : 7 - *Dihydroxy* - 3' - *benzyloxy* - 4' - *methoxyflavone* (*O-Benzylidismetin*).—An intimate mixture of phloracetophenone (5 g.), *O-benzylisovanillic anhydride* (60 g.), and sodium *O-benzylisovanillate* (12 g.) was heated (oil-bath at 190–195°) for 6 hours, and the viscous reddish-brown mass was then poured as completely as possible into alcohol (200 c.c.). The residue in the flask was chipped out when cold and washed out with alcohol and the whole was refluxed for 2 hours. A solution of potassium hydroxide (25 g.) in water (30 g.) was added and the mixture was boiled gently for 30 minutes and then evaporated under diminished pressure. The residue was dissolved in water and saturated with carbon dioxide, giving a yellowish-brown flocculent precipitate, which was redissolved in 2% sodium hydroxide solution and reprecipitated by carbon dioxide (dry wt., 15 g.). Attempts to crystallise this material were unsuccessful, but after treatment with boiling alcoholic potassium

hydroxide about 2 g. of a yellow substance remained undissolved; this was dissolved in 2% sodium hydroxide solution, and the flavone regenerated by means of carbon dioxide. The product now crystallised from acetic acid in pale yellow clusters of needles, m. p.  $240^{\circ}$  after sintering at  $237^{\circ}$  (Found: C, 70.6; H, 4.7.  $C_{23}H_{18}O_6$  requires C, 70.8; H, 4.6%). The alcoholic potassium hydroxide filtrate was also worked up and, by taking advantage of the insolubility of the impurities in alcohol, a further equal quantity of *benzyldiosmetin*, m. p.  $237^{\circ}$ , was recovered.

*O-Triacetyldiosmetin*.—A solution of *O*-benzyldiosmetin (0.4 g.) in acetic acid (25 c.c.) was boiled and transferred to the steam-bath; a solution of hydrochloric acid (2 g.) saturated at  $0^{\circ}$  was then gradually introduced, giving a deep yellow solution. After 10 minutes, a further amount (1 g.) of the acid was added, the heating continued for 30 minutes, and the mixture was finally boiled. Water (30 c.c.) was added to the filtered solution and the pasty precipitate was collected and dried; it could not, however, be crystallised at this stage.

The crude product (0.3 g.) was boiled with acetic anhydride (10 c.c.) and a drop of pyridine for 2 hours and the acetate produced was crystallised from alcohol and then from ethyl acetate, giving colourless needles, m. p.  $195-196^{\circ}$  (Found: C, 72.3; H, 5.3. Calc. for  $C_{22}H_{18}O_9$ : C, 72.3; H, 5.2%). This specimen was identical in every way with specimens of triacetyldiosmetin from two sources, kindly supplied by Professor Oesterle. A mixture of the natural and the synthetic specimen gave an undepressed melting point.

*Diosmetin* (I).—A mixture of the synthetic triacetyldiosmetin (0.3 g.) with alcohol (5 c.c.) and 2% potassium hydroxide solution (10 c.c.) was heated on the steam-bath for 15 minutes, and the flavone isolated from the clear yellow solution by acidification with acetic acid. The substance, crystallised from alcohol and then twice from alcohol-ethyl acetate, formed yellow needles, sintering at  $248^{\circ}$  and melting at  $253-254^{\circ}$  (Found in a specimen dried at  $150^{\circ}$  in a high vacuum: C, 64.3; H, 4.2. Calc. for  $C_{16}H_{12}O_6$ : C, 64.0; H, 4.0%). A mixture with natural diosmetin (sintering at  $245^{\circ}$  and melting at  $253-255^{\circ}$ ) sintered at  $245^{\circ}$  and melted at  $253-254^{\circ}$ . In all respects, the two specimens had identical properties.

*Benzylvanillic Anhydride*,  $[CH_2Ph \cdot O \cdot C_6H_3(OMe) \cdot CO]_2O$ .—The benzylation of vanillin (276 g.) was effected in aqueous solution (compare Gomberg and Buchler, *J. Amer. Chem. Soc.*, 1920, 42, 2059) by means of benzyl chloride (150 g.) and potassium hydroxide, the reaction mixture being heated (oil-bath at  $110-120^{\circ}$ ) for  $10\frac{1}{2}$  hours. After crystallisation, 165 g., m. p.  $63-64^{\circ}$ , were obtained.

On oxidation with potassium permanganate in acetone solution, the aldehyde (70 g.) furnished crystalline *O*-benzylvanillic acid (60 g.), m. p. 168—169°.

*O*-Benzylvanillic acid (97 g.) was finely ground, suspended in dry ether (375 c.c.) and pyridine (40 g.), to which thionyl chloride (28 g.) in ether (30 c.c.) was added, and the whole kept at 0° for 12 hours. Crushed ice was then introduced and the solid was washed successively with ice-cold 2*N*-hydrochloric acid, water, 2*N*-sodium carbonate, and water and dried (80 g., m. p. 135°; benzylvanillic acid, 9 g., was recovered from the ether and washings). The *anhydride* crystallised from ethyl acetate in slender lustrous needles, m. p. 135—136° (Found: C, 72.2; H, 5.4.  $C_{30}H_{26}O_7$  requires C, 72.3; H, 5.2%).

5 : 7-*Dihydroxy-4'-benzyloxy-3'-methoxyflavone*.—An intimate mixture of phloracetophenone (4.5 g.), sodium *O*-benzylvanillate (12 g.), and *O*-benzylvanillic anhydride (40 g.) was heated (oil-bath at 180—185°) for 3 hours subsequent to fusion to a mobile, dark red liquid. The product was refluxed with alcohol (175 c.c.); a solution of potassium hydroxide (17 g.) in water (20 c.c.) was gradually added, and the boiling continued for 30 minutes. The solution was distilled (170 c.c. collected) and the residue was dissolved in water (200 c.c.), heated to 60°, and saturated with carbon dioxide. The buff precipitate was collected (7 g.), redissolved in aqueous potassium hydroxide, and reprecipitated by carbon dioxide (yield, 5 g.). The crude flavone was then acetylated by gently refluxing it with acetic anhydride (20 c.c.) and a drop of pyridine for 2 hours. The acetyl derivative, which separated on cooling (2 g.), crystallised from ethyl acetate in slender white needles, m. p. 195° (1.6 g.) (Found: C, 68.2; H, 4.8.  $C_{27}H_{22}O_8$  requires C, 68.4; H, 4.6%).

This 5 : 7-*diacetoxy-4'-benzyloxy-3'-methoxyflavone* (1.2 g.) was hydrolysed by means of alcoholic potassium hydroxide on the steam-bath and, when the diluted solution was acidified, a yellow solid was precipitated (1.03 g.). The substance was very sparingly soluble in most organic solvents and could not be crystallised, but after being washed and dried it was almost pure; m. p. 265—267° after softening at 262° (Found: C, 70.0; H, 4.9.  $C_{23}H_{18}O_6$  requires C, 70.7; H, 4.6%.  $C_{23}H_{18}O_6 \cdot \frac{1}{2}H_2O$  requires C, 70.0; H, 4.7%). This 5 : 7-*dihydroxy-4'-benzyloxy-3'-methoxyflavone* gives a yellow-brown coloration with alcoholic ferric chloride.

5 : 7 : 4'-*Trihydroxy-3'-methoxyflavone* (II).—The benzyl derivative last described (0.8 g.) was suspended in acetic acid (45 c.c.), heated on the steam-bath, and treated gradually with concentrated hydrochloric acid (3 c.c.). After 10 minutes, a further quantity (1.5 c.c.) of concentrated hydrochloric acid was added, and the heating

continued for 30 minutes; the mixture was finally boiled. The solution was decanted from a small unattacked residue, and, on addition of water (30 c.c.), gave a flocculent yellow precipitate, which was collected and dried (0.5 g.) (Found: C, 63.9; H, 4.4; MeO, 10.3%). This product was acetylated in the usual manner and gave 0.4 g., m. p. 212°, which, crystallised from ethyl acetate, formed soft white needles, m. p. 220—221° (0.35 g.; recrystallised, 0.29 g., m. p. 220—221°) (Found: C, 61.9; H, 4.4.  $C_{22}H_{18}O_9$  requires C, 62.0; H, 4.2%).

On hydrolysis by means of alcoholic potassium hydroxide, 5:7:4'-triacetoxy-3'-methoxyflavone gave in the first place bright yellow needles of the potassium salt of the trihydroxymethoxyflavone; these were collected and dissolved in water and afforded on acidification the pure flavone, m. p. 328—330°, as a yellow precipitate (Found in material dried in a vacuum: C, 62.8; H, 4.2; MeO, 9.3.  $C_{16}H_{12}O_6 \cdot \frac{1}{2}H_2O$  requires C, 62.7; H, 4.2; 1MeO, 9.5%). This very sparingly soluble substance crystallised from nitrobenzene in yellow prismatic needles, m. p. 330—331° (Found: C, 63.9; H, 3.9; MeO, 9.8.  $C_{16}H_{12}O_6$  requires C, 64.0; H, 4.0; 1MeO, 9.7%). Like diosmetin, the flavone is a very weak mordant dye. It is much more sparingly soluble and intensely coloured than is diosmetin.

### CIX.—*Anthoxanthins. Part XII. Transition from a Flavylum Salt to a Flavone, illustrated by a New Synthesis of Scutellarein Tetramethyl Ether.*

By ROBERT ROBINSON and GEROLD SCHWARZENBACH.

ALTHOUGH the pyrones stand in the relation to the pyrylium salts that the pyridones bear to the alkylpyridinium salts, and although the latter can be very readily changed to the pyridones by oxidation, yet there are surprisingly few recorded examples of the production of pyrones by direct or indirect processes from members of the pyrylium group.

Bülow and Wagner (*Ber.*, 1903, 36, 1941) found an isolated example in the oxidation of 7-hydroxy-4-carboxyflavylum betaine

(I) (formulated previously as a pyranol) to 7-hydroxyflavone (II) by means of chromic acid in acetic acid solution. This we have confirmed, but, although the conditions have been somewhat improved, the yield of the flavone remains highly unsatisfactory.

Moreover, the reaction is not a general one, and proposed applications to the synthesis of scutellarein failed. *Anisoylpyruvic acid*,  $\text{MeO}\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{CH}_2\cdot\text{CO}\cdot\text{CO}_2\text{H}$ , obtained by the usual method, has been condensed with 2 : 6-dimethoxyquinol and with antiarol in the presence of hydrogen chloride, furnishing the flavylum salts (III) and (IV), respectively.

In spite of various attempts, neither these salts nor the related *betaines* could be oxidised to scutellarein derivatives. It was, however, possible to achieve our object indirectly by applying the Hofmann reaction to the amide of the acid (IV). The chief difficulty was the preparation of the required *anisoylpyruvamide* (V). If a convenient method of preparation of compounds of this type could be devised, the new flavone synthesis now to be described might acquire considerable importance, since it is applicable to certain types of structure not readily built up by hitherto known processes. Some of the more obvious routes to the *aroylpyruvamide*s have been tested without success, and we were forced back upon an interesting but indirect series of reactions due to Mumm and Münchmeyer (*Ber.*, 1910, **43**, 3335), who obtained benzoylpyruvamide. The stages in the present case were the following :

Anisoylacetaldehyde (Pratt, Robinson, and Williams, J., 1924, **125**, 202) was converted into its *oxime*,  $\text{MeO}\cdot\text{C}_6\text{H}_4\cdot\text{CO}\cdot\text{CH}_2\cdot\text{CH}\cdot\text{NOH}$  (VI), and this was dehydrated by the action of acetyl chloride, giving 5-anisylisooxazole (VII). The *methosulphate* of this base reacted with potassium cyanide in aqueous solution with formation of  $\alpha$ -methylimino- $\beta$ -anisoylpropionitrile (VIII), which was hydrolysed to anisoylpyruvamide (V) by means of dilute hydrochloric acid.

Anisoylpyruvamide and antiarol with the help of hydrogen chloride yielded a product containing 4-carbamyl-5 : 6 : 7 : 4'-tetramethoxyflavylium chloride (IX), and this, on treatment with potassium

hypochlorite and potassium hydroxide in methyl-alcoholic solution, reacting doubtless as the pseudo-base, gave another pseudo-base

which could be transformed into 4-amino-5:6:7:4'-tetramethoxyflavylum picrate (X). The corresponding base is, doubtless, the flavone-imine (XI), and the tetramethoxyflavone (XII) resulted when the imine was treated with boiling dilute aqueous sodium hydroxide. The existence of the flavone-imine recalls that of a xanthone-imine obtained by the condensation of phloroglucinol with salicylonitrile under the conditions of the Hoesch reaction (Nishikawa and Robinson, J., 1922, 121, 839); the resistance to hydrolysis by acids and

other properties are parallel in the two series.

The substance (XII) had the melting point and other properties of scutellarein tetramethyl ether (Molisch and Goldschmiedt, *Monatsh.*, 1910, 31, 439), and we were able to establish the identity by direct comparison with a specimen prepared from scutellarein. For providing the latter, we are greatly indebted to Professor E. Späth and Dr. F. Wessely.

Scutellarein has been previously synthesised by Bargellini (*Gazzetta*, 1915, 45, 69), who submitted pentamethoxydibenzoylmethane (XIII) to the action of hydriodic acid; the reaction might have

proceeded in the two directions indicated. Actually, scutellarein (XIV) was produced and the reaction was correctly interpreted in the light of certain analogies. The present unambiguous synthesis confirms these deductions and supplies a proof of the constitution of scutellarein.

## EXPERIMENTAL.

*7-Hydroxy-4-carboxyflavylium Derivatives.*—Bülow and Wagner (*loc. cit.*) did not crystallise the chlorides obtained by the condensation of resorcinol, benzoylpyruvic acid or its ester, and hydrogen chloride, so the following data may be recorded.

7-Hydroxy-4-carboxyflavylium betaine (I) decomposes at 248°, the corresponding picrate decomposes at 226°; on solution in ethyl-alcoholic hydrogen chloride and gradual addition of ether, *7-hydroxy-4-carboxyflavylium chloride* (decomp. 250°) crystallised in orange-red leaflets (Found: Cl, 11.6.  $C_{18}H_{11}O_4Cl$  requires Cl, 11.7%).

7-Hydroxy-4-carbethoxyflavylium picrate decomposes at 225° and similarly yields *7-hydroxy-4-carbethoxyflavylium chloride*, orange leaflets decomposing at 198° (Found: Cl, 10.2.  $C_{18}H_{15}O_4Cl$  requires Cl, 10.5%).

The oxidation of the betaine to 7-hydroxyflavone does not proceed satisfactorily; a slight improvement followed on the adoption of the following conditions:

A solution of chromic anhydride (0.7 g.) in water (10 c.c.) was added to one of 7-hydroxy-4-carboxyflavylium betaine (0.7 g.) in hot 25% sulphuric acid (30 c.c.); carbon dioxide was then briskly evolved and an orange precipitate (0.45 g.) was formed. After crystallisation, 7-hydroxyflavone (0.15 g., m. p. 240°) was obtained.

Our further experience has shown that this is a special case, and the reaction is by no means a general one. It fails in the scutellarein series described below.

*Anisoylpyruvic Acid and its Ethyl Ester.*—A mixture of *p*-methoxyacetophenone (79 g.) and ethyl oxalate (77 g.) was added to a solution of sodium ethoxide (25 g. of sodium) in alcohol (400 c.c.), the whole refluxed for  $\frac{1}{2}$  hour, and the alcohol evaporated. An aqueous solution of the residue was saturated with carbon dioxide and filtered, and the crude acid (64 g.) precipitated by the addition of hydrochloric acid. This substance crystallised from alcohol in pale brown needles or irregular prisms, decomp. at 162.5° (Found: C, 54.9; H, 5.0; loss at 110° in a vacuum, 7.6.  $C_{11}H_{10}O_5 \cdot H_2O$  requires C, 55.0; H, 5.0;  $H_2O$ , 7.5%). The yield can be improved by carrying out the condensation in the cold and subsequently hydrolysing the ester, but this is hardly worth doing.

A mixture of *p*-methoxyacetophenone (13.5 g.), ethyl oxalate (13 g.), sodium ethoxide (from 2 g. of sodium) and alcohol (35 c.c.) was kept for 12 hours at 0° and then added to ether. The cake of sodium derivative was collected and decomposed at 0° in aqueous solution with carbon dioxide (yield, 16 g.).

*Ethyl anisoylpyruvate* crystallised from alcohol in colourless

prisms, m. p.  $54^{\circ}$  (Found : C, 62.3; H, 5.7.  $C_{13}H_{14}O_5$  requires C, 62.3; H, 5.6%).

6-*Hydroxy-5:7:4'-trimethoxy-4-carboxyflavylum Derivatives* (Chloride, III).—A solution of 2:6-dimethoxyquinol (4.25 g.) and anisoylpyruvic acid (5.6 g.) in acetic acid (50 c.c.) was saturated with hydrogen chloride at  $90-100^{\circ}$  for 1 hour, then cooled to  $0^{\circ}$ , and ether (150 c.c.) added without interrupting the passage of hydrogen chloride. The dark red solid was collected (5.8 g.), and a portion converted into the *picrate* in hot alcoholic solution by the addition of picric acid; the derivative crystallised immediately in dark red leaflets which decomposed at  $224^{\circ}$  (Found : C, 49.6; H, 3.8; N, 7.2.  $C_{25}H_{19}O_{14}N_3 \cdot H_2O$  requires C, 49.7; H, 3.5; N, 6.9%). This *picrate* was suspended in pure methyl alcohol and hydrogen chloride introduced until it dissolved; on the addition of ether, the chloride crystallised in dark red needles, decomposing at  $170-180^{\circ}$  and readily soluble in water and alcohol.

Another portion of the crude chloride was dissolved in hot aqueous sodium acetate, and the filtered solution acidified with acetic acid. The *betaine* separated in red needles, and the substance could be recrystallised from alcohol, forming very small, green prisms, decomp.  $182^{\circ}$  (Found : C, 59.6; H, 5.0.  $C_{19}H_{16}O_7 \cdot 1\frac{1}{2}H_2O$  requires C, 59.6; H, 5.0%), sparingly soluble in water and giving a bright orange solution in sulphuric acid.

5:6:7:4'-*Tetramethoxy-4-carboxyflavylum Derivatives* (Chloride, IV).—A solution of antiarol (9.2 g.) and anisoylpyruvic acid (11.6 g.) in acetic acid (60 c.c.) was saturated with hydrogen chloride at  $100^{\circ}$  for 3 hours, cooled, and dry ether (200 c.c.) added, hydrogen chloride being passed meanwhile. After being kept at  $0^{\circ}$  for 12 hours, the solid was collected (21 g., air-dried) and this chloride was converted into the *betaine* by solution in aqueous sodium acetate and acidification with acetic acid. The orange needles obtained were readily soluble in water and could be recrystallised from alcohol in a similar form, m. p.  $127-130^{\circ}$  (Found : C, 59.8; H, 5.6. Found in material dried at  $100^{\circ}$  in a vacuum: C, 65.1; H, 5.2.  $C_{26}H_{18}O_7 \cdot 1\frac{1}{2}H_2O$  requires C, 60.4; H, 5.3%.  $C_{20}H_{18}O_7$  requires C, 64.9; H, 4.9%).

The related *picrate* crystallised from alcohol in deep orange needles, decomp.  $204-205^{\circ}$  (Found : C, 50.4; H, 4.1; N, 7.1.  $C_{26}H_{21}O_{14}N_3 \cdot H_2O$  requires C, 50.6; H, 3.7; N, 6.8%).

The oxidising agents tested with the object of preparing *O*-tetramethylscutellarein were chromic acid in acetic acid and dilute sulphuric acid solutions, persulphate in dilute sulphuric acid, lead peroxide and acetic acid, manganese dioxide and dilute sulphuric acid and hydrogen peroxide in acetic acid, and finally potassium

ferricyanide in neutral and in alkaline solution; in all cases, the results were negative.

The action of phosphorus pentachloride on the betaine appeared to proceed normally, giving the acid chloride flavylum chloride, but the action of ammonia or hydrazine on this derivative did not give the anticipated results.

*Anisoylacetaldoxime* (VI).—The sodium salt of  $\omega$ -hydroxy-methylene-*p*-methoxyacetophenone (45 g.) (Pratt, Robinson, and Williams, *loc. cit.*) was dissolved in ice-water (600 c.c.), and hydroxylamine hydrochloride (25 g.) in water (50 c.c.) added; separation of the *oxime* began immediately. The substance (yield, 25 g.) crystallised from benzene in colourless microscopic needles, m. p. 120° (Found: C, 62.4; H, 5.7; N, 7.4.  $C_{10}H_{11}O_3N$  requires C, 62.3; H, 5.7; N, 7.3%). It retained benzene tenaciously, and the determination of nitrogen was carried out with a specimen giving C, 63.3; H, 5.6%, and probably containing a trace of the solvent.

*5-Anisylisooxazole* (VII).—Claisen (*Ber.*, 1891, 24, 132) has shown that the dehydration of the *oxime* of benzoylacetaldehyde with acetyl chloride yields phenylisooxazole, whereas the use of acetic anhydride leads to the formation of  $\omega$ -cyanoacetophenone, which is also obtained by the action of alkalis on phenylisooxazole.

Finely powdered anisoylacetaldoxime (10 g.) was added to acetyl chloride (10 g.) with cooling; a vigorous reaction and brisk evolution of hydrogen chloride ensued. The excess of the reagent was removed by evaporation and the oily residue was mixed with 3% sodium hydroxide solution (150 c.c.); the oil then quickly solidified. The product crystallised from 80% alcohol (100 c.c.) in almost colourless, flat prisms, m. p. 63° (yield, 7.5 g.) (Found: C, 68.7; H, 5.1; N, 8.0.  $C_{10}H_9O_2N$  requires C, 68.7; H, 5.1; N, 8.0%). On boiling for 5 minutes with alcoholic sodium hydroxide, *5-anisylisooxazole* was transformed into the isomeric  $\omega$ -cyano-*p*-methoxyacetophenone, which crystallised from alcohol in colourless needles, m. p. 131° (Found: C, 68.9; H, 5.2; N, 8.1%) in good agreement with the statement of Bargellini (*Gazzetta*, 1911, 41, 748), who prepared the compound in another way.

The *methosulphate* was obtained by heating a mixture of anisylisooxazole (8.9 g.) and pure methyl sulphate (5.3 g.) on the steam-bath. Reaction occurred at about 90° and soon afterwards the whole crystallised with evolution of heat. The salt was washed with acetone and separated on the addition of ether to its alcoholic solution in bright yellow crystals, m. p. 142.5° (Found: N, 4.5; S, 10.4.  $C_{12}H_{15}O_6NS$  requires N, 4.7; S, 10.6%). The golden-yellow picrate has m. p. 147.5°.

$\alpha$ -Methylimino- $\beta$ -anisoylpropionitrile (VIII).—Potassium cyanide

(5 g.) in water (50 c.c.) was very gradually added to a solution of anisylisooxazole methosulphate (6.5 g.) in ice-cold water (50 c.c.). The precipitate obtained (4.5 g.) consisted of the pure *nitrile*, m. p.  $109^{\circ}$  (not raised by crystallisation); it separated from alcohol in pale yellow needles or well-shaped prisms (Found: C, 66.6; H, 5.6; N, 13.0.  $C_{12}H_{12}O_2N_2$  requires C, 66.8; H, 5.6; N, 13.0%). The solution in sulphuric acid had a dark purple colour. Experiments on the condensation of this substance with antiarol had no definite outcome.

*Anisoylpyruvamide* (V).—Anisoylpyruvic acid could not be directly converted into its amide either by way of the chloride or through the ester by means of ammonia. Nor could the amide be obtained by the condensation of ethyl oxamate and *p*-methoxyacetophenone.

Methyliminoanisoylpropionitrile (23 g.) was powdered and agitated with *N*-hydrochloric acid (500 c.c.) for 36 hours, and the product isolated (19 g.). The *amide* was sparingly soluble in hot ethyl alcohol and crystallised from *isoamyl* alcohol in colourless microscopic needles, decomp.  $192^{\circ}$  (Found: C, 59.8; H, 5.2; N, 6.0.  $C_{11}H_{11}O_4N$  requires C, 59.7; H, 5.0; N, 6.3%). The solution in sulphuric acid was reddish-brown. The substance, when boiled with concentrated hydrochloric acid, was hydrolysed to anisoylpyruvic acid.

The acid mother-liquor from the preparation described above contained 10% more than the theoretical amount of volatile bases, so it might be advantageous to interrupt the process at an earlier stage. There was also a considerable loss on crystallisation of the crude product.

*4-Carbamyl-5:6:7:4'-tetramethoxyflavylium Chloride* (IX).—Owing to the very great ease with which the amide group in this salt is hydrolysed, we have not obtained a pure specimen of the substance, but a product which must consist of it to a large extent was prepared in the following manner.

Hydrogen chloride was led into a solution of antiarol (7.0 g.) and anisoylpyruvamide (8.0 g.) in purified acetic acid at  $70^{\circ}$  for  $1\frac{1}{2}$  hours; ammonium chloride separated. The mixture was cooled and kept saturated with hydrogen chloride for 24 hours, then diluted with ether and kept in the ice-chest for 4 hours. The product was washed with ether and dried at  $100^{\circ}$  in a vacuum, giving a dark brownish-red mass with a green reflex (9.5 g.). Attempts to isolate the picrate of the amide gave only the already described tetramethoxycarboxyflavylium picrate, which crystallised from acetic acid in an anhydrous condition (Found: C, 52.1; H, 3.9; N, 7.1.  $C_{26}H_{21}O_{14}N_3$  requires C, 52.1; H, 3.5; N, 7.0%). The identity of this picrate with the substance previously obtained was proved by a comparison

of colour reactions and decomposition points, and the related chloride was prepared and found to be free from nitrogen.

*4-Amino-5:6:7:4'-tetramethoxyflavylium Picrate* (X).—The crude chloride (9.5 g.) obtained as described in the last section was dissolved in methyl alcohol (75 g.) and cooled to 0°, a cooled solution of potassium hypochlorite (33 c.c. from 1.77 g. of chlorine, 4.82 g. of potassium hydroxide, and water) added, and the mixture heated on the steam-bath for  $\frac{1}{2}$  hour. Acetic acid (50 c.c.) and a solution of picric acid (12 g.) in acetic acid (100 c.c.) were successively introduced; a yellow *picrate* crystallised on cooling, and this was collected and washed with acetic acid and ether (yield, 4.8 g. in this experiment, but much less when more alkali was employed). The salt crystallised from acetic acid in flat golden-yellow prisms (3.0 g.), very sparingly soluble in all solvents and decomposing at 281° (Found: C, 52.6; H, 4.0; N, 9.7.  $C_{25}H_{22}O_{12}N_4$  requires C, 52.6; H, 4.1; N, 9.8%). The corresponding chloride was obtained in pale pink needles by passing hydrogen chloride into a suspension of the *picrate* in acetic acid and adding ether. The base obtained on treatment with aqueous sodium hydroxide was a sticky, very pale yellow precipitate.

*5:6:7:4'-Tetramethoxyflavone (Scutellarein Tetramethyl Ether)* (XII).—*4-Amino-5:6:7:4'-tetramethoxyflavylium chloride* (0.7 g.) was refluxed with 10% sodium hydroxide solution (7 c.c.) for 45 minutes, ammonia being evolved and the substance becoming a dark brown oil. When this was washed with very dilute hydrochloric acid, it became solid and bright yellow; the substance crystallised from alcohol (charcoal) in thick colourless prisms (S), m. p. 161° (Found: C, 66.9; H, 5.6. Calc. for  $C_{19}H_{18}O_6$ : C, 66.6; H, 5.3%).

The crude *scutellarein* kindly supplied by Professor Späth was methylated by means of an excess of methyl sulphate and 15% sodium hydroxide solution in presence of acetone; the impurities formed as a result of oxidation were insoluble in ether, and, when the washed and dried extract was concentrated to a small bulk, *scutellarein tetramethyl ether* crystallised in colourless prisms. After one crystallisation from alcohol, the specimen (N) had m. p. 161°, undepressed by admixture with an equal amount of (S).

The two specimens had identical properties and gave indistinguishable yellow to orange solutions in mineral acids of various concentrations. Very characteristic is the fact that the ether is partly extracted from ethereal solution even by 2% hydrochloric acid, and that it dissolves in hot 10% hydrochloric acid to a yellow solution, from which the hydrochloride separates as a mass of woolly yellow needles on cooling. On addition of mercuric chloride to the hot solution of the hydrochloride, there is an immediate pre-

cipitation of the very sparingly soluble, pale yellow mercurichloride. The microscopic appearance of the crystals of (S) and (N) and of their hydrochlorides was the same, and the solubility properties also were compared.

The methoxyl content of *O*-tetramethylscutellarein should be 36.25%, but a Zeisel-Pregl estimation gave MeO, 34.22%, and even a Herzig-Meyer-Pregl estimation gave only MeO, 34.7%. Apparently, a fraction of the methyl attached to oxygen is transferred to carbon in the course of the demethylation process.

The authors wish to thank the Swiss Commission of the Ramsay Memorial Fellowships Trust for grants which have enabled one of them to take part in the investigation.

UNIVERSITY COLLEGE, LONDON.

CX.—*Strychnine and Brucine. Part X. The Degradation of Dinitrostrycholcarboxylic Acid: its Recognition as a Derivative of Quinoline and the Consequent Modifications of the Constitutional Formulae for the Strychnos Bases proposed in Part VII.*

By KOTTIAZATH NARAYANA MENON, (the late) WILLIAM HENRY PERKIN, jun., and ROBERT ROBINSON.

UNEXPECTEDLY, the esterification of dinitrostrycholcarboxylic acid (Tafel, *Annalen*, 1898, **301**, 336; compare Part IX, this vol., p. 382) with ethyl alcohol and a mineral acid catalyst affected two hydroxyl groups and afforded *ethyl dinitro-O-ethylstrycholcarboxylate*,  $C_9NH_2(NO_2)_2(OH)(OEt) \cdot CO_2Et$  (I). This ester reacted with hydrazine in the normal manner, yielding the *hydrazide*,  $C_9NH_2(NO_2)_2(OH)(OEt) \cdot CO \cdot NH \cdot NH_2$  (II), and the further stages of the Curtius reactions also gave good results, the *urethane*,  $C_9NH_2(NO_2)_2(OH)(OEt) \cdot NH \cdot CO_2Et$  (III), being the final product.

It will be recalled that dinitrostrycholcarboxylic acid cannot be degraded by boiling with nitric acid; this urethane, however, in which  $\cdot NH \cdot CO_2Et$  replaces  $\cdot CO_2H$ , is readily attacked by the reagent and yields picric acid.

This result is inconsistent with the suggestion that strychol is a dihydroxyisoquinoline, because derivatives of this series would undoubtedly yield trinitro-*m*-hydroxybenzoic acid and not picric acid.

We have examined the behaviour of *m*-hydroxybenzaldehyde

and *m*-hydroxybenzoic acid with boiling nitric acid, and no trace of picric acid could be detected by the sensitive potassium salt method of isolation.

Further, if strychol is thus to be recognised as a dihydroxyquinoline, the formation of picric acid proves that both hydroxyl groups are in the pyridine nucleus, in view of the fact established in Part IX (*loc. cit.*) that the quinoline nitrogen always furnishes a hydroxyl group in the oxidation-nitration process.

Furthermore, Mr. J. Resuggan, to whom we are greatly indebted for undertaking the preparation of large quantities of dinitrostrycholcarboxylic acid, has isolated a by-product of the oxidation of strychnine with nitric acid. This we have identified as 3:5-dinitrobenzoic acid, and its formation is evidently due to elimination of an amino-group in accordance with the scheme :

An analogous reaction is that involved in the production of nitroanisic acid from harmaline by oxidation with nitric acid (O. Fischer and Boesler, *Ber.*, 1912, 45, 1934) :

Confirmation was obtained in the transformation of the urethane (III) into 5:7-dinitroisatin (IV), which was accomplished by hydrolysis with sulphuric acid and subsequent oxidation by permanganate in acid solution. This dinitroisatin does not appear to have been previously prepared and has been obtained in good yield by the nitration of isatin in sulphuric acid solution.

In Part IX, it was clearly proved that strychol is not 2:4-dihydroxyquinoline, and therefore dinitrostrycholcarboxylic acid must be represented by one of the formulæ V and VI (or a pyridone tautomeride). Either of these structures serves to accommodate

the fact established by Tafel that dinitrostrychol behaves as a monobasic acid towards potash but as a dibasic acid towards baryta.

Having found that dinitrostrycholcarboxylic acid yielded a diethyl

ester, we were led to attempt the direct esterification of dinitrostrychol, and, using methyl alcohol, we obtained with greater ease than formerly the known dinitrostrychol monomethyl ether,  $C_9NH_3(NO_2)_2(OH) \cdot OMe$ . This substance reacts with hydrazine in boiling methyl-alcoholic solution with formation of *dinitrohydrazinodeoxystrychol*,  $C_9NH_3(NO_2)_2(OH) \cdot NH \cdot NH_2$  (VII), a base which forms very sparingly soluble salts and a sparingly soluble, pale yellow *isopropylidene* derivative,  $C_9NH_3(NO_2)_2(OH) \cdot N_2H \cdot CMe_2$ . Unfortunately, the oxidation of this hydrazine with ferric chloride regenerates dinitrostrychol: other conditions, however, are in course of investigation. We are of the opinion that the acidic hydroxyl of dinitrostrychol is that in position 3, but we have not yet been able to get decisive experimental evidence on the point. Synthetical work in the 2 : 3- and 3 : 4-dihydroxyquinoline groups is in progress.

Irrespective of the outcome of these further researches, certain conclusions in regard to the constitutions of strychnine and brucine now appear to be fully justified.

The *isoquinoline* structure (Fawcett, Perkin, and Robinson, Part VII, J., 1928, 3082) was advanced mainly in order to illustrate a mode of symbolisation of the reactions of strychnine which had been developed since 1912; especially, it was desired to emphasise the ether nature of the bases, the possession of one ethylenic double bond, and a theory (*loc. cit.*, p. 3086) of the course of the degradations to strychninolone and curbine brought to light by Leuchs and his collaborators (for references, see Part VII, *loc. cit.*, p. 3085). It is unfortunate that these ideas, which we consider to be fundamentally sound, were linked with a view of the nature of dinitrostrychol-carboxylic acid, the inherent improbability of which was almost immediately disclosed by the investigations of Leuchs and of Wieland on the products obtained by breaking down the aromatic nucleus of the alkaloids.

The new conception which we now bring into the discussion is that the hydroxyl in position 3 in the quinoline ring of dinitrostrycholcarboxylic acid marks the position of the b-N of strychnine; it appears to us that this hypothesis is the only one that can explain the appearance of the hydroxyl in this position.

In this connexion, we have prepared 6 : 8-dinitrohydrocarbostyryl, and have not yet succeeded in attempts to oxidise this substance in position 3 either by means of nitric acid or in other ways.

Embodying, now, the views advanced in Part VII, apart from those connected with dinitrostrycholcarboxylic acid, we find that strychnine must be represented by the expression (VIII).

All the many possibilities based on (VIII) must have a bridged

ring, shown in one plausible example (IX); the conceivable variations are obvious.

The new structure (VIII) has many advantages over earlier suggestions, and can be justified experimentally in every detail; the main points are the following:—

(1) The quinoline skeleton with b-N at 17, as already explained, gives naturally dinitrostrycholcarboxylic acid (V or VI).

(2) The N-CO group cannot be at 1, 2, because it must be expanded to  $\text{-N}\cdot\text{CO}\cdot\text{CH}_2\text{-}$  in view of the formation of benzylidene-strychnine (Part VIII, J., 1929, 967).

(3) The properties of strychnidine and most clearly of the dihydro-strychnidines (A) and (B) prove that the second oxygen atom of the bases has ether function. The attachment of the ether oxygen atom at 11 has already been discussed (Part VIII, *loc. cit.*).

(4) The new formula allows the permanganate oxidation of strychnine (Leuchs) to proceed entirely in one section of the molecule: the  $\text{N}\cdot\text{CH}_2\text{-}\overset{\cdot}{\text{C}}\text{:CH}\cdot\text{CH}_2\text{-O-}$  becomes  $\text{N}\cdot\text{CO}\cdot\overset{\cdot}{\text{C}}(\text{OH})\cdot\text{CO}\cdot\text{CH}_2\text{-O-}$ , and this, being an amide of a  $\beta$ -ketonic acid, can yield

by hydrolysis. The position chosen for b-N thus gives an excellent explanation of the formation of dihydrostrychninonic acid (and of dihydrobrucinonic acid), which is a difficulty for other formulations. Further oxidation gives strychninonic acid,  $\text{N}\cdot\text{CO}\cdot\overset{\cdot}{\text{C}}\text{O}\cdot\text{CO}_2\text{H}\cdot\text{CH}_2\text{-O-}$ .

(5) Leuchs has recently examined many strychnine (brucine) derivatives in which nucleus (a) has been broken down; almost all of these substances absorb two oxygen atoms on oxidation with bromine and water, a third oxygen atom being taken up on treatment of the product with mercuric oxide. These changes are clearly represented by the scheme:

The double bond at 13, 14 is affected in every case. This gives

important support to the view that strychnine contains the group figured at 13, 14 and, indirectly, to our theory of the course of the permanganate oxidation.

(6) The hydrogen atom at  $C_{12}$  is requisite for the transference of the double bond in the strychninolone series from 11—10 to 11—12.

(7) Some considerations respecting the reduced strychnine derivatives will be discussed in a later communication.

For the above and other reasons, we consider that the structure (VIII) is almost certainly correct; it can with some show of probability be concluded that  $C_4$  bears a hydrogen atom and that  $C_{20}$  is attached to  $C_2$ ; analogy with quinine then allows us provisionally to adopt (IX) as a working hypothesis.

The attachment of a hydrogen atom to  $C_4$  seems to be required in order to explain the nature and formation of a base  $C_{17}H_{20}O_3N_2Br_2$  which H. Leuchs, Mildbrand, and R. Leuchs (*Ber.*, 1922, 55, 2703) obtained along with Hanssen's acid,  $C_{19}H_{22}O_6N_2$ , by treating cacotheline (nitrate of nitrobruciquinone hydrate) with bromine (Hanssen, *Ber.*, 1887, 20, 452; Ciusa and Scagliarini, *Roy. Accad. Lincei*, 1910, 19, 504). On treatment with baryta, the bromo-compound yields a base,  $C_{17}H_{22}O_5N_2$  (Leuchs, *Ber.*, 1929, 62, 1929), which can be oxidised by means of chromic acid, yielding Wieland's acid,  $C_{17}H_{22}O_6N_2$ , also obtainable by the direct oxidation of brucine (Wieland and Münster, *Annalen*, 1929, 469, 216) or mono-amino- or diamino-strychnine (Leuchs and Kröhnke, *Ber.*, 1929, 62, 2176) or strychnine (Cortese, *Annalen*, 1929, 476, 280) by means of chromic acid.

Wieland's acid appears to be a dibasic keto-acid in which the amide group is hydrolysed, and the following partial formulæ will serve best to illustrate the manner in which we envisage these complex relationships: Brucine (X) (compare Part III, J., 1925, 127, 1158), cacotheline (XI), Hanssen's acid (XII),  $C_{17}H_{20}O_3N_2Br_2$  (XIII),  $C_{17}H_{22}O_5N_2$  (XIV), Wieland's acid,  $C_{17}H_{22}O_6N_2$  (XV),  $C_{17}H_{20}O_7N_2$  by the action of bromine on XV (XVI) (Leuchs and Hoffmann, *Ber.*, 1929, 62, 2307),  $C_{17}H_{20}O_8N_2$  by the action of mercuric oxide on XVI (XVII) (Leuchs and Hoffmann, *Ber.*, 1930, 63, 440).

Even the substance (XIV), which is considered to contain an aldehyde group immobilised by internal condensation with an  $-NH\cdot CO-$  group, can be oxidised at the double bond in the usual way, yielding successively  $C_{17}H_{22}O_7N_2$  and  $C_{17}H_{22}O_8N_2$  (Leuchs, *Ber.*, 1929, 62, 1935).

The compound  $C_{17}H_{20}O_8N_2$  (XVII) can also be obtained from Hanssen's acid (XII), for example, by conversion by means of bromine into  $C_{19}H_{22}O_8N_2$ , then by mercuric oxide into  $C_{19}H_{22}O_9N_2$ .

and finally by permanganate into  $C_{17}H_{20}O_8N_2$  and oxalic acid; or  $C_{19}H_{22}O_8N_2$  can be directly oxidised by permanganate (Leuchs, *Ber.*, 1925, 58, 1730; Leuchs, Bender, and Wegener, *Ber.*, 1928, 61,

2353; Leuchs and Hoffmann, *Ber.*, 1929, 62, 1253; 1930, 63, 440). The interpretation of these changes along the lines already laid down offers no difficulties. Another important series of substances is

obtained by reducing Hanssen's acid (XII) to  $C_{19}H_{24}O_6N_2$  (XVIII) by means of sodium amalgam (Leuchs, *Ber.*, 1929, 62, 1929).

Permanganate changes the reduced Hanssen's acid to  $C_{19}H_{24}O_9N_2$  (XIX) (Leuchs and Kröhnke, *Ber.*, 1929, 62, 2599), and it is very interesting that an isomeride has been obtained from (XVIII) by using bromine and then either mercuric oxide or permanganate. The explanation seems to be that the amide ring opens and closes again in a new position; the intermediate is then  $C_{19}H_{26}O_9N_2$  (XX) and the isomeric  $C_{19}H_{24}O_9N_2$  would be (XXI) (Leuchs, Mildbrand, and Leuchs, *Ber.*, 1922, 55, 2412; Leuchs and Kröhnke, *Ber.*, 1929, 62, 2599).

Again, the Hanssen  $C_{16}$ -acid,  $C_{16}H_{20}O_4N_2$ , which Wieland and Münster (*loc. cit.*) obtained along with the Wieland acid by the oxidation of brucine with chromic acid also takes up two oxygen atoms on oxidation with bromine and a third on subsequent treatment with mercuric oxide (Leuchs and Hoffmann, *Ber.*, 1930, 63, 446).

On the basis of these formulæ, we are able to predict that the substances (XVII), (XIX), (XXI) and the acid  $C_{16}H_{20}O_7N_2$  from the Hanssen  $C_{16}$ -acid should contain a  $-CH_2 \cdot CO_2H$  fragment detachable in the form of glycollic acid or a derivative under the appropriate conditions.

The above formulæ require in some cases that the molecule should contain more carbonyl groups than have been experimentally recognised, but this is not unusual and in our experience strychnidone

(Clemons, Perkin, and Robinson, J., 1927, 1589) gave a disemicarbazone, but the analogous brucidone (Gulland, Perkin, and Robinson, *ibid.*, p. 1627) gave only a monosemicarbazone. Similar remarks apply to the number of carboxyl groups, but, broadly, the agreement between theory and experiment is remarkable.

Returning to a consideration of (VIII), the attachment of one of the carbons of the bridge ring to carbon at position 2 seems reasonable in view of the stability of Wieland's acid (XV) to chromic acid, and because there are reasons for attributing blocked hydroaromatic character to both ring B and ring D and (2) is the common position.

It is hoped that experimental evidence bearing on this aspect of the problem will shortly be submitted to the Society.

The provisional formula (IX) contains the whole of the cinchonine skeleton of carbon and nitrogen atoms and, of course, two carbon atoms more. This is probably going too far in the search for analogies, but there is evidently some underlying relation between the two alkaloids.

It must be clearly stated that the formulæ (XI—XXI) given above are based on relations established by Leuchs in a series of brilliant investigations. For example, he has described in words the precise connexion between Hanssen's acid and Wieland's acid which is illustrated in our formulæ. It has, however, never been previously suggested that the whole series can be correlated by means of definite constitutional formulæ, and, having developed expressions for the alkaloids, it was necessary for us to show that such correlation is feasible.

#### EXPERIMENTAL.

*Ethyl Dinitro-O-ethylstrycholcarboxylate* (I).—Dinitrostrycholcarboxylic acid was refluxed for 7 hours with a large excess of 5% alcoholic sulphuric acid, and the product collected after the addition of water. It was washed with aqueous sodium carbonate and then with water, and crystallised from alcohol in almost colourless, soft needles, m. p. 111—112° (Found: C, 48.0; H, 3.9; EtO, 25.5.  $C_{14}H_{13}O_8N_2$  requires C, 47.9; H, 3.7; 2EtO, 25.6%). The ester is insoluble in aqueous sodium carbonate; on heating with aqueous sodium sulphite, yellow, orange and blood-red solutions are successively obtained.

*O-Ethyl dinitrostrycholcarbohydrazide* (II).—Ethyl O-ethyl dinitrostrycholcarboxylate (1 g.) was dissolved in the minimum quantity of boiling alcohol, and 95% hydrazine hydrate (1.6 g.) added; a yellow solid separated within a few minutes from the deep red solution and, after heating on the steam-bath for 15 minutes, the product was collected and thoroughly washed with alcohol (yield,

1.0 g.). The *hydrazide* crystallised from alcohol in pale yellow, woolly needles, m. p. 218—219° (decomp.) (Found: C, 43.1; H, 3.4; N, 20.5.  $C_{12}H_{11}O_7N_5$  requires C, 42.7; H, 3.3; N, 20.8%).

This derivative is moderately readily soluble in alcohol; addition of water to its solution in acetic acid gives a precipitate of the free base. The hydrochloride is sparingly soluble in dilute hydrochloric acid, but dissolves on heating, and addition of acetone causes a rapid separation of the *isopropylidene* derivative in colourless needles. The hydrazide is insoluble in aqueous sodium carbonate.

*Dinitrostrychylurethane* (III).—*O*-Ethyldinitrostrycholcarbohydrazide (0.5 g.) was dissolved in acetic acid (60 c.c.), and powdered sodium nitrite (0.5 g.) added to the cooled solution; shortly afterwards, the whole was poured into water (250 c.c.) and the precipitated azide was collected and dried in a vacuum. This substance melted with decomposition at 110° and dissolved slowly in aqueous sodium carbonate, doubtless as the result of hydrolysis.

The azide was added to excess of alcohol, and the mixture boiled until evolution of nitrogen ceased. The product crystallised from acetic acid in clusters of yellow needles, m. p. 199—200° (yield, 2.1 g. of the pure substance from 4 g. of the hydrazide) (Found: C, 45.9; H, 3.9; N, 15.7.  $C_{14}H_{14}O_8N_4$  requires C, 45.8; H, 3.8; N, 15.3%). This *urethane* is sparingly soluble in most organic solvents and is insoluble in aqueous sodium carbonate. It is unaffected by bromine in boiling acetic acid solution. Dilute aqueous sodium hydroxide causes the crystals to become orange and, on heating, an orange solution is obtained from which hydrochloric acid precipitates an orange-brown substance.

*Degradation of dinitrostrychylurethane.* (A) Nitric acid (40 c.c., *d* 1.42) was heated to about 60° and the urethane (1 g.) added; the mixture was then gently heated until a vigorous reaction set in, accompanied by evolution of nitrous fumes. When this ceased, the solution was boiled and concentrated to a small bulk. The picric acid formed was isolated as its sodium salt, regenerated, and identified after crystallisation by its properties and by its m. p. and mixed m. p. 122°.

(B) The urethane (1 g.) was dissolved in concentrated sulphuric acid (25 c.c.), and the yellow solution heated over a free flame until a rapid evolution of gas occurred and slackened. The yellow colour disappeared simultaneously and a dull purplish-brown colour replaced it. Water was then added drop by drop to the hot solution until the liquid was diluted to 200 c.c. *N*/10-Potassium permanganate was rapidly added to the hot solution until an excess appeared, and then a further volume (100 c.c.) was added and the mixture heated until the oxidising agent was reduced. The solution

was filtered from an insoluble orange-brown substance, cooled, and thoroughly extracted with ether.

The extract was dried with sodium sulphate and the solvent removed, leaving a yellow residue which crystallised from pure benzene and then from acetic acid in bright yellow plates, m. p. 209—210°, and at the same temperature when mixed with 5:7-dinitroisatin prepared by the method described below. The characteristic properties of the dinitroisatin were all exhibited by this specimen.

By means of the sodium sulphite and indophenine colour reactions, the formation of dinitroisatin from dinitrostrychol derivatives by many different methods was indicated. For example, it is produced by the direct oxidation of dinitrostrychol, but the yield in this case is very unsatisfactory.

If the dilute sulphuric acid solution obtained by the hydrolysis of the urethane is neutralised with ammonia, an orange base is precipitated, and this can be redissolved in dilute hydrochloric acid to a yellow solution. Addition of nitrite slightly intensifies the colour, and the diazonium salt produced couples with  $\beta$ -naphthol to give a crimson azo-compound. It is very remarkable that this base can itself be coupled with diazo-salts to give quite intensely coloured substances, the nature of which is obscure. For example, *p*-nitrobenzenediazonium acetate yields a brick-red substance which behaves like an azo-compound. The anomaly arises from the circumstance that, according to our views, there is no free position in the nucleus containing the amino-group. Addition of a little nitrite to a weakly acid solution of the amine produces a violet precipitate which is due to the diazotisation of a part of the base and coupling with the remainder; this can be proved by separating the reactions. Oxidation of acid solutions of the amine from the urethane by ferric chloride and other mild reagents gives quantitatively a reddish-brown, sparingly soluble substance, apparently of indigoid or indirubinoid nature.

*5:7-Dinitroisatin* (IV).—A solution of isatin (5 g.) in sulphuric acid (50 c.c.) was cooled to 0°, and potassium nitrate (10 g., yield poor; 25 g., yield 56%; 50 g., yield almost quantitative) added in small portions so that the temperature did not rise above 15°. The mixture was then heated at 50—55°, until a sample diluted with water gave no precipitate (about 3 hours), cooled, and poured on ice. The solution was extracted five times with ether (200 c.c. on each occasion), the combined extracts were washed free of mineral acid by means of aqueous sodium bicarbonate and dried by means of magnesium sulphate, and the ether was distilled, leaving a yellow solid residue. This substance is sparingly soluble in benzene and

crystallises therefrom in yellow prisms, or from acetic acid in bright canary-yellow, microscopic plates, m. p. 209—210° (Found : C, 40.7; H, 1.4; N, 17.7.  $C_8H_3O_6N_3$  requires C, 40.5; H, 1.3; N, 17.7%). This isatin derivative exhibits a very strong indophenine reaction and, when treated with aqueous sodium sulphite, it develops a characteristic, stable, bluish-red coloration.

It dissolved in aqueous sodium carbonate to an orange solution, the colour of which quickly faded and a colourless crystalline sodium salt separated. On boiling with aqueous sodium hydroxide, ammonia was evolved and the solution doubtless then contained a dinitrohydroxyphenylglyoxylate. Dinitroisatin (0.5 g.) was boiled with nitric acid (25 c.c., *d* 1.42), and the liquid concentrated to a small bulk : picric acid, m. p. 122°, undepressed by admixture with an authentic specimen, was isolated from the product.

6 : 8-Dinitrohydrocarbostyryl,  $(NO_2)_2C_6H_2 \begin{smallmatrix} \text{CH}_2 \cdot \text{CH}_2 \\ \text{NH} - \text{CO} \end{smallmatrix}$ —A mixture of *o*-nitrobenzaldehyde (10 g.), malonic acid (15 g.), pyridine (100 c.c.), and piperidine (2 c.c.) was heated on the steam-bath for 30 minutes and then boiled for 30 minutes. On the addition of water and hydrochloric acid, pure *o*-nitrocinnamic acid was precipitated in almost theoretical yield.

The process of Friedländer and Weinberg (*Ber.*, 1882, 15, 1423) for the preparation of hydrocarbostyryl from ethyl *o*-nitrocinnamate works equally well with the acid, and hydrocarbostyryl is readily accessible in this way.

The nitration (of 1 mol.) was accomplished by adding sodium nitrate (5 mols.) to a solution in sulphuric acid, and completing the reaction by heating on the steam-bath. The substance crystallised from acetic acid in stout colourless needles, m. p. 175° (Found : C, 45.7; H, 3.1; N, 17.6. Calc. for  $C_9H_7O_5N_2$  : C, 45.6; H, 2.9; N, 17.7%).

The dinitrohydrocarbostyryl, m. p. 177°, obtained by van Dorp (*Rec. trav. chim.*, 1904, 23, 304) by the action of boiling dilute hydrochloric acid on a  $\beta$ -(dinitroaminophenyl)propionic acid is doubtless identical with our compound; van Dorp records that the m. p. was about 165°, raised to 177° by many recrystallisations.

Aqueous sodium carbonate does not dissolve this substance, but the solution in aqueous sodium hydroxide is yellow and, on boiling, ammonia is evolved; the orange-yellow solution must then contain dinitrohydroxyphenylpropionic acid.

Boiling with nitric acid did not change this very stable substance, and it was also unaffected by bromine in hot acetic acid solution. The demeanour of dinitrohydrocarbostyryl towards alkalis

suggests that the acidic hydroxyl of dinitrostrychol is that in the  $\beta$ -position.

*O-Methyldinitrostrychol*.—This monomethyl ether has been obtained by the variation of Tafel's procedure (*Annalen*, 1898, **301**, 345) described in Part IX (*loc. cit.*), and also in good yield by methylation with methyl sulphate and potassium hydroxide in methyl-alcoholic solution, but the most convenient method is by direct esterification with boiling 8% methyl-alcoholic sulphuric acid, the yield being quantitative. The derivative crystallised from the hot solution, and, after recrystallisation from xylene, had m. p. 195—196°.

Attempts to prepare a dimethyldinitrostrychol have been fruitless.

*Dinitrohydrazinodeoxystrychol* (VII).—Hydrazine hydrate (20 c.c. of 95%) was added to a suspension of *O*-methyldinitrostrychol (5 g.) in boiling methyl alcohol (250 c.c.). The methyl ether rapidly passed into the orange solution, but, before this process was completed, a new substance separated in voluminous yellow needles. The mixture was boiled for 10 minutes and filtered hot; the yellow crystalline residue (2.9 g.) had m. p. 202—204° (decomp.) (Found in material dried at 120° in a vacuum over phosphoric oxide: C, 41.1; H, 2.7; N, 21.3; MeO, 9.5%). This substance is a base exhibiting the reactions of a hydrazine, but the analyses, which have been confirmed, do not fit a simple formula.

The filtrate deposited a sandy, orange, crystalline powder (2.3 g.) which could be recrystallised by solution in warm acetic acid and addition of water; the pale yellow needles had m. p. 253° (decomp.) (Found in air-dried material from two different preparations: C, 38.5, 38.4; H, 3.1, 3.1; N, 25.0, 25.1; MeO, trace.  $C_9H_7O_5N_5 \cdot H_2O$  requires C, 38.2; H, 3.2; N, 24.7%). This *hydrazine* is very sparingly soluble in most organic solvents; when covered with acetic acid, it gives a colourless acetate which dissolves on heating. The hydrochloride crystallises in colourless needles, and the sulphate, which is very sparingly soluble in dilute sulphuric acid, crystallises in pearly leaflets. Solution in 2% hydrochloric acid occurred readily on gentle heating, and, on the addition of ferric chloride, a clear solution was obtained which soon clouded with evolution of nitrogen on boiling. The precipitate was collected, crystallised from acetic acid, and identified with dinitrostrychol by its properties and m. p. (284°), undepressed by admixture with a specimen prepared from dinitrostrycholcarboxylic acid. Similarly, dinitrostrychol was obtained by addition of *N*/10-potassium permanganate to a solution in 2% hydrochloric acid, although the amount of the reagent consumed was only about 30% in excess of the quantity required to supply one oxygen atom to one molecule of the base.

These experiments gave rise to the suspicion that the substance is the hydrazine salt of dinitrostrychol, although the behaviour towards acids was not in harmony with such a view and the preparation of anhydrous derivatives disproved it.

The *acetyl* derivative separated in flocculent colourless needles from a hot solution of the base in acetic acid, to which a few drops of acetic anhydride were added. The substance was very sparingly soluble and devoid of basic properties; it had m. p. 311–313° (decomp.) (Found in material dried at 100°: C, 42.9; H, 3.2; N, 22.7.  $C_{11}H_9O_6N_5$  requires C, 43.0; H, 2.9; N, 22.8%). The *isopropylidene* derivative,  $C_9NH_3(NO_2)_2(OH) \cdot NH \cdot N : CMe_2$ , crystallised from a boiling solution of the base in acetone or when acetone was added to a hot solution in dilute hydrochloric acid: recrystallised from much acetone, it formed slender, very pale yellow, microscopic needles, m. p. 279–281° (decomp.) (Found in material dried at 100°: C, 47.3; H, 3.5; N, 22.8.  $C_{12}H_{11}O_5N_5$  requires C, 47.2; H, 3.6; N, 23.0%). This very sparingly soluble derivative is insoluble in boiling dilute hydrochloric acid, but, when suspended in boiling acetone, it dissolves immediately on the addition of a drop of concentrated hydrochloric acid.

*Isolation of 3:5-Dinitrobenzoic Acid from the Products of the Oxidation of Strychnine by Means of Nitric Acid.*—Strychnine (100 g.) was dissolved in 20% nitric acid (4000 c.c.) and heated on the steam-bath for 120 hours, the volume being maintained by addition of 20% nitric acid as found necessary. The liquid was then concentrated to about 200 c.c., cooled, and kept for 36 hours. The solid was collected and washed with nitric acid; it then afforded, after boiling with nitric acid (75 c.c.,  $d$  1.42), about 10 g. of dinitrostrycholcarboxylic acid of m. p. 295–300°. The filtrate was added to water (1500 c.c.); a red gum was then deposited and a yellow solid remained in suspension. This was extracted with ether: the residue obtained from the washed and dried extract was an orange gum (about 10 g.), which was carefully heated on the steam-bath with nitric acid (90 c.c.,  $d$  1.42) and water (60 c.c.). The cooled solution deposited some picric acid, the filtrate from which was concentrated to half its volume; the glistening plates which then separated were recrystallised from alcohol. This product (3–4 g.) was analysed and, although the results showed it to be a mixture, a clue to its nature was obtained. A wasteful crystallisation from ethyl acetate gave the pure substance in colourless needles, m. p. 204°, alone or mixed with a specimen of 3:5-dinitrobenzoic acid.

Addition of aqueous sodium hydroxide to a solution of this acid

in acetone produces an intense pure blue coloration, which becomes reddish-violet on the addition of water.

The authors wish to thank Mr. F. Hall for assistance in connexion with the analyses.

### CXI.—*Intramolecular Rearrangement in the Isomeric Tetrachloro-derivatives of p-Tolylhydrazones.*

By FREDERICK DANIEL CHATTAWAY and ARTHUR B. ADAMSON.

THE chlorination of the *p*-tolylhydrazones of *m*- and *p*-nitrobenzaldehyde at the ordinary temperature yields a series of compounds closely resembling the corresponding bromo-compounds.

The least halogenated products that can be isolated contain two atoms of chlorine, one in the *p*-tolyl nucleus in an *o*-position with respect to the nitrogen atom and a second in the  $\omega$ -position. The same compounds are obtained by careful chlorination of the corresponding hydrazones of 3-chloro-*p*-tolylhydrazine.

Further chlorination at the ordinary temperature introduces a third atom of chlorine into the remaining *o*-position in the *p*-tolyl nucleus :

These compounds have the usual properties of  $\omega$ -halogenated compounds. On boiling with sodium acetate and acetic acid they are converted into the corresponding  $\beta$ -acetyl-hydrazides of *m*- or *p*-nitrobenzoic acid, and they are converted into the corresponding hydrazidines by the action of concentrated aqueous ammonia.

On brominating *m*- or *p*-nitrobenzaldehyde-*p*-tolylhydrazone, only three atoms of bromine can be introduced into the molecule even when a large excess of halogen is used and the temperature allowed to rise (this vol., p. 157). When, however, an acetic acid suspension of either of these hydrazones is saturated with chlorine and the temperature allowed to rise, the resulting compound contains four atoms of chlorine in the molecule :

These tetrachloro- compounds are not affected by acetic anhydride and indeed can be recovered unchanged after boiling for several hours with acetic anhydride and a drop of concentrated sulphuric acid. They do not react with hot alcoholic ammonia. They liberate iodine from a solution of potassium iodide in dilute acetic acid. When treated with phenylhydrazine, they do not yield formazyl derivatives but undergo reduction to  $\omega$ -chloro-*m*- or -*p*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone : mild reduction with tin and cold hydrochloric acid also yields the same compound.

The fourth atom of chlorine cannot therefore have entered either the *p*-tolyl or the nitrobenzaldehyde nucleus.

On heating with acetic acid slightly diluted with water, they undergo a curious, exothermic, intramolecular change, considerable heat being evolved, since the mixture maintains itself at the boiling point for several minutes without external heating.

The new compounds thus formed have the same composition and molecular weight as those from which they are produced, but are much less soluble in all solvents and have much higher melting points. They have also a lighter colour, being pale yellow whilst the parent substances are deep orange, and are very unreactive. They do not react with hot alcoholic ammonia or boiling acetic anhydride, nor do they yield  $\omega$ -chloro-*m*- or -*p*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone when treated with phenylhydrazine or on mild reduction. Vigorous reduction with tin and hydrochloric acid completely breaks down the molecule and yields in each case 3 : 5-dichloro-*p*-toluidine. Boiling with acetic acid and sodium acetate gives white viscid solids which cannot be crystallised but on hydrolysis yield *m*- or *p*-nitrobenzoic acid. As in the case of the parent substances, therefore, the fourth atom of chlorine in the transformation products cannot be substituted in either the *p*-tolyl or the nitrobenzaldehyde nucleus.

It seems therefore probable that the structure of these isomerides may be best represented as  $\omega$ -chloro-*m*- or -*p*-nitrobenzaldehyde-3 : 5 : N-trichloro-*p*-tolylhydrazone (I) and 3 : 5-dichloro-*p*-tolueneazo-*m*- or -*p*-nitrophenyldichloromethane (II) :

Certain facts, however, are difficult to reconcile with this supposition. For example, one would expect the compound containing the azo-linkage to have the deeper colour, whereas it is pale yellow. Also one would expect the CCl<sub>2</sub> group to be reactive and easily

hydrolysed, but it is remarkably stable and is not affected by boiling with concentrated hydrochloric acid or alcoholic ammonia.

The action of chlorine upon  $\omega$ -bromo-*m*-nitrobenzaldehyde-3 : 5-dibromo-*p*-tolylhydrazone yields a similar compound,

This also is converted into an isomeride of higher melting point by boiling with acetic acid slightly diluted with water :

Corresponding compounds are not produced under similar conditions by the action of chlorine upon *m*- and *p*-nitrobenzaldehyde-phenylhydrazone, the highest chlorination product being  $\omega$ -chloro-*m*- or -*p*-nitrobenzaldehyde-2 : 4 : 6-trichlorophenylhydrazone.

The chlorination of *o*-nitrobenzaldehyde-*p*-tolylhydrazone follows a normal course. The first product which can be isolated is  $\omega$ -chloro-*o*-nitrobenzaldehyde-3-chloro-*p*-tolylhydrazone. Saturation with chlorine at the ordinary temperature yields  $\omega$ -chloro-*o*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone.

These two  $\omega$ -chloro-compounds are rather more stable than the corresponding bromo-compounds and can be recrystallised unchanged from alcohol. They readily yield the corresponding *ketoendoaryliminodihydrobenzisodiazole oxides*, which are violently explosive, when a little concentrated aqueous ammonia is added to their solution in benzene. On mild reduction, these explosive compounds lose one atom of oxygen and are converted into the corresponding *ketoendoaryliminodihydrobenzisodiazoles* :

If the temperature is allowed to rise during the chlorination of *o*-nitrobenzaldehyde-*p*-tolylhydrazone, the hydrazone is rapidly decomposed and consequently a higher chlorination product such as is formed in the case of *m*- and *p*-nitrobenzaldehyde-*p*-tolylhydrazone cannot be obtained.

#### EXPERIMENTAL.

##### *The Chlorination of m-Nitrobenzaldehyde-p-tolylhydrazone.*

$\omega$ -Chloro-*m*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone.—Chlorine was slowly passed into a suspension of 5 g. of *m*-nitro-

benzaldehyde-*p*-tolylhydrazone in 50 c.c. of acetic acid. The hydrazone dissolved and almost immediately  $\omega$ -chloro-*m*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone began to separate as a bright yellow solid. When the mixture had become almost solid, chlorination was stopped and the solid collected. It crystallised from acetic acid, in which it was moderately easily soluble, in bright yellow, elongated plates, m. p. 137° (Found : Cl, 29.6.  $C_{14}H_{10}O_2N_3Cl_3$  requires Cl, 29.7%).

*m*-Nitrobenz- $\beta$ -acetyl-3 : 5-dichloro-*p*-tolylhydrazide,

—2 G. of  $\omega$ -chloro-*m*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone, 2 g. of anhydrous sodium acetate, and 40 c.c. of acetic acid were boiled under reflux for 2 hours. The resulting solution was poured into 100 c.c. of cold water. The hydrazide, which separated as a white solid, crystallised from alcohol, in which it was moderately easily soluble, in small prisms, m. p. 173° (Found : Cl, 18.5.  $C_{16}H_{13}O_4N_3Cl_2$  requires Cl, 18.6%).

A lower chlorination product of *m*-nitrobenzaldehyde-*p*-tolylhydrazone could not be isolated in a pure state.

$\omega$ -Chloro-*m*-nitrobenzaldehyde-3 : 5 : *N*-trichloro-*p*-tolylhydrazone (I).

—A suspension of 5 g. of *m*-nitrobenzaldehyde-*p*-tolylhydrazone in 50 c.c. of acetic acid was saturated with chlorine, the temperature being allowed to rise to about 60°. The bright yellow  $\omega$ -chloro-*m*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone first separated, but this slowly redissolved, forming an orange solution. From this, on standing for 12 hours at the ordinary temperature,  $\omega$ -chloro-*m*-nitrobenzaldehyde-3 : 5 : *N*-trichloro-*p*-tolylhydrazone slowly separated. After being washed with a very little acetic acid, this crystallised from alcohol, in which it was easily soluble, in orange four-sided prisms, m. p. 95° (Found : C, 43.1; H, 2.3; N, 10.7; Cl, 36.3; *M*, cryoscopic in benzene, 375.  $C_{14}H_9O_2N_3Cl_4$  requires C, 42.8; H, 2.3; N, 10.7; Cl, 36.1%; *M*, 393).

*Action of Phenylhydrazine on  $\omega$ -Chloro-*m*-nitrobenzaldehyde-3 : 5 : *N*-trichloro-*p*-tolylhydrazone.*—2 G. of phenylhydrazine were added to a solution of 2 g. of the hydrazone in 20 c.c. of acetic acid and warmed until a brisk reaction started. The solution became dark brown and on cooling,  $\omega$ -chloro-*m*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone separated, m. p. 137° after several crystallisations from acetic acid.

*Reduction of  $\omega$ -Chloro-*m*-nitrobenzaldehyde-3 : 5 : *N*-trichloro-*p*-tolylhydrazone.*—4 G. of the hydrazone were dissolved in 30 c.c. of acetic acid, 15 c.c. of hydrochloric acid and 3 g. of granulated tin were added, and the mixture was warmed gently for a few minutes.  $\omega$ -Chloro-*m*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone separ-

ated as an oil which quickly solidified; m. p. 137° after crystallisation from acetic acid.

*Intramolecular Rearrangement of  $\omega$ -Chloro-m-nitrobenzaldehyde-3 : 5 : N-trichloro-p-tolylhydrazone (I) into 3 : 5-Dichloro-p-tolueneazo-m-nitrophenyldichloromethane (II).*—5 G. of the hydrazone were dissolved in 100 c.c. of hot acetic acid, 5 c.c. of water added, and the solution raised to the boiling point. A brisk reaction took place, the mixture continued boiling for several minutes without external heating, and 3 : 5-dichloro-p-tolueneazo-m-nitrophenyldichloromethane separated as a pale yellow solid. The mixture was heated until there was no further separation of solid. After cooling, the product was collected and washed with alcohol, in which it was practically insoluble; it crystallised from acetic acid, in which it was moderately easily soluble, in pale yellow needles, m. p. 165° (Found : C, 43.0; H, 2.4; N, 10.6; Cl, 35.9; *M*, ebullioscopic in benzene, 388.  $C_{14}H_9O_2N_3Cl_4$  requires C, 42.8; H, 2.3; N, 10.7; Cl, 36.1%; *M*, 393).

*Reduction of 3 : 5-Dichloro-p-tolueneazo-m-nitrophenyldichloromethane.*—To 5 g. of the dichloromethane, suspended in a mixture of 50 c.c. of acetic acid and 50 c.c. of hydrochloric acid, 5 g. of granulated tin were added and the mixture was heated until a clear, almost colourless solution was formed. This was cooled, made alkaline with caustic soda, and steam-distilled. 3 : 5-Dichloro-p-toluidine separated in the distillate as a white solid and was identified by means of its acetyl derivative, which crystallised from alcohol in colourless prisms, m. p. 207°, identical with a specimen prepared by the chlorination of aceto-p-toluidide.

*Reaction of 3 : 5-Dichloro-p-tolueneazo-m-nitrophenyldichloromethane with Sodium Acetate and Acetic Acid.*—A mixture of 3 g. of the dichloromethane, 3 g. of anhydrous sodium acetate, and 60 c.c. of acetic acid was boiled under reflux for 2 hours. The clear solution obtained was cooled and poured into 200 c.c. of cold water; a colourless semi-solid mass then separated which could not be made to crystallise. It was therefore boiled under reflux with a mixture of 25 c.c. of alcohol and 25 c.c. of hydrochloric acid for 2 hours; the solution obtained was cooled and made alkaline, and the alcohol distilled off. After filtration from tarry matter, the colourless liquid was acidified with hydrochloric acid; ether then extracted *m*-nitrobenzoic acid, m. p. 140° after crystallisation from water.

#### *The Chlorination of p-Nitrobenzaldehyde-p-tolylhydrazone.*

*$\omega$ -Chloro-p-nitrobenzaldehyde-3-chloro-p-tolylhydrazone.*—A very slow stream of chlorine was passed into a solution of 2 g. of *p*-nitrobenzaldehyde-p-tolylhydrazone in 150 c.c. of acetic acid, cooled in

running water. In a few minutes  $\omega$ -chloro-*p*-nitrobenzaldehyde-3-chloro-*p*-tolylhydrazone separated as an orange flocculent solid. Chlorination was then stopped. The product, after being washed with water, crystallised from acetic acid, in which it was moderately easily soluble, as a felted mass of slender, bright orange prisms, m. p. 163° (Found: Cl, 21.9.  $C_{14}H_{11}O_2N_3Cl_2$  requires Cl, 21.9%).

3-Chloro-*p*-tolyl-*p*-nitrobenzenylhydrazidine,

which separated when a suspension of 2 g. of  $\omega$ -chloro-*p*-nitrobenzaldehyde-3-chloro-*p*-tolylhydrazone in 20 c.c. of alcohol was heated with 2 c.c. of concentrated aqueous ammonia, until a clear dark purple solution was formed, and then cooled, crystallised from alcohol, in which it was moderately easily soluble, in deep purple prisms, m. p. 162° (Found: Cl, 11.8.  $C_{14}H_{13}O_2N_4Cl$  requires Cl, 11.7%).

*p*-Nitrobenz- $\beta$ -acetyl-3-chloro-*p*-tolylhydrazide,

separated as a white solid when the solution obtained by boiling 2 g. of  $\omega$ -chloro-*p*-nitrobenzaldehyde-3-chloro-*p*-tolylhydrazone, 2 g. of anhydrous sodium acetate, and 40 c.c. of acetic acid under reflux for 2 hours was poured into 100 c.c. of cold water. It crystallised from alcohol, in which it was moderately easily soluble, in small colourless prisms, m. p. 164° (Found: Cl, 10.2.  $C_{16}H_{14}O_4N_3Cl$  requires Cl, 10.2%).

$\omega$ -Chloro-*p*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone.—This was obtained, in the same way as the *m*-nitro-compound, from 4 g. of *p*-nitrobenzaldehyde-*p*-tolylhydrazone in 100 c.c. of acetic acid; the intermediately formed 3-chloro-*p*-tolylhydrazone separated but quickly redissolved. The 3 : 5-dichloro-*p*-tolylhydrazone crystallised from acetic acid, in which it was moderately easily soluble, in slender, bright yellow prisms, m. p. 139° (Found: Cl, 29.6.  $C_{14}H_{10}O_2N_3Cl_3$  requires Cl, 29.7%).

3 : 5-Dichloro-*p*-tolyl-*p*-nitrobenzenylhydrazidine crystallises from alcohol in orange-yellow plates, m. p. 159° (Found: Cl, 21.2.  $C_{14}H_{12}O_2N_4Cl_2$  requires Cl, 21.2%).

*p*-Nitrobenz- $\beta$ -acetyl-3 : 5-dichloro-*p*-tolylhydrazide crystallises from alcohol in small colourless prisms, m. p. 183° (Found: Cl, 18.8.  $C_{16}H_{13}O_4N_3Cl_2$  requires Cl, 18.6%).

$\omega$ -Chloro-*p*-nitrobenzaldehyde-3 : 5 : N-trichloro-*p*-tolylhydrazone, obtained, in the same way as the *m*-nitro-compound, from 10 g. of *p*-nitrobenzaldehyde-*p*-tolylhydrazone in 70 c.c. of acetic acid, crystallised from acetic acid, in which it was easily soluble, in irregular orange plates, m. p. 97° (Found: C, 42.3; H, 2.6; N, 10.9; Cl, 35.9; *M*, cryoscopic in benzene, 383.  $C_{14}H_9O_2N_3Cl_4$  requires C, 42.8; H, 2.3; N, 10.7; Cl, 36.1%; *M*, 393).

This compound was treated in the manner described under  $\omega$ -chloro-*m*-nitrobenzaldehyde-3 : 5 : N-trichloro-*p*-tolylhydrazone and its behaviour was exactly similar. It gave  $\omega$ -chloro-*p*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone, m. p. 139°, on treatment with phenylhydrazine or on reduction with tin and hydrochloric acid and was converted by boiling dilute acetic acid into 3 : 5-dichloro-*p*-tolueneazo-*p*-nitrophenyldichloromethane, which crystallised from acetic acid, in which it was moderately easily soluble, in bright yellow, elongated plates, m. p. 188° (Found : C, 43.1; H, 2.4; N, 10.9; Cl, 35.8; *M*, ebullioscopic in benzene, 410.  $C_{14}H_9O_2N_3Cl_4$  requires C, 42.8; H, 2.3; N, 10.7; Cl, 36.1%; *M*, 393).

The azo-compound gave 3 : 5-dichloro-*p*-toluidine (acetyl-derivative, m. p. 207°) on reduction with tin and hydrochloric acid and was converted by boiling acetic acid and anhydrous sodium acetate into a white viscid solid, which gave *p*-nitrobenzoic acid, m. p. 238°, on hydrolysis.

*The Chlorination of  $\omega$ -Bromo-*m*-nitrobenzaldehyde-3 : 5-dibromo-*p*-tolylhydrazone.*

$\omega$ -Bromo-*m*-nitrobenzaldehyde-N-chloro-3 : 5-dibromo-*p*-tolylhydrazone.—A rapid stream of chlorine was passed into a suspension of 5 g. of  $\omega$ -bromo-*m*-nitrobenzaldehyde-3 : 5-dibromo-*p*-tolylhydrazone in 50 c.c. of hot acetic acid. From the orange solution produced, on cooling,  $\omega$ -bromo-*m*-nitrobenzaldehyde-N-chloro-3 : 5-dibromo-*p*-tolylhydrazone slowly separated. This crystallised from alcohol, in which it was easily soluble, in deep orange prisms, m. p. 77° (Found : C, 32.0; H, 1.7; N, 8.1; Cl + Br, 52.8.  $C_{14}H_9O_2N_3ClBr_3$  requires C, 31.9; H, 1.7; N, 8.0; Cl + Br, 52.3%).

By the method used in the two previous rearrangements, the chlorodibromotolylhydrazone was converted into 3 : 5-dibromo-*p*-tolueneazo-*m*-nitrophenylchlorobromomethane, which crystallised from acetic acid, in which it was moderately easily soluble, in pale yellow needles, m. p. 157° (Found : C, 32.1; H, 1.8; N, 7.9; Cl + Br, 52.3.  $C_{14}H_9O_2N_3ClBr_3$  requires C, 31.9; H, 1.7; N, 8.0; Cl + Br, 52.3%).

*The Chlorination of o-Nitrobenzaldehyde-p-tolylhydrazone.*

$\omega$ -Chloro-*o*-nitrobenzaldehyde-3-chloro-*p*-tolylhydrazone.—A slow stream of chlorine was passed into a suspension of 5 g. of *o*-nitrobenzaldehyde-*p*-tolylhydrazone in 25 c.c. of acetic acid until the hydrazone just dissolved, forming a dark brown solution. From this,  $\omega$ -chloro-*o*-nitrobenzaldehyde-3-chloro-*p*-tolylhydrazone slowly separated. It crystallised from alcohol, in which it was easily

soluble, in orange rhombic plates, m. p.  $103^{\circ}$  (Found: Cl, 21.7.  $C_{14}H_{11}O_2N_3Cl_2$  requires Cl, 21.9%).

*3-Keto-1 : 2-endo-3'-chloro-p-tolylimino-2 : 3-dihydro-1 : 2-benzisodiazole 1-Oxide*.—This separated as a bright yellow solid when a solution of  $\omega$ -chloro-*o*-nitrobenzaldehyde-3-chloro-*p*-tolylhydrazone (3 g.) in benzene was warmed with 3 c.c. of concentrated aqueous ammonia. It crystallised from alcohol, in which it was moderately easily soluble, in bright yellow, rhombic plates, explosion point  $134^{\circ}$  (Found: Cl, 12.1.  $C_{14}H_{10}O_2N_3Cl$  requires Cl, 12.3%).

*3-Keto-1 : 2-endo-3'-chloro-p-tolylimino-2 : 3-dihydro-1 : 2-benzisodiazole*.—A solution of stannous chloride (2 g.) in hydrochloric acid was added to a solution of the explosive compound (2 g.) in 5 c.c. of acetic acid and 5 c.c. of hydrochloric acid. On dilution with water, the product separated as a pale yellow solid. It crystallised from alcohol, in which it was easily soluble, in colourless needles, m. p.  $173^{\circ}$  (Found: Cl, 13.2.  $C_{14}H_{10}ON_3Cl$  requires Cl, 13.1%).

*$\omega$ -Chloro-*o*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone*.—A suspension of 5 g. of *o*-nitrobenzaldehyde-*p*-tolylhydrazone in 25 c.c. of acetic acid, cooled to the ordinary temperature in running water, was saturated with chlorine. The hydrazone dissolved and a deep yellow solution was finally obtained, from which  *$\omega$ -chloro-*o*-nitrobenzaldehyde-3 : 5-dichloro-*p*-tolylhydrazone* slowly separated. It crystallised from alcohol, in which it was easily soluble, in pale yellow, six-sided plates, m. p.  $87^{\circ}$  (Found: Cl, 29.8.  $C_{14}H_{10}O_2N_3Cl_3$  requires Cl, 29.7%).

*3-Keto-1 : 2-endo-3' : 5'-dichloro-*p*-tolylimino-2 : 3-dihydro-1 : 2-benzisodiazole 1-oxide*, obtained in a similar way to the preceding oxide, crystallised from alcohol, in which it was moderately easily soluble, in bright yellow, six-sided plates, explosion point  $155^{\circ}$  (Found: Cl, 21.9.  $C_{14}H_9O_2N_3Cl_2$  requires Cl, 22.0%). On reduction with stannous chloride it gave *3-keto-1 : 2-endo-3' : 5'-dichloro-*p*-tolylimino-2 : 3-dihydro-1 : 2-benzisodiazole*, which crystallised from alcohol, in which it was easily soluble, in colourless six-sided prisms, m. p.  $202^{\circ}$  (Found: Cl, 22.9.  $C_{14}H_9ON_3Cl_2$  requires Cl, 23.2%).

THE QUEEN'S COLLEGE LABORATORY,  
OXFORD.

[Received, January 29th, 1930.]

# ANNUAL GENERAL MEETING,

THURSDAY, MARCH 27TH, 1929, AT 4 P.M.

THE President, Professor J. F. THORPE, C.B.E., D.Sc., F.R.S., was in the Chair.

The Report of the Council for 1929—1930, together with the Balance Sheets and Statements of Accounts for 1929, was presented by the PRESIDENT, and the TREASURER made a statement regarding the finances of the Society. The adoption of the Report and Accounts, proposed by Dr. J. A. VOELCKER and seconded by Professor J. KENNER, was carried unanimously.

## REPORT OF COUNCIL, 1929—1930.

### *I. Fellowship Statistics.*

THE number of Fellows at the 31st December, 1928, was 3980. During 1929, 210 Fellows were elected and 8 reinstated, as against 203 and 11 in 1928, giving a gross total of 4198. Deaths of 49 Fellows were recorded, 107 resigned, and the names of 117 were removed from the List of Fellows for non-payment of Annual Subscriptions, the corresponding figures for last year being 40, 135, and 99, respectively. The total number of Fellows at the 31st December, 1929, was 3925, showing a decrease of 55, as against 60 the previous year.

The Council records with sorrow the death on the 17th September of a distinguished Fellow of the Society, Professor W. H. Perkin, who served as President from 1913 to 1915 and on the Council for a total of twenty years. At its meeting on the 17th October, the Council passed a special resolution of sympathy, which was read at the Ordinary Scientific Meeting and conveyed to Mrs. Perkin by the President, who, together with the Secretaries and other Members of Council, represented the Society at the funeral. A comprehensive account of the life and work of Professor Perkin is being prepared by Mr. A. J. Greenaway, Professor R. Robinson, and Professor J. F. Thorpe, and will be published in the Journal.

The Society has also to mourn the loss of two of its Honorary Fellows, Professor Charles Moureu, elected on the 1st March, 1923, who was the first President of the Union Internationale de Chimie and a former President of the Société Chimique de France, and Dr. T. B. Osborne, who was elected on the 7th March, 1912. An obituary notice of Dr. Osborne appeared in the Journal for 1929, p. 2974, and Sir William J. Pope is preparing an obituary notice of Professor Moureu.

During 1929, 11 Honorary Fellows were elected, the total number at the end of the year being 31.

## II. *Jubilee Fellows.*

The congratulations of the Society have been sent to the following Fellows who have attained their Jubilee as Fellows :

	Elected.
William Thomas Gent .....	April 17th, 1879.
William Stone .....	April 17th, 1879.
Alfred Walter Stokes .....	April 17th, 1879.
Charles Slater .....	April 17th, 1879.
Frank Litherland Teed .....	April 17th, 1879.
Victor Herbert Veley .....	April 17th, 1879.
George Richard Tweedie .....	June 19th, 1879.
Joji Sakurai .....	June 19th, 1879.
George Stacey Albright .....	December 18th, 1879.
Wyndham Rowland Dunstan .....	December 18th, 1879.
Joshua Knowles .....	December 18th, 1879.
Henry Forster Morley .....	December 18th, 1879.
Alexander Scott .....	December 18th, 1879.
George Stallard .....	December 18th, 1879.
William Macnab .....	February 19th, 1880.
Alexander Kenneth Miller .....	February 19th, 1880.

## III. *Journal.*

The Journal for 1929 contains 2981 pages, of which 2899 pages are occupied by 400 memoirs and 31 notes, the remaining 82 pages being devoted to Obituary Notices (13 pages), two Lectures (29 pages), the Report of the Annual General Meeting (17 pages), the Presidential Address (19 pages), and Table of Atomic Weights (4 pages). The volume for 1928 contains 438 memoirs and 28 notes, occupying 3216 pages.

During 1929, 466 papers were offered to the Society for publication in the Journal; of these, 21 were declined. The corresponding numbers for 1928 are 501 and 15. The average interval between the dates of receipt and of publication of papers is 9.8 weeks for 1929, and 10.75 weeks for 1928.

The Council records its sincere appreciation of the arduous and responsible work undertaken by Fellows in refereeing papers submitted for publication.

## IV. *Abstracts.*

The "A" Abstracts for 1929 contained 10,463 abstracts, occupying 1500 pages, compared with the corresponding figures for 1928 of 9456 and 1408 respectively. These comprised 5346 in General, Physical, and Inorganic Chemistry, 189 in Geochemistry, 2326 in Organic Chemistry, and 2602 in Biochemistry. The corresponding figures for 1928 were 4718, 224, 2236, and 2268.

The expansion of published chemical work, reflected in the 10 per cent. increase in the number of abstracts for 1929 as compared

with 1928, still continues. From the figures quoted in the foregoing paragraph, it will be seen that the increase has been specially marked in the sections of General, Physical, and Inorganic Chemistry and Biochemistry. The total of 10,463 "A" abstracts for 1929 may be compared also with corresponding figures for earlier years, such as 5978 (in 1913), 5572 (in 1923), and 7978 (in 1926). The number of "B" abstracts in 1929 was 9717, so that the total number of abstracts published by the Bureau in one year has now exceeded the 20,000 figure.

*Annual Index.* The Joint Annual Index for the 1928 abstracts covered 576 pages, as compared with 514 pages in the previous year. The cost of printing was £1187 16s. 10d., and the cost of paper £261 17s. 5d., representing an increase in both respects, although the cost of printing *per page* was £2 1s. 3d. in 1928, as compared with £2 4s. 2d. in 1927.

*Collective Index.* During the past year the Bureau devoted much consideration to the question of a Collective Index for the period 1923-32, and the relevant facts and figures were submitted to the two Councils concerned. With the sanction and substantial financial support of both bodies, and with the further aid of a grant promised by the Royal Society, the Bureau expects to proceed with the preparation of the Index, as soon as it appears that adequate support from subscribers is forthcoming.

#### V. Library.

Excluding the evenings on which meetings of the Chemical Society were held, there were 7567 attendances during the past year as compared with 8037 in 1928. Of the 7567, 4962 were made by Fellows of the Chemical Society, while 2605 were made by Members of Contributing Societies, as against 2669 in 1928.

The number of books borrowed during 1929 was 5402, as against 5262 the previous year; of these 1466 were issued by post, as against 1337 in the preceding year.

The additions to the Library comprise: 231 books, of which 71 were presented, 690 volumes of periodicals and 150 pamphlets; as against 281 books, 664 volumes of periodicals and 138 pamphlets last year. The total number of volumes added during the year was 921, showing a decrease of 24. The Library now contains 33,753 volumes, consisting of 10,159 books and 23,594 bound volumes of periodicals.

#### VI. General.

*Lectures.* The first Pedler Lecture, entitled "The Early History of the Synthesis of Closed Carbon Chains," was delivered by Professor

W. H. Perkin on the 30th May, and has been published in the Journal for 1929 (p. 1347). The second Liversidge Lecture, given by Professor H. Freundlich on the 12th December and entitled "Surface Forces and Chemical Equilibria," has also been published in the Journal (1930, p. 164).

On the 25th April Sir Harold Hartley delivered a Memorial Lecture on the Life and Work of the late Theodore W. Richards, which will be published during 1930.

The Council has conveyed its thanks to these lecturers.

Professor G. von Hevesy and Professor Niels Bohr have accepted the invitation of Council to be the Hugo Müller and Faraday Lecturers respectively in 1930.

*Anniversary Meeting.* The Annual General Meeting was held at the University of Leeds on the 21st March, and the Anniversary Dinner, at which the chief guests were the Viscount Lascelles, K.G. (the present Earl of Harewood), the Vice-Chancellor of the University, and the Lord Mayor of Leeds, was held the same evening in the Town Hall. The large attendance at these functions has confirmed the Council in its view that there is a general desire on the part of the Fellows that Annual Meetings should be held in the Provinces at frequent intervals. An account of the Annual General Meeting appears in the Journal, p. 817, and a report of the Dinner in the Proceedings (p. 37).

*Representatives at Celebrations and on Committees.* The President, accompanied by the Senior Secretary, represented the Society at the Paul Schutzenberger Centenary Celebrations in Paris on the 7th November, 1929, and presented an address of congratulation. The President also represented the Society at the opening of the Imperial Chemical Industries' Agricultural Station at Maidenhead.

Principal R. H. Raikes represented the Society at the Centenary Celebrations of the South African College at Cape Town, and presented the Society's congratulatory Address. The Prince Ginori Conti was the Society's delegate at the III<sup>ème</sup> Congrès National de Chimie Pure et Appliquée at Florence, and the Society was represented by Mr. R. Truszkowski at the II<sup>ème</sup> Congrès des Chimistes Polonais at Poznan, by Dr. L. H. Lampitt at the IX<sup>ème</sup> Congrès de Chimie Industrielle at Barcelona, and by Dr. K. Fisher at the Conference on Educational Films in London.

Professor C. S. Gibson, Mr. A. J. Greenaway, Dr. J. T. Hewitt, Professor G. T. Morgan, and the Treasurer have continued to be the Society's members of the Bureau of Chemical Abstracts, and the Society's representatives on the Federal Council for Chemistry are Professor C. S. Gibson, Sir William J. Pope, and Professor J. F.

Thorpe. Professor R. Whytlaw Gray has been appointed by the Council to represent the Society on the recently formed Colloid Committee of the Faraday Society, and Professor W. A. Bone represented the Society on the Committee appointed by the Association of British Chemical Manufacturers to consider amendments in the Patents and Designs Acts (see p. 856).

*Liebig Portrait.* The copy of the "Muspratt" portrait of Liebig, which, as stated in the last Report of Council, had been painted by Mr. G. A. Pownall, was presented on behalf of the Society to the German Chemical Society on the 8th May by the President, when he and the Senior Secretary attended a special meeting in Berlin.

*Longstaff Medal.* The Longstaff Medal for 1930 has been awarded to Dr. W. H. Mills for his distinguished researches in organic chemistry especially in relation to stereochemistry. The presentation will be made at the Annual General Meeting on the 27th March.

*Fellowship Statistics.* The statistics given at the beginning of this report show that the diminution in the number of Fellows referred to in the last report still persists, and the matter is being carefully considered by the Council, which has appointed a Committee to enquire into the matter. This Committee has presented an *interim* report which, in particular, draws attention to the fact that a falling-off in membership concerns also the Society of Chemical Industry, and that close co-operation between the two societies may be desirable in any steps which may be taken to remedy this state of affairs. The matter is still under consideration and an announcement will be made in due course.

The action of the Council in approaching Chemical Societies abroad with a view to the mutual publication of terms of membership has met with a cordial response, and particulars received by the Society from the Deutsche Chemische Gesellschaft, the Norsk Kjemisk Selskap, the Real Sociedad Española de Física y Química, and the Suomalaisten Kemistien Seura were included at the end of the Journal for January, 1930.

*A Central Building in London for Scientific and Technical Institutions.* There would appear to be little need to remind Fellows of the urgent necessity for larger and more convenient accommodation for the Society, which has occupied its present apartments since 1874, when the number of Fellows was 733. In May, the President informed the Council that he had been approached with respect to

the possibility of the Chemical Society co-operating in a scheme for providing in London a Central Building for housing certain scientific and technical institutions. A Committee was appointed to enquire into and report upon the scheme, and in June the Council, on the recommendation of this Committee, agreed to the principle involved. The President (or in his absence, the Senior Secretary) was appointed to serve on the General Exploring Committee, and the President, Professor C. S. Gibson, and Dr. F. L. Pyman were elected to serve on a Joint Chemical Committee composed of representatives appointed by the Chemical Society, the Society of Chemical Industry, the Institution of Chemical Engineers, and the Institution of the Rubber Industry. This Joint Committee has met on several occasions, and the Council hopes shortly to be in a position to make an important announcement indicating the progress that has been made.

*Presidency.* In view of the important part which the President of the Society must take in the furtherance of the scheme, and in order that continuity of effort may be maintained, the Council has nominated the retiring President for another term of office. Professor Thorpe has accepted nomination on the understanding that he is at liberty to place his resignation in the hands of the Council at the end of the first year of the new period of office.

*Patents and Designs Acts.* In the Proceedings for June, the Council directed the attention of Fellows to the arrangements made by the Federal Council for Chemistry in connection with the preparation of a joint memorandum representing the considered views of chemists as to whether any, and if so what, amendments in the Patents and Designs Acts, or changes in the practice of the Patent Office, were desirable. Fellows were invited to send suggestions for consideration by the Committee of the Association of British Chemical Manufacturers, which was also acting as the Committee of the Federal Council for Chemistry. The Council is informed that the memorandum has now been presented to the Board of Trade.

*Nomenclature.* The Council has received from the Bureau of the Union Internationale de Chimie a request to publish in the Journal the proposed reforms in the Nomenclature of Organic and Inorganic Chemistry adopted by the Council of the Union Internationale. The matter was referred to the Federal Council for Chemistry and, at its suggestion, the Secretaries wrote informing the Bureau of the Union that the Federal Council, representing the opinion of British chemists, considered that publication of these reports should be postponed until they had been further considered by Committees on which the opinion of all adherents to the Union was represented.

*Atomic Constants.* The Council has directed the attention of the Federal Council for Chemistry to the desirability of the regular publication of International Tables of Atomic Constants.

The *List of Fellows*, published this year by the direction of the Council, was issued in October. This list, in addition to the usual information, indicates the various Constituent Organisations of the Federal Council for Chemistry of which Fellows are members.

*Journal of Physical Chemistry.* The Council was informed in October that the Chemical Foundation had agreed to be responsible for the business arrangements of the *Journal of Physical Chemistry*. Professor A. J. Allmand and Professor F. G. Donnan have been appointed by the Council to represent the Society on the British Editorial Board for a further period of two years.

*Annual Reports.* The volume of Annual Reports for 1929 includes, in addition to the usual subjects, a report on Crystallography and a biennial report on Mineralogical Chemistry.

The Council desires to thank those who have contributed to this volume.

*Research Fund.* Applications for research grants received during the year amounted to £901 and the sum allotted was £736 (Proceedings, pp. 74 and 123).

*Bequest and Gifts.* The Council has received intimation that under the will of the late Professor W. H. Perkin the sum of £1000 subject to a life interest has been bequeathed to the Publications Fund of the Society. It has also gratefully accepted an offer to present to the Society a life-size bronze plaque of Professor Perkin from his colleagues and students. The offer was made through Professor J. F. Thorpe, Chairman of the Perkin Memorial Fund Committee.

The Proceedings for January 1930 (pp. 1 and 2) contain an account of the presentation to the Society of a Silver Mace by Mr. Ayerst Henham Hooker to commemorate his attaining his Jubilee as a Fellow. Professor Joji Sakurai, who has also recently celebrated his jubilee as a Fellow, has sent a contribution of £10 to mark the occasion (Proceedings 1929, p. 69). The Council records its particular appreciation of the generosity of these two jubilee Fellows, and has also expressed its thanks to Mr. Basil Holmes for a framed photograph (dated 1878) of a group of Fellows of the Royal Society, and to Mr. E. W. J. Neave for a set of Journals from 1921 to 1927.

The Annual Chemical Dinner, in which the Chemical Society co-operated, was held in the Connaught Rooms on the 8th November, the principal guest of the evening being the Rt. Hon. Lord Dewar.

The Chemical Club has met eleven times during the year, and now dines on the days of the meetings of Council and of special lectures at the New Lauriers Restaurant, 102, Jermyn Street, S.W. 1.

### VII. *Financial.*

*General Purposes Account.* The income of the Society for 1929 is less than that for 1928 by £94 3s. 7d. and the expenditure greater by £133 12s. 10d.

The chief reason for the decreased income is the loss of £306 17s. in the amount received as Annual Subscriptions. There is an increase of £64 13s. 7d. in income tax recovered, and of £158 11s. 9d. on deposit interest, the latter being due to the Society placing on deposit the money received on account of the sales of publications. Administration Expenses have increased by £12 19s. 9d. The sum paid as salaries is £93 18s. 4d. in excess of that for last year; in this is included a bonus of £55 granted to the staff in consideration of the extra work involved in the Society acting as its own publisher. It has also been necessary to engage an extra junior clerk. Furniture, House Expenses, and Repairs are less than last year by £59 2s. 1d., Miscellaneous Expenses by £39 3s. 2d., and the sum transferred to the Publications Fund Account by £723 7s. 2d. Increased expenditure was incurred of £58 3s. 2d. in Miscellaneous Printing and Stationery and of £40 10s. 5d. in Expenses of Meetings. The sum of £350 transferred to Pensions Fund Account is £200 in excess of that for last year. The contribution to the Library is £118 15s. 1d. higher than in 1928. £500 has been transferred to the Special Publication Fund Account to form a Sinking Fund which shall meet in part the cost of the preparation and publication by the Bureau of Chemical Abstracts of the Collective Index 1923-1932. The Council has further resolved that the sum of £250 shall be transferred to this fund in January of each year from 1930 to 1933 inclusive and that the Special Publications Fund shall finance the project up to an amount not exceeding £2000.

*Publications Fund Account.* Omitting from the income account the sums of £243 19s. 5d. in 1929 and £220 3s. 11d. in 1928, which have been capitalised, and the sums transferred from General Purposes Account, the income for 1929 exceeds that for 1928 by £588 6s. 6d. This is mainly due to an increase of £540 5s. 10d. in the sales of publications, which is approximately the sum paid last year as commission to the former Publishers and represents a considerable saving to the Society.

*Journal.* The total expenditure on the Journal shows a decrease of £360 1s. 3d. compared with last year. The cost of printing and

paper is down by £389 8s. 7d. owing to the number of pages being 235 less; distribution and banding are less by £52 8s. 6d. Editorial salaries have increased by £113.

*Abstracts.* Expenditure on account of the Abstracts this year shows an advance of £84 0s. 1d. over that for 1928. Printing is higher by £97 4s. 10d. owing to there being 92 more pages, and to the cost of the index being increased by £78 5s. 1d. The saving of £102 4s. 1d. in the cost of paper is due to an excess of stock having been purchased in 1928.

*List of Fellows.* The List of Fellows cost £143 14s. 9d. as against £129 8s. 2d. when it was issued in 1927.

*Library.* The contribution from the General Funds of the Society exceeds that for 1928 by £118 15s. 1d. The sum spent on books and periodicals and on binding is greater by £93 8s. 3d. and salaries are higher by £32 12s. 6d. It will be seen that approximately a quarter of the total sum expended on the Library is met by the Contributing Societies.

*Staff Pensions Fund Account.* If the sum of £9 11s. 3d. under Miscellaneous Receipts be disregarded it will be seen that the expenditure exceeds the income from investments by £92 14s. 10d. The Council decided that the sum of £350 should be transferred from General Purposes Account to meet this deficit and that the balance should be invested. The capital of the fund now stands at £907 14s. The Council desires to emphasise the need for further donations in order that the income from the Fund may be such as will enable it to meet the present charges and the further demands that in course of time will be made upon it.

*General.* A contribution of £50 has been made to the Federal Council for Chemistry for the year 1929, and a donation of £5 has been sent to the New International Association for Testing Materials.

The thanks of the Council have been conveyed to the Royal Society for the sum of £250 received from the Government Publications Grant towards the cost of the Society's publications for 1929, and to Imperial Chemical Industries, Ltd., for a contribution of £100 to the Publications Fund.

The sum of £200 on the Publications Fund Account has been invested in London Midland and Scottish Railway 4 per cent. Guaranteed Stock, and the 5 per cent. War Loan Stock 1929-1947 amounting to £11,149 11s. 10d. has been converted into 5 per cent. Conversion Loan, 1944-1964.

A vote of thanks to the Auditors, Dr. O. L. Brady, Dr. A. E. Dunstan, and Dr. P. Haas, for auditing the Accounts for 1929 was proposed by the TREASURER, seconded by Professor C. S. GIBSON, and carried, acknowledgment being made by Dr. O. L. BRADY.

It was moved from the Chair and carried that Professor J. C. Drummond, Dr. P. Haas, and Dr. J. Kenyon be elected Auditors to audit the Accounts of the Society for 1930.

A vote of thanks to the Treasurer, Secretaries, Foreign Secretary, Council, and Committees for their services during the past year was proposed by Professor C. K. INGOLD and seconded by Mr. E. HINKS. Acknowledgment was made by Professor F. G. DONNAN.

In presenting the Longstaff Medal for 1930 to Dr. W. H. Mills, F.R.S., the PRESIDENT said :—

“Dr. Mills, it is my pleasant duty to present to you the Longstaff Medal which has been unanimously awarded to you by the Council.

“The Medal was established by a resolution of Council dated December 21st, 1876, by which it was agreed to accept a donation of £1000 to the Research Fund by Dr. Longstaff on the understanding that ‘a gold medal of not less value than £20 be awarded triennially to the Fellow of the Society who, in the opinion of Council, has done the most to promote Chemical Science by research.’

“Chemists generally will welcome the decision of Council to award this medal to you because you have contributed a long and steady series of papers to our Transactions on subjects of the highest importance to the advancement of Chemical Science. Of these I would mention particularly your admirable investigations of the cyanine dyes and their uses as photographic sensitisers—information which proved to be of the greatest service to our fighting forces during the Great War—but more especially your researches on the occurrence of optically active forms of those substances which possess molecular dissymmetry such as the ketodilactone of benzophenone-2 : 4 : 2' : 4'-tetracarboxylic acid and the pyridylhydrazone of cyclohexylene dithiocarbonate.

“By these investigations you have definitely established the fact that the cause of the absence of optical activity among aromatic derivatives due to the uniplanar character of the benzenoid structure is no longer effective when two rings are joined in such a manner as to make them lie in different planes and you have recently emphasised this fundamental conclusion by resolving benzenesulphonyl-8-nitro-1-naphthylglycine and

thus showing that the inhibition of free rotation about a single bond leads to molecular dissymmetry.

"All this work has required the exercise of the highest attributes of the Research Chemist; infinite patience, high knowledge, clear reasoning, and great manipulative skill. It is, therefore, with the greatest pleasure that I hand you the Medal on behalf of the Council, and express the hope that you will continue in the future to add to your achievements by further enriching the science our Society was founded to foster."

Dr. MILLS made acknowledgment.

The Harrison Memorial Prize for 1929 was then presented to Dr. R. P. Linstead by the PRESIDENT, who said :—

"Dr. Linstead, it is my pleasant duty to present to you the Harrison Memorial Plaque and Prize which has been unanimously awarded to you by the Committee appointed under the Trust Deed, consisting of the Presidents of The Chemical Society, The Society of Chemical Industry, The Pharmaceutical Society, and The Institute of Chemistry.

"The description of the Award is best given in the words of the late Sir George Beilby, the Chairman of the Harrison Memorial Committee, who said 'with the balance of the sum collected (after defraying the cost of the War Memorial) it was decided to create a fund to provide, every three years, a prize of approximately £150, to be awarded to the Chemist, man or woman, not over thirty years of age, who shall have made the most meritorious original contributions to chemical science during the previous five years. It is to be given for distinguished research in any branch of chemistry, pure or applied, and no restriction is to be placed upon the manner in which the prize is to be utilised by the recipient.'

"It is seldom that a research worker within the age limits demanded by the Trust Deed strikes out a line for himself and does not merely elaborate and extend the research problems on which he has been trained. Nevertheless, during the period required by the Deed you have succeeded in devising and establishing on a sure basis a means by which it is now possible to determine the relative proportions of the constituents present in equilibrium mixtures formed by the interchange of the  $\alpha\beta$ - and  $\beta\gamma$ -structures of substances exhibiting three-carbon tautomerism, and have thus supplied a method by which the close and quantitative study of this fundamental phenomenon can be effected.

"In awarding this prize and plaque I have to remind you

that they were founded to commemorate an exceptional man who gave his life for his country just as surely as if he had been killed on the field of battle and to express the hope that throughout your life you may be guided by his high sense of service and his great devotion to duty."

Brief acknowledgment was made by Dr. LINSTEAD.

The PRESIDENT delivered his Address, entitled: "Internal Co-operation." A vote of thanks to the President for his services in the Chair during the past year and for his Address was proposed by Professor H. B. BAKER and seconded by Professor W. P. WYNNE. This was carried with acclamation and acknowledged by the PRESIDENT.

It was announced that the following had been elected to fill the vacancies on the Council for the year 1930—31 :—

*President.*—J. F. Thorpe.

*Vice-Presidents who have filled the office of President.*—P. F. Frankland, A. Scott.

*Vice-Presidents who have not filled the office of President.*—A. Lapworth, F. L. Pyman.

*Ordinary Members of Council :—*

*Town Members :* T. J. Drakeley, R. H. A. Plimmer, C. K. Tinkler.

*Country Members :* H. M. Dawson, E. Hope, J. Kendall.

## PRESIDENTIAL ADDRESS.

Delivered at the ANNUAL GENERAL MEETING, March 27th, 1930.

By JOCELYN FIELD THORPE, C.B.E., D.Sc., F.R.S.

### *Internal Co-operation.*

I FIND, on looking through a number of Presidential addresses given before the Society in the past, that usually it has been the custom to devote the address given at the end of the second and final year of office to matters relating to the progress of the Society during the previous two years, leaving the earlier or first address to deal either with some subject of scientific interest with which the President was personally familiar or with the discussion of some wide problem which, at the moment, was of general interest to the Fellows. The Fellows have elected me to another term of office, and I am grateful to them for doing so, because it shows that they have a certain confidence in my desire to further the interests of the Society during the difficult period that is before us. Nevertheless, I am fully determined to take advantage of the permission accorded me to submit my resignation to the Council at the end of the first year of the new period, so that the present occasion constitutes not only the second address of the first term but also the first address of the new term, and next year I shall be in a position to survey the progress made by the Society during my three completed years of office. It is my intention, therefore, to use this occasion to express views and opinions on certain aspects of our Science and to elaborate certain matters which formed the subject of my address at Leeds last year.

### *The Need for Uniformity of Effort.*

In my address to the Society last March I dealt with Co-operation in Science and Industry. It is my intention to-day to deal with the more intimate matter of internal co-operation, affecting as it does the immediate future of the Society. In the previous address it was stated that "the war, although one of the greatest economic disasters the world has yet experienced, gave, without question, a stimulus to discovery and production which no other event could have occasioned." The war did more than this, for it showed the results and achievements which could be accomplished by united efforts towards a common end. The world needed such a lesson, and the amazing development in Science and Industry that has taken place since that great upheaval must be ascribed to the fact that the nations are now applying the lessons learnt in war to the more settled but not less arduous conditions of peace. Indeed, the spirit

Reproduction of Mace presented by Mr. Ayerst Henham Hooker, F.I.C., on January 16th, 1930.

of co-operation or rationalisation is now directing human progress in numerous directions, and not only is leading to internal co-operation within specific branches of activity, but is causing many groups dealing with related subjects to join together in their own and in the national interests. For it is certain that the next twenty years will witness a struggle for supremacy in scientific effort and in the industrial application of science throughout the world which will be even more intense than was the struggle between the contending nations during the war, and that only those nations will succeed in this struggle who have equipped themselves with knowledge and with the ability and foresight to apply that knowledge by united effort towards the achievement of a common purpose.

### *The Need for a Scheme.*

In the previous address it was pointed out that it is chiefly to the chemical and allied industries—mining and metallurgy—that the country turns for the utilisation of its potential productive capacity, because it is their function, aided by the engineer, to make available its mineral, vegetable, animal, and atmospheric wealth. It must be recognised, therefore, that the separation into isolated units of the organisations dealing with the scientific and technical development of the three basic industries mentioned—namely those of Mining, Metallurgy, and Chemistry—is not in accordance with the existing state of scientific knowledge, and that the Nation and Empire cannot utilise to the full the forces inherent in them unless some scheme can be devised by which close co-operation between these groups can be effected. Such a scheme would have to be framed so as to enable the constituent organisations to retain their autonomy, but it should be drawn up in such a manner as to ensure that full opportunity would be afforded for general intercourse and discussion.

At the present time the organisations dealing with the subjects mentioned above are housed—some very inadequately—in various parts of the metropolis, and there are few facilities for the interchange of thought and ideas. There is no general meeting-room, and although most of the Societies and Institutions involved have libraries sufficient for the immediate daily needs of such of their members as are resident in London, such libraries are scattered and are not readily available for anyone who wishes to obtain information, even on specific subjects, and especially on those related to border-line enquiries. Data connected with matters not immediately within the province of any one particular subject but belonging to two or more of them are at present difficult to find. A general Library and Information Bureau is therefore one of the chief requirements of the Scheme: others are a Central Meeting-Room,

secretarial offices closely in touch with one another, and such provision for social amenities as may be necessary to permit of intercourse between the members of the various branches during their leisure moments and to provide a centre for visitors from overseas.

In the chemical world the need for such a scheme has been recognised for ten years past, and efforts have been made from time to time to give effect to it. But, for one reason or another, each scheme has failed to reach fruition, mainly because it involved the raising of capital by means of a loan or some other form of financial commitment which it was felt unwise to ask the various Societies and Institutions to bear.

The Societies dealing with Chemistry, as indeed those dealing with other branches of science and industry, are not wealthy bodies. Most of them possess a small accumulated capital, but the main source of income is the subscriptions derived from their members. The chief item of expenditure is the cost of their publications, the administrative expenses being comparatively small. It is only by the exercise of rigorous economy that it is possible to provide for a small credit balance at the end of each year, and it would therefore be unwise to saddle the Societies with a debt which would necessitate the payment of interest and the creation of a sinking fund. Any scheme therefore which could be regarded favourably as a means of linking up the Chemical Societies under one roof would involve the collection of a sufficient fund by public subscription, and, hitherto, the sum regarded as necessary for this purpose has been too large to be within the sphere of practical accomplishment. The need, however, is urgent, because other nations, notably the French, are actively engaged in co-ordinating their chemical activities, and the Americans already have their "Chemists' Club" in New York. Unless, therefore, something is done, and that quickly, we shall be handicapped in the struggle with which we are faced.

Former Presidents have emphasised the need for such a scheme on the part of our own Society, and even twenty years ago it was regarded as inevitable. The reason for this is that our apartments in Burlington House, which were given us rent free by the Government fifty years ago, have long since ceased to provide us with adequate accommodation. The meeting-room is too small, and is incapable of being suitably ventilated. The seating, which has been arranged so as to give the maximum seating capacity, is unsuitable. Everyone who has occupied this Chair and who has witnessed the contortions necessary to enable the occupants of the cross benches on the west side to see the screen will have sympathised with those who have had to seat themselves there. On occasions,

such as those of our special lectures, we cannot use this meeting-room owing to lack of space, and have to seek accommodation elsewhere. The Library is now so overcrowded that recourse has to be had to shelving books in double rows—a most undesirable procedure. Moreover, all available space throughout the building—including the cellars—has to be used for the storage of books, involving in the case of cellar storage possible loss by flooding, which cannot adequately be covered by insurance. The other Chemical Societies have no accommodation other than office facilities and for the most part make use of our meeting-room. There must, therefore, be general agreement, apart from reasons of national policy, that the need for new quarters is imperative. Indeed, the change in the case of the Library cannot be longer delayed, as the normal increase represents some 900 volumes yearly.

A scheme is now about to be launched by which, for a sum approximately half that required for new premises under the older projects, the Society may be housed in a "Chemistry House," together with the allied organisations, the Society of Chemical Industry, the Institution of Chemical Engineers, and the Institution of the Rubber Industry. This scheme is of such vital interest to every member of these Societies that I make no apology for outlining it to you and discussing its most important practical aspects.

#### *The Proposed Scheme.*

Two years ago a scheme was started having for its object the housing together of the chief Societies and Institutions connected with the scientific and technical development of the mining and metallurgical industries, namely :—

- The Empire Council of Mining and Metallurgical Institutions ;
- The Institution of Mining and Metallurgy ;
- The Institution of Mining Engineers ;
- The Iron and Steel Institute ;
- The Institution of Petroleum Technologists ;
- The Institute of Metals ; and
- The Institute of Fuel,

the idea being to house these bodies under one roof in much the same manner as had already been accomplished by the Civil and by the Mechanical Engineers. In June of last year it was considered that the scheme could not be complete and effective without the inclusion of the Chemists, and the Councils of the Chemical Society, the Society of Chemical Industry, the Institution of Chemical Engineers, and of the Institution of the Rubber Industry were approached to collaborate. Each Council agreed to join the scheme on the understanding—

- (1) That the money asked for by public subscription was forthcoming;
- (2) That adequate accommodation was provided.

It was agreed to appoint three members from each Council to serve as a Committee, the function of which was to prepare plans and formulate a scheme for the provision of a "Chemistry House."

The original plan as contemplated by the Societies representing Mining and Metallurgy provided for the occupation of three-fifths of a site situated in Victoria Street, Westminster. The site is the property of the Ecclesiastical Commissioners, who are prepared in principle to grant a long lease at a ground rent which it is within the capacity of the constituent Societies to pay. As soon as the Chemical group signified their intention of participating in the scheme it was agreed that the whole site should be taken up, the two-fifths remaining over from the original scheme being assigned for the purposes of the Chemical group, and becoming therefore the "Chemistry House" of our requirements. The approximate cost of acquiring the existing lease of the site, which has twenty-two years to run, and of erecting a suitable building thereon has been estimated, after careful enquiry, at £325,000. This sum, however, does not provide for furnishing the new building, so it has been agreed to issue an appeal for £350,000. In other words, two-fifths of this sum, or £140,000, will have to be provided by the Chemical group as its share towards the complete cost. It has been arranged that the ground rent shall be paid by each Society contributing yearly an amount equal to but not more than it pays as rent for its present premises, and as this amount will certainly be more than that required to pay the rent, the excess will be utilised to defray the cost of upkeep and the expenses of services common to all Societies housed within the building.

#### *Area Available.*

The total "carpet" area available in the new building will be approximately 8,500 square feet for each floor. One complete floor will be occupied by the general Library and the whole of the top floor will be utilised as a restaurant and club. There will be a large Meeting Hall to hold 500 people in the main portion of the building, probably on the ground floor opposite the main entrance. This will leave five floors available for the Societies entering into the scheme, and in the case of "Chemistry House" these floors will have two-fifths of 8,500 square feet, or 3,400 square feet each. There will be a smaller meeting-room—to hold 200—in the Chemistry wing for the use of the Chemical group, although the group will have the use of the larger meeting-room when occasion requires. It is evident,

therefore, that the space available is more than adequate for the needs of the Societies entering into the scheme and provides ample room for expansion. In order, however, that the building should be occupied from the start, it has been arranged to let such space as may be available to "Tenant" Societies who would hold leases for an agreed period and pay an agreed rent. Thus, in the Chemical wing, the Chemical Society and the Society of Chemical Industry would each occupy one floor of 3,400 square feet. The Institution of Chemical Engineers requires only 1,200 square feet, so on the floor occupied by this Institution there would be 2,200 square feet available for the Entrance Hall, Ante-Room, and Meeting-Room. The Institution of the Rubber Industry has intimated that it requires only 1,000 square feet of space, so the remainder of the space on its floor, together with one complete floor, or 5,800 square feet in all, will be available for "Tenant" Societies of the Chemical group. These "Tenant" Societies will be in every case entities directly connected with the industries represented by the constituent bodies. They may include the Association of British Chemical Manufacturers, the National Federation of Iron and Steel Manufacturers, and the Mining Association of Great Britain, and other groups of the same category.

#### *The Library.*

As already mentioned, one complete floor throughout the whole building will contain the General Library. This Library will include the Libraries already in the possession of the constituent Societies, and the 33,000 volumes now in our possession will be handed over to form the nucleus of the new Library. In consideration of this it has been agreed that our Society shall continue, as in our present quarters, to be housed rent free. The Library will be sectionalised, and each section will remain under the control of the sectional Librarian. In effect, therefore, our Library, Librarian, Library staff, and Library Committee will continue to function in the new building in the same way as they do now. Moreover, there is no reason to anticipate that there would be any falling off in the outside contributions to the upkeep of our Library. The constituent Societies would continue as a matter of course to pay their share, and outside bodies would be even more anxious to contribute than they now are, owing to the increased facilities provided.

The Central Library is, indeed, one of the chief features of the scheme. It will contain at the beginning some 70,000 volumes exclusive of pamphlets, and will probably be augmented by some 2,000 volumes yearly. The inevitable overlapping between scientific and technical Libraries in respect of books and periodicals dealing with borderland subjects will disappear, or, alternatively, will

provide duplicate copies which can be utilised for the purpose of lending. There will be an efficient Bureau of Information by whose aid the enquirer will be directed to the source from which the information he requires can be obtained. In fact such a Library will be unique in its completeness and accessibility and will be a point of attraction not only for business men and students at home, but also for those visitors from overseas who desire to keep themselves abreast of modern developments in the subjects dealt with. No one can foresee what effect such a source of information, and indeed of power, housed centrally and easily accessible, may have on the future development of Science and Industry.

The restaurant on the top floor will be the means by which meetings under social conditions can be arranged. It is intended that there shall be several small dining-rooms in which the existing dining clubs of the various Societies can meet, leaving the larger restaurant and dining-room for general purposes. The Chemical Industry Club and the Oil Industry Club have now under consideration the question of joining as "Tenants." Should they decide to do so, special rooms would be provided for them on the top floor. The Clubs would, however, retain complete autonomy and would be "private" in the sense that only those persons whom they decided to elect as members could use their premises.

#### *General.*

It seems, therefore, that at last we are in a fair way to realise the "Chemistry House" of our needs at a cost which is about half that which would be necessary if Chemists were forced to act alone. This achievement has been possible only because the present spirit of collaboration and the desire towards uniformity of effort have caused the various Societies and Institutions which are parties to the scheme to come together to form a solid band. Ten years ago it would probably have been impossible to do this, and if the present effort fails it may be another fifty years before conditions are again favourable.

The economic advantages of the scheme will be numerous. Many details of office organisation can be pooled, service can be shared along general lines. Internal printing, such as the printing of notices, circulars, and so forth—an expensive item under present conditions—can be done in a small printing press on the premises, and other economies can be effected in several directions. Let us therefore exert all our energies to take advantage of the moment, and do everything in our power to further a project which cannot but be fraught with good for all of us and for the Nation and Empire as a whole; each of us doing what he can to further the cause by

contributing what he is able to contribute, but more especially by convincing those who are in a position to help substantially that the scheme is vital to the future of organised Science and Industry in this country.

*Financial.*

The problem of raising the necessary money causes some anxiety in view of the present great depression of industry and the incidence of high taxation. In any case, the general appeal cannot be launched until after the Budget. We must look to the industries concerned to provide the greater proportion of what we require, and we hope that they will regard it as being to their advantage to do so, and will also look on it as a kind of thank-offering for past services and for the manner in which the Scientific and Industrial Institutions have provided them with information in the past. It is not too much to say that no Chemical Industry would exist to-day if there had not been the free interchange of thought and information which the Societies have been formed to promote and foster. Not that I have found any marked desire on the part of those engaged in industry to repudiate this debt; on the contrary, except in one or two instances, I have found, as Chairman of the Appeal Committee, not only a desire, but even eagerness to do all that was possible. It is rather the air of uncertainty that pervades all things industrial at the moment that prevents many definite promises being given. Nevertheless, when the general appeal is issued it will contain a list of definite promises amounting to £130,000, including some munificent personal donations, such as £10,000 from Mr. Robert Mond, £1,000 from Mr. Emile Mond, £1,000 from Sir Robert Hadfield, £250 from Sir Charles Parsons, and £105 from Mr. Horatio Ballantyne. A petition was sent to the Chancellor of the Exchequer asking for a Treasury contribution. Such a petition involved no new principle, since, by the housing of a number of Societies in Burlington House, the Government of that day admitted its obligation to Science. Seeing that one of the petitioning Societies, our own, would vacate the premises then allotted to them, it seemed a simple extension of the principle involved to ask for some monetary consideration. A deputation waited on the Financial Secretary, being introduced by the President of the Royal Society, and several speakers laid the case before him. The answer, however, was "non-possumus," although sympathy was expressed with the object in view. It is possible that another appeal made in more favourable circumstances may meet with a different answer, but it seems that we must rely for some time to come on ourselves, and on those of our friends who sympathise with our desire to give effect to the scheme.

*Domestic Co-operation.*

In my previous address I discussed at some length the advantages which were likely to accrue through the formation of larger combines in industry. I did not do much more than mention at the time the benefits which might be expected to attend a similar process in Chemical Science, because I felt that the time was not then suitable to discuss so difficult a problem. Nevertheless, I did call attention to the advantages enjoyed by the American nation in having but one Chemical Society which could speak for the whole of Chemistry and regulate its publications and conferences. Since then the situation has changed considerably owing to the elaboration of the scheme described above for housing the Chemical Societies under one roof, and I feel that I shall not be guilty of an indiscretion if I examine for a moment the manner in which it might be possible to give effect to that outward and visible sign of union which is now contemplated. It is not my intention to suggest that any such system as that found in the United States is now applicable in this country, because there is no doubt that the principle of combined effort, although admirable and effective in certain directions, contains features which are not altogether desirable. Partial de-centralisation is often more effective than complete centralisation. For example, it would be undesirable and, indeed, impracticable to have the same President, Officers, and Council of the Chemical Society and the Society of Chemical Industry. It would be a practical impossibility to find the men who could give the time adequately to fill these offices. I am speaking on my own behalf, and I am sure also on behalf of my friend the President of the Society of Chemical Industry, when I say that most of our leisure moments are occupied by the business of the Society we serve and that we should not contemplate with equanimity any suggestion that either of us should take over the work of the other in addition to his own. Any such step would tend to throw the control of the combined Societies into the hands of salaried officials, and many of us feel that so long as we can get competent men able and willing to give the time to act in honorary capacities it is desirable to do so.

When the Society of Chemical Industry was formed as a separate entity in 1881, it took over certain definite functions which it has since performed in accordance with the terms of its constitution. The terms Scientific and Technical possessed in those days very definite meanings, and they still possess, or have had attached to them by custom, meanings which enable a decision to be reached, on broad lines, as to the matters falling within either sphere. It is possible to say, in clear cases, whether any communication is scientific in the sense that it deals with the elaboration of some

subject on lines which, for the moment, may be regarded as based on purely scientific hypothesis or theory or whether it is technical in that it is concerned with the description of some chemical operation of acknowledged mechanism carried out on the large scale. It is rather in the matter of the discussion of such questions that co-operation can, in the first instance, be effected. Formerly there was a fairly distinct line of demarcation between the Scientific Chemist and the Technical Chemist, but to-day it is doubtful whether any Scientific Chemist exists who is not interested on the technical side, and the Technical Chemist who is not interested on the scientific side is becoming increasingly rare. Indeed, the whole trend of modern development is to diminish the difference between these two types, and in the not distant future this difference will entirely disappear.

### *The First Step to Reunion.*

The first step towards co-operation between the two branches of our science must be one that will lead to conditions which will enable papers to be read and discussion to be held on both technical and scientific subjects by all those who have the interests of both sections at heart. Such joint meetings must be so arranged that persons interested in both aspects may be present and speak. Here in London such facilities already exist, but they are not yet sufficiently wide in character. I would suggest, therefore, as a first step, that meetings of the four constituent bodies forming the Chemical wing of the new building, namely the Chemical Society, the Society of Chemical Industry, the Institution of Chemical Engineers, and the Institution of the Rubber Industry, should be open to all members of those Societies and Institutions. Such a proposal applies also to those "Tenant" Societies who intend to use the Chemistry wing.

In the provinces, where there are not so many meetings, it would be necessary to arrange composite programmes, so that not only would members of all the constituent Societies be able to attend and take part in the discussions, but also the local Committees controlling such meetings should themselves be composite bodies. The Chairman or President could be chosen from one or other section as circumstances permitted, as could also the Secretaries, although for the immediate future a system of joint Secretaries might, with advantage, be inaugurated.

In effect, therefore, the suggestion is that membership of any one "constituent" or "Tenant" Society under the new scheme should confer on the member the right to read papers and to attend meetings of each Society, whether held in London or as sectional

meetings in the provinces, and that the programmes provided at the sectional meetings should embrace subjects on both the scientific and the technical side. This suggestion must be taken in conjunction with further suggestions which will be made later and in which a scheme is outlined for determining the conditions of membership of the Societies.

### *Publications.*

It may be assumed that one of the chief reasons why a person belongs to one or more of the Chemical Societies is to obtain their publications. If this is so, it may well be that the cause of the annual drop in membership which some Societies are now experiencing may be due to the increased facilities afforded by works' libraries in supplying the requirements of their staffs. Indeed it has been said that some firms have notified their employees that the need for joining Societies no longer exists, because their own libraries contain all the required literature. The large General Library, which is the chief feature of the new housing scheme, should undoubtedly serve as an attraction and inducement for new members to join at least one of the constituent Societies, but unless there exists in the future as there has existed in the past a general desire among the younger men to join the Societies as a matter of principle, it is to be anticipated that a general decline in membership will occur.

The publications of the two chief Chemical Societies are :

- (1) The Journal of the Chemical Society, containing the Transactions of the Society;
- (2) The Proceedings of the Chemical Society, containing mainly matters concerning the business of the Society;
- (3) The Journal of the Society of Chemical Industry;
- (4) Chemical Abstracts A (pure) and B (applied);
- (5) "Chemistry and Industry."

"Chemistry and Industry" contains under one cover the Transactions of the Society of Chemical Industry and the B Abstracts. There are other incidental publications such as the Annual Reports, but as the cost of these is, at present, defrayed by sales, they need not be considered for the moment.

The publications of the American Chemical Society are similar in character, being the Journal, Chemical Abstracts, Industrial and Engineering Chemistry, and its News Edition. There is no official British equivalent to "Industrial and Engineering Chemistry," but there is a periodical very similar to it in general appearance called "The Industrial Chemist," which is published by a London firm. In my opinion steps should be taken to ascertain whether it might

not be practicable to rearrange the publications of the two Societies in the following way :

- (1) Chemical Transactions. To contain the Transactions of the Chemical Society and the Transactions of the Society of Chemical Industry in those cases where no elaborate illustration of plant or apparatus is required (published monthly).
- (2) Abstracts A and B published together.
- (3) A publication on the lines of "Industrial and Engineering Chemistry" to contain the Transactions of the Chemical Society and of the Society of Chemical Industry in those cases where elaborate illustration of plant or apparatus is required (published monthly).
- (4) "Chemistry and Industry"—the news edition—(published weekly containing the Proceedings of the Societies).

Publications 2, 3, and 4 should yield considerable revenues from advertisements—especially (3), and it is possible also that this publication might be regarded by the Institution of Chemical Engineers as a means of issuing its more elaborate papers.

It is not my intention to suggest ways and means by which the above result can best be accomplished. Such a problem will have to be most carefully investigated by a Joint Committee of both Societies, but it cannot be denied that there is a certain degree of unnecessary duplication between chemical publications as a whole, and that if this duplication could be removed and the various publications consolidated an increased circulation would be attained, especially among the outside public, with a consequent increase in the number and quality of the advertisements. The object to be achieved is the unification of our chemical publications by bringing together under an Editorial Board the publications of two and possibly more constituent Societies, and to include with these such outside publications as circumstances may permit.

#### *Finance.*

It is assumed that the publications mentioned above could be carried into effect for the same or a less sum than that now necessary to produce the existing publications of the two Societies. Now, the total membership of the Chemical Society and the Society of Chemical Industry, allowing for those members who belong to both, is of the order of 8,000,\* and the main question that arises is this, Is it possible that a reduction in the present rates of subscription to the two Societies could economically be effected in the case of joint membership of both Societies? For example, would it be financially possible to allow all joint members the right to receive

\* In this and similar cases I have purposely kept to round numbers.

the publications suggested above on payment, say, of a subscription of £3 10s. instead of the £5 10s. which they would pay under present conditions? \* The obvious answer to this question is that any such scheme would have to be retrospective and include those members who already belong to both Societies—some 1,000 in all—leading to a considerable loss of revenue. This, however, need not act as a deterrent to the introduction of the new system, because the 3,000 members of the Chemical Society who are not now members of the Society of Chemical Industry and the 4,000 members of the Society of Chemical Industry who are not now members of the Chemical Society would have the option of paying the composite fee and receiving the full benefits provided, but those who do not take advantage of this option would have to give extra payment for such publications as they may require over and above those to which their individual subscriptions entitle them.

The chief hardship would undoubtedly rest with those who are already members of both Societies, because, as stated previously, the Societies could not face the financial loss entailed by those members paying a composite fee which would be considerably less than they now pay to both Societies. A change such as that contemplated must be gradual, and no action must be taken that will lead to a sudden drop in the annual income of either Society.

For the time being, therefore, the members who already belong to both Societies would have to continue to bear the cost of the full subscription to each Society, and the reduced or joint contribution could only be made operative in the case of new members.

The essence of the proposed scheme is that *new members must be required to join both Societies*. It is true that the present joint members might easily resign and re-join under the new scheme, but this would have to be prevented by Regulation. The joint contribution of £3 10s. which I have suggested is purely tentative: the right figure can only be determined by the Joint Committee of the two Societies with actuarial help. I have merely suggested it to form the basis of investigation, but I do not think it is far wrong.

For many years to come there would, therefore, be the following classes of members :

- (1) New members who must join both Societies at a composite fee of, say, £3 10s. annually.
- (2) Old members of the two Societies who would continue to pay (ex gratia) their present contributions to both Societies.
- (3) Old members of each Society who would continue to pay their present contributions as members of each Society and remain such unless they signified their desire to become

\* It is suggested that all entrance fees should be abolished.

joint members, when they would pay the composite contribution of £3 10s.

Those who decided still to remain members of each Society would continue to pay the subscription required by each Society, but such members would receive, free of charge, only those publications which each Society regarded as adequate.

If, therefore, this scheme is workable actuarially and is agreed to by the Societies concerned, it means that after the lapse of, say, thirty years, membership would be confined to Class 1 only, and the two Societies, while having their own President, Officers, and Council, and thus retaining complete autonomy as regards organisation and finance, would have a common membership and joint publications. The scheme must be examined carefully by an actuary, but it is thought that the loss of revenue, due to the composite subscription, would be more than compensated for by the increase of membership due both to new members joining and to those old members of Class 3 who elect to become joint-members. Personally, I feel some sympathy with the members of Class 2, being one of them myself, but I feel sure that most of them will realise that the action suggested is necessary in the interests of co-operation.

Let us therefore devote our energies in the immediate future firstly towards making the scheme for a central House an accomplished fact not only by giving help ourselves, but also by inducing others to help. It must be remembered that the membership of the constituent bodies combined in the scheme amounts to over 20,000, and that if each of these members acts in the manner suggested above a substantial sum towards the cost of the scheme will be forthcoming. Secondly, let each member of our two Societies do what he can to further the scheme of amalgamation, based on some such plan as I have outlined in this address. Difficulties there are sure to be, but most difficulties of detail can be settled when the broad outlines of the scheme are established.

There is undoubtedly a strong feeling among members of both Societies that the time has now come to close, in some measure, the break made in 1881. If that feeling is real and if strong opposition is lacking from either side we shall achieve the object in view and bring about a union which circumstances now favour and which, in the opinion of many of us, is in accordance with the best interests of the two Societies and of Chemistry generally. If no union can be effected at the present juncture it will be due to opposition from within, and those opposing must remember that the same set of conditions is not likely to recur for many years to come and that failure under the very favourable circumstances of the moment will probably mean complete failure hereafter.

We have, in effect, the opportunities of forming a Chemical Society divided into two administrative sections, each section autonomous as regards internal administration and finance but with unified publications and a membership gradually becoming common to both. The Councils of the two sections would continue, as hitherto, to deal with routine administration, leaving the work of the section to be carried out, as at present, by Committees of Council. Financial matters would have to be arranged "pro rata" by a Joint Financial Board, but each section would have its own Finance Committee for the purpose of financial administration within its own domain.

The Publication Committees of each section would continue to function as now and would determine which of the communications submitted to them should be published and in which publication. There would have to be a joint Editorial Board composed of members of both Councils, whose duty it would be to direct the publications issued jointly.

The Bureau of Chemical Abstracts, which under the proposed scheme will deal with the unified abstracts and the joint indexes, would continue to act as it does at present and would retain its present constitution. The Library Committee would also retain its present form and carry out its work in the same manner.

Regarding the two other constituent Societies, the Institution of Chemical Engineers and the Institution of the Rubber Industry, the former has already expressed its wish to be associated with British Chemical Abstracts, and it may be possible that the variety and scope of the other publications for which provision is made under the scheme will appeal to this body as a suitable means for publishing its scientific and technical communications. If this should happily be the case, the Institution would have to be represented on the joint Editorial Board and on the joint Finance Board. Unfortunately, it is not possible in this case to arrive at a common membership, since the Institution is, in part, a professional body, the membership of which carries a qualification. So far as the Institution of the Rubber Industry is concerned steps must be taken to ascertain in how far and in what manner it is prepared to be associated with the scheme.

It will probably require twelve months' work on the part of a joint Committee to elaborate all necessary details and explore every avenue leading in the desired direction, but let us be ready, when the fiftieth anniversary of the foundation of the Society of Chemical Industry occurs next year, to put forward a well-conceived and agreed plan of amalgamation which can be put into operation at once.

*The Dyestuffs Act.*

In my address last year I mentioned the Dyestuffs (Import Regulation) Act as illustrating one of the ways in which Government could co-operate in order to protect "young and struggling industries against competition from similar but established industries abroad." This Act was passed in December 1920 and came into force on January 15th, 1921. It prohibited, for a period of ten years, the importation into the United Kingdom of all synthetic dyestuffs and all intermediate products used in their manufacture, but permitted certain materials not available in this country to be introduced by licence.

The Act, which has been of very great value in assisting the establishment of a Dyestuffs industry in this country, comes to an end, therefore, at the close of this year, unless it should be extended for a further period.

There is perhaps a tendency in certain quarters to-day to consider the Dyestuffs industry only from the point of view of the supply of dyestuffs to the colour users. There is, however, another very important aspect to which we as members of the Chemical Profession must give full consideration. I refer to the fact that a successful and well-established Dyestuffs industry establishes in the country having such an industry a certainty of development in the field of organic chemistry. Firms are enabled to create large research organisations employing many of the most capable chemists in the country, and from these organisations there arise all kinds of organic developments, not alone in dyestuffs, but in very many other branches of industry.

Such Research Organisations are recruited from the Research Schools in our Universities and University Institutions, leading not only to the employment of many research chemists trained therein, but also to their own development.

The history of the great German dye firms in the past has shown this clearly, since most of the successful lines into which these firms have ventured have arisen from research work carried on originally for the Dyestuffs industry. It appears important, therefore, that a broad view should be taken of the establishment of a Dyestuffs industry, and that full weight should be given to the importance to the nation of the development of Organic Chemistry.

During the Great War the importance of this was clearly seen, for not only did the great German Dyestuffs firms assist from the military point of view—they also operated very extensively in regard to many organic developments which were of an entirely civil character.

---

## OBITUARY NOTICES.

## FREDERICK WILLIAM DOOTSON.

BORN AUGUST 10TH, 1863; DIED DECEMBER 12TH, 1929.

By the untimely death of F. W. Dootson at the comparatively early age of 66 years, the University of Cambridge lost an able and devoted teacher and his friends in the Chemical Laboratory a congenial and gifted colleague.

There is little of general interest to record about Dootson's earlier years, but his connexion with Cambridge dates from 1891, when he entered Fitzwilliam Hall as an undergraduate. Shortly after graduating in the Natural Sciences Tripos, he attached himself to Trinity Hall, and for many years devoted himself to the interests of the students as a private tutor. From the time of taking his first degree up to the date of his death he was identified with the University Chemical Laboratory, where his success as a teacher, first as Demonstrator and later as University lecturer, will long be gratefully remembered.

Shortly after graduating, Dootson became interested in the chemistry of citrazinic acid, a subject on which his teacher, the late W. J. Sell, had published several memoirs. A paper published by Sell and Dootson on the action of phosphorus pentachloride on citrazinic acid in 1897 led to a systematic study of the chlorine derivatives of pyridine. The results of these investigations were published at frequent intervals in the *Journal* between 1898 and 1903. Dootson also published a paper on the "Halogen Derivatives of Acetonedicarboxylic Acid" (*J.*, 1899, 75, 169), and in another paper, entitled "Condensation of Methyl Acetonedicarboxylate. Constitution of Orcinoltricarboxylic Esters" (*J.*, 1900, 77, 1196), he demonstrated a very simple method for transforming an aliphatic into a benzenoid compound.

After 1903, Dootson's administrative duties in the laboratory increased considerably and he was of necessity drawn away from research. During the period of the War, however, he was actively occupied with experimental preparative work on various substances of national importance. His last memoir, entitled "A Note on Thermal Diffusion" (*Phil. Mag.*, 1917, 33, 248), was published jointly with Dr. S. Chapman.

To past and present generations of Cambridge students, however, the most enduring memory of Dootson will be that of an attractive

and successful teacher of the more elementary branches of chemistry. His admirable capacity for organisation made him a valuable help to his Professor and a very kindly friend to other members of the Departmental Staff. Dootson was a man of many interests: not only was he essentially a "well-read man," but he developed his appreciation of art in a more practical way as a very successful amateur oil painter.

He died, as he would have wished, in harness, after a very short illness. Among the many tributes to his memory, the writer ventures to quote from a letter written by an eminent Member of the Faculty of Medicine to Mrs. Dootson. "... I should like to add my appreciation of Dr. Dootson's work as a teacher. He was a friend to every student, and every student valued his kindly and unsparing help."

A. J. BERRY.

---

### HENRY JOHN HORSTMAN FENTON.

BORN 1854; DIED JANUARY 13TH, 1929.

HENRY JOHN HORSTMAN FENTON was born at Ealing in 1854. He received his earlier education at Magdalen College School, Oxford, and afterwards went to King's College, London, where he studied chemistry under Bloxam. During the time that Fenton was at King's College the Clothworkers' Company instituted an exhibition in physical science tenable for three years by a non-collegiate student at Cambridge. Fenton applied successfully for this exhibition and, in accordance with its conditions, entered the University of Cambridge in the Lent Term, 1875. In his first year at Cambridge he gained an entrance scholarship at Christ's College, where he was admitted in May 1876. He was then 22 and thus older than the majority of undergraduates. His chemical knowledge and experience were also greatly in advance of those of men of the same university standing, and while still an undergraduate he was made an assistant demonstrator by Professor Liveing. He had a very independent spirit, and it was therefore perhaps not unnatural that he chafed at the discipline then imposed on members of the University *in statu pupillari* and not infrequently came into conflict with University and College authorities. In fact to the end he cherished a certain antagonistic attitude towards university authority. He took the Natural Sciences Tripos in 1877—it was at that time not divided into two parts—and was placed in the First Class along with, amongst others, Adam Sedgwick, the zoologist, F. O. Bowen, afterwards Professor of Botany at Glasgow, and Alex. Hill, sometime Master of Downing.

On the resignation of the then University Demonstrator of Chemistry, John Wale Hicks, of Sidney Sussex, afterwards Bishop of Bloemfontein, W. J. Sell was appointed to succeed him and an "Additional Demonstratorship of Chemistry" was instituted by the University and the post was assigned to Fenton.

The University Department of Chemistry was then accommodated in a building since removed, which stood on the southern part of the east side of the Old Botanic Garden site and afterwards served as part of the Pathological Laboratory.

Several of the Colleges had their own chemical laboratories and these were run in competition with the University laboratory. This competition continued for many years after the erection in 1887 of the new University Chemical Laboratory facing Pembroke Street, though in an ever-lessening degree as the college laboratories one by one were given up. The greater part of the teaching in the University Laboratory was carried on by Sell and Fenton and in spite of their different temperaments the two men worked together in harmony until their association was terminated by the death of Sell in 1915.

Fenton's lectures were for many years an outstanding feature in the instruction given in the University Laboratory. He took immense pains in their preparation and although in lecturing he affected an air of indifference and a somewhat indolent manner, actually he delivered them with very great care, and he was extraordinarily successful in stimulating the interest of the abler men. He scrupulously avoided dogmatism. He endeavoured, so far as possible, to present each subject as a debatable question on which there were diverse views to be discussed, to balance the evidence for and against every inference, and to induce his hearers to use their own judgment and draw their own conclusions. The value of his lectures was greatly enhanced by the informal discussions which he encouraged: at the close of every lecture a number of eager young men would come down to the lecture table and engage with him in discussion, often prolonged, of the subjects in which he had aroused their interest. Those who brought their difficulties to him found him unexpectedly sympathetic, and he would deal exceedingly gently with one who asked a thoughtless or an ill-considered question.

The course of experimental work in general and physical chemistry which he devised to illustrate his lectures was very carefully thought out, and during the 'eighties, and even later, the type of laboratory work being done by his class was probably unique. Although his chief interest always seemed to be in general and physical chemistry, the greater part of his original work was carried out in organic

chemistry. His earlier work consisted of a series of investigations on the action of hypochlorites on urea and related compounds. A pupil of his (Mr. Street), wishing to estimate urea, happened to use, instead of sodium hypobromite, a strongly alkaline solution of sodium hypochlorite and found that only half the expected quantity of nitrogen was evolved. Fenton followed up this observation and discovered that the missing half of the nitrogen was present in the solution as sodium cyanate. He gave an explanation of the phenomenon a few years later. At the same meeting of the Chemical Society (June 20th, 1895) at which Walker and Hambly communicated their well-known experiments on the transformation of ammonium cyanate into urea Fenton read a paper giving an account of experiments he had been making on the same subject, using the action of sodium hypobromite to measure the rate of change. Finding that the transformation of the ammonium cyanate was never complete, he inferred that ammonium cyanate and urea were in tautomeric equilibrium and concluded that, whilst the more reactive hypobromite attacked both the urea and the ammonium cyanate (liberating all the nitrogen from the former and that present as ammonium from the latter), the hypochlorite attacked the ammonium cyanate only and thereby disturbed the equilibrium of the system so that the whole of the urea was finally converted into nitrogen and sodium cyanate. In other papers he showed that hypochlorites and hypobromites liberated different amounts of nitrogen from several nitrogenous compounds and in this manner he proved that ammonium carbonate in presence of water was in equilibrium with a small proportion of ammonium carbamate :

What is probably to be regarded as his most important work is that connected with the discovery and investigation of dihydroxy-maleic acid. It extended over many years, for the initial observation from which it grew was made during his first year as an undergraduate at Cambridge. The story current in the laboratory in later years was that a fellow student, amusing himself by mixing reagents at random, chanced to obtain a violet coloration, which he showed to Fenton. Fenton was keenly interested in the observation, and he found out the essential reagents which were concerned in the production of the colour, namely, tartaric acid, a ferrous salt, hydrogen peroxide, and excess of caustic alkali. He reported the discovery in a letter to the *Chemical News*, entitled "On a New Reaction of Tartaric Acid" and dated Christ's College, Cambridge, April 25th, 1876. He was at first disposed to regard the colour as being due to the production of a ferrate, but a few years later (in

1881) he published a second letter in the *Chemical News* in which he showed that the colour arose from an iron derivative of an oxidation product of tartaric acid, since the colourless solution obtained after removal of the iron gave the colour again on the addition of a ferrous or ferric salt.

After several years he took up the problem again, and in 1894 he discovered how the new oxidation product could be isolated—it could be salted out from the reaction mixture by the addition of fuming sulphuric acid—and in a series of papers extending over the years 1894 to 1902 he described its reactions and relationships. It had the formula  $C_4H_4O_6$ ; its formation from tartaric acid thus involved only the loss of two atomic proportions of hydrogen. It was a dibasic dihydroxy-acid; it showed no ketonic reactions; it could be reduced to racemic acid and oxidised to dihydroxytartaric acid. It was therefore either dihydroxyfumaric acid or dihydroxymaleic acid. It readily gave a diacetyl cyclic anhydride with acetyl chloride and was transformed into an isomeric acid by hydrobromic acid. Fenton therefore regarded it as dihydroxymaleic acid :

Its production from *d*-tartaric acid thus involves the *trans*-elimination of the two hydrogen atoms lost, and its reduction to racemic acid the *trans*-addition of hydrogen.

The most interesting reaction of the new acid was perhaps that brought about by heating with water. Two molecules of carbon dioxide were eliminated and glycollaldehyde was formed :

On re-examining this reaction with H. Jackson, he obtained the resulting glycollaldehyde in a bimolecular crystalline form. It had a sweet taste (it could be regarded as the simplest sugar) and Fenton showed subsequently that it could be degraded by Wohl's method to formaldehyde. With Ryffel, he showed that dihydroxymaleic acid could be oxidised to mesoxalic semialdehyde, a compound of considerable interest on account of its close relationship to the hypothetical trihydroxyacrylic acid of which uric acid is the diureide.

Nevertheless attempts to synthesise uric acid by condensing this compound with urea yielded only glycouril and carbon dioxide.

Further investigations showed that the new reagent—hydrogen peroxide in conjunction with ferrous salts—which acted on tartaric acid in so characteristic a manner, constituted a specific and valuable oxidant for certain classes of compounds. With H. Jackson, Fenton showed that di- or poly-hydroxy-alcohols with vicinal hydroxy-groups were smoothly and rapidly oxidised to hydroxy-aldehydes; for instance, glycol gave glycollaldehyde, glycerol glyceraldehyde, erythritol erythrose, and mannitol mannose. Monohydric alcohols, however, were not attacked. With H. O. Jones, he examined the effect of the new reagent on acids.  $\alpha$ -Hydroxy-acids were oxidised rapidly and with evident heat-evolution to the corresponding keto-acids; acids of other classes were unaffected. Thus glycollic acid was shown to be oxidised to glyoxylic acid, lactic acid to pyruvic acid, tartronic acid to mesoxalic acid, and glyceric acid to hydroxypyruvic acid, whilst from malic acid there was formed the previously unknown free oxalacetic acid. Fenton and Jones examined the reactions of this acid in some detail and among other observations found that its phenylhydrazone, heated with water, decomposed in two ways, either losing carbon dioxide to give pyruvic acid phenylhydrazone, or undergoing dehydration to a pyrazolone derivative. The relative proportion of these products depended on the hydrogen-ion concentration of the solution, and on this fact an approximate method of comparing the strengths of acids could be based.

The observation that dihydroxymaleic acid was converted into its diethyl ester by the action of an ethereal solution of hydrogen bromide led him to examine the action of this mixture on compounds of other classes. With Miss M. M. Gostling, he found that various carbohydrates, in particular fructose, gave a purple colour when dissolved in ether and treated with hydrogen bromide, and this proved to be due to an oxonium salt of a yellow crystalline compound which could be thus obtained in considerable quantity and was shown to be  $\omega$ -bromomethylfurfuraldehyde.

Among other observations of interest which he made may be mentioned the reduction of carbonic acid by magnesium to formaldehyde and the formation of a crystalline explosive compound of formaldehyde and hydrogen peroxide of the composition  $C_2H_6O_4$  and the probable constitution  $HO\cdot CH_2\cdot O\cdot O\cdot CH_2\cdot OH$ .

Fenton was gifted with keen powers of observation and acuteness of interpretation and the whole of his experimental work is marked by its elegance.

Of his books, those best known are his "Notes on Qualitative Analysis," which was based originally on a small book published by Liveing, but was greatly expanded in successive editions, and his

"Outlines of Chemistry." He was elected into the Royal Society in 1899, and served on the Council of that body from 1913 until 1916. He was made an honorary fellow of his College in 1911.

He was naturally a shy man and was exceedingly sensitive to chaff or criticism; he endeavoured to conceal his shyness by assuming a certain *hauteur* which tended to repel some of those who would have sought his friendship. He had a very strong sense of fairness, but his pertinacity in defending views in which he was in a minority of one sometimes made him a difficult member of University bodies. He married in 1892, Edith, daughter of George Ferguson of Richmond. He left no children. He gave up his lectureship in 1924 and went to live at Hove, but the last years of his life were greatly clouded by illness. He died in a nursing home in London on January 13, 1929, at the age of 74.

W. H. M.

---

### HENRY WILSON HAKE.

BORN DECEMBER 17TH, 1851; DIED JANUARY 18TH, 1930.

H. WILSON HAKE, who died in January aged 78, was the last surviving son of Dr. Thomas Gordon Hake, author of "Madeline," "Parables and Tales," and other poetic works.

He was educated privately up to 1872 and then went to the University of Giessen, where he took his Ph.D. (1875), and subsequently to Bonn for a short post-graduate course, studying under Professors Will and Kekulé. He formed a close friendship with the younger Will. After travelling for some time with his father in Italy, he returned to England and became an assistant to Thudichum, with whom the writer had for some two years previous been associated in researches chiefly concerning the chemistry of brain-matter.

For some years we were intimately acquainted and during that time we communicated a joint note to the Chemical Society on "Some New Reactions in Organic Chemistry," which was published with a supplemental note in the *Pharmaceutical Journal* of May 12th, 1877. We also contributed to the *Quarterly Journal of Science* (January, 1877) a joint critical essay on "Physiology and its Chemistry at Home and Abroad."

Hake became acquainted with my old friend Thomas Farries and upon leaving Thudichum he took charge of the laboratory of his firm (Messrs. Burgoyne, Burbidge, Cyriax, and Farries) for about one year: he was then appointed Lecturer on Chemistry at Queenswood College, Stockbridge, Hants (1879—1885). In 1885 he became Assistant Lecturer on Chemistry at

Westminster Hospital Medical School and assisted Dr. A. Dupré in his analytical and consulting practice; he also collaborated with him in the production of a "Manual of Inorganic Chemistry," published in 1886. In 1897 he succeeded Dupré as Lecturer on Chemistry and Toxicology and although the Chemistry Department was discontinued in about 1907 he continued to coach students for the D.P.H. degree and lectured on Toxicology up to June, 1929—some six months prior to his decease.

Hake was an examiner in Chemistry for the Civil Service Commission from 1894—about 1918, and for the Royal College of Physicians from 1898—1902: during the period 1901—about 1917 he was Lecturer on Toxicology at the London (Royal Free) Hospital School of Medicine for Women and from about 1922—1926 he served as Examiner on Public Health to the Conjoint Board of Physicians and Surgeons. He also served for many years as Gas Examiner to the Wandsworth Borough Council. In addition to his other activities he specialised in the analyses of mineral and ordinary waters and did a good deal of consulting work on poisons, drugs, medicines, etc. Among his publications may be mentioned a joint paper with Thudichum on "The Estimation of Hydrogen occluded by Copper, with Special Reference to Organic Analysis" (J., 1876); a joint paper with A. Dupré on "The Estimation of Organic Carbon in Air" (J., 1881); "A Preliminary Note on the Absorption of Moisture by Deliquescent Salts" (P., 1896); a note on "Further Experiments on the Absorption of Moisture by Deliquescent Substances" (P., 1897); an article entitled "Chemistry and Medicine" (*Westminster Hospital Reports*, Vol. 3, 1887); a further paper on the same subject (*ibid.*, Vol. 5); a joint paper with Dr. William Murrell on "Green, Blue, Magenta, and other coloured Urines" (*Edinburgh Med. J.*, 1906); a joint paper with Dr. S. Monckton Copeman entitled "A Study of the Variations in the Secretion of Hydrochloric Acid in the Gastric Contents of Mice and Rats as compared with the Human Subject, in Cancer" (*Proc. Roy. Soc.*, 1908, B, Vol. 80); "Report on Ferro-Silicon with Special Reference to the Poisonous Gases evolved" (extracted from supplement to the 38th Annual Report, Local Government Board, 1908—1909; Cd. 4958); joint Report with Dr. S. Monckton Copeman and S. R. Bennett, M.A., on the "Nature, Uses, and Manufacture of Ferrochrome and other Ferro-Alloys" (Reports, Local Government Board, New Series, No. 93, 1911); "The Action of Chlorine on the Blood" (*Lancet*, July 10th, 1915); and "Some Problems in Toxicology" (Post-graduate Lecture at the Westminster Hospital, 1924).

Hake became a Fellow of the Chemical Society in 1876, and a

Fellow of the Institute of Chemistry in 1878 and served on the Council (1901—1904). As will be obvious from what has been written above, he was specially interested in Toxicology and almost up to the time of his death he was occupied in the preparation of notes with a view to the publication of a text-book on that subject.

In 1890 Hake married Miss Mabel Mann (youngest daughter of Richard Mann of Bromley, Kent), who died in 1924, leaving as issue one son (the present Director of the National Portrait Gallery) and two daughters. Hake took the greatest possible interest in the education of his children. He was a good lecturer and teacher and had a great love of nature. Highly cultivated, of charming manners and retiring disposition, he was a lovable man and it is a matter of great regret to me as an old friend that I was able to see so little of him since our early intimate association.

CHARLES T. KINGZETT.

### WILLIAM WALKER JAMES NICOL.

BORN JUNE 27TH, 1855; DIED MARCH 19TH, 1929.

WILLIAM WALKER JAMES NICOL, the only son of William Walker Nicol and Marianne Ballantyne Nicol, both belonging to old Border families, and the nephew of James Nicol, Professor of Natural History, who elucidated the nature of the rock formation of the North-west Highlands, was born in Edinburgh in 1855. He was educated first in England, and later at the Edinburgh Academy, where he was a contemporary of the late Lord Haldane; in 1872 he proceeded to the Edinburgh University, where he took the M.A. degree. Attracted by chemistry, he turned his special studies in this direction in Professor Crum Brown's laboratory, and gained the medal of the year and the Hope Prize Scholarship, taking also the B.Sc. and finally the D.Sc. degree. After working at Berlin University under Professor A. W. Hofmann, he returned for a short time to Edinburgh University as demonstrator, and in 1876 was appointed lecturer at the newly founded University College, Bristol, now the University of Bristol. In 1880, Mason College, Birmingham, now the University of Birmingham, was founded, and in 1881, with William Augustus Tilden as professor, Nicol joined the staff as lecturer in chemistry: he retained this post until his retirement in 1894, following on Tilden's removal to the Royal College of Science, South Kensington.

During this period of 18 years Nicol proved himself a very successful lecturer and teacher. As a lecturer he was clear and logical and his lectures were appreciated, not only by his students, but by

wider and more popular audiences to whom he gave numerous lectures in the West of England and the Midlands, partly as University Extension Lectures and partly under the Gilchrist Trustees. As a teacher in the laboratory, he was indefatigable in his individual attention to his students, being at all times both able and willing to help them in their difficulties.

At this period, especially in newly founded Chemical Departments, the time of the members of the staff taken up in lecturing and in the daily work of the laboratory was frequently so great as to leave but little for research, and the equipment and apparatus available were often very limited. Nicol, however, always devoted as much time as could be spared from other duties to research work : he was greatly helped in this respect by the possession of an exceptionally good mechanical aptitude and an unusually skilful manipulative capacity, which enabled him to construct his own apparatus, whether of wood, metal, or glass, thus minimising the difficulties which many would have experienced owing to lack of equipment. At the outset, while in Berlin and later in Edinburgh, he carried out short investigations in organic chemistry, but the bent of his mind was much more towards inorganic and physical chemistry, and it was especially in this direction that he turned during his stay in Birmingham.

The particular problem which attracted Nicol was that of "solution," and from 1882 to 1894 he carried out a long series of investigations on the physical constants of salt solutions, and especially of their molecular volumes, these being ascertained with the high degree of accuracy characteristic of his work. In the controversies of the period, which just preceded the rapid development of physical chemistry in the 'nineties, he took a considerable part as an opponent of the "hydrate" theory of solution : he also acted as Secretary of the British Association Committee on Solution. He was a very expert photographer, and worked out the "Kallitype" printing process, in which silver nitrate and ferric salts were employed.

After his retirement from active teaching work in 1894, although he continued his chemical investigations for a time, Nicol's interests tended more and more to the fulfilment of the mechanical bent of his versatile inventive mind. One outlet of this, joined with his love of natural scenery and of the open air, was found in caravanning in the wildest parts of the Scottish Highlands, and along the narrowest and most difficult of roads in various types of caravan, first with a horse and later with the motor as tractor, the caravans, full of ingenious contrivances, being built and fitted entirely by himself.

Externally rather quiet and reserved, Nicol felt no great inclination for large meetings or social functions, but those who were regularly brought into contact with him soon learned how thin was this external layer, and beneath it soon recognised his high-minded sense of honour, his innate courtesy, and his intellectual capacity, and that these were combined with a great personal hospitality and a strong sense of dry humour. To those intimate with him he was to the end, even when opportunities of meeting became rare, a friend who continued always the same.

During most of his life Nicol enjoyed very robust health, and it was a legitimate source of pride to him that throughout the whole time he spent in Birmingham he was never for a single day absent from his work through illness. During the last year or so, however, his health failed, and he died in his 74th year on March 19th, 1929. He leaves a widow and one daughter, Dr. E. A. Traquair Nicol, who, after taking the B.A. degree at Cambridge and the Ph.D. at Edinburgh, is now carrying out zoological research in the laboratory of the latter University.

H. G. C.

---

### SAMUEL RIDEAL.

BORN, 1863; DIED NOVEMBER 13TH, 1929.

DR. SAMUEL RIDEAL, who died on November 13th last at the age of sixty-six, had been a Fellow of the Society since 1882, and for the greater part of his life was a familiar figure at its meetings and at those of kindred societies.

Rideal was born in 1863, being the son of Mr. John Rideal of Sydenham, and was educated at Dulwich College and at the Royal School of Mines, whence he migrated to University College, London; there he completed his degree course and acted for several years as an assistant teacher, first under Professor Williamson and later under Sir William Ramsay. He took Chemical Honours in his B.Sc. Degree and only two years later was awarded the Doctorate at the very early age of twenty-three—a considerable achievement in the days when the D.Sc. was awarded, not, as later, for original work, but as the result of an examination of almost encyclopædic range demanding, not only a severe course of intense reading, but also the possession of an exceptionally retentive memory. His investigational work in chemistry, which was varied and continuous and gave him a wide reputation, came later.

In 1886, however, he contributed to the *Transactions* of our Society by a paper on the "Action of Ammonia on Chromyl Dichloride" (J., 1886, 49, 367), and in 1889 a paper on the "Action of Ammonia on Tungsten Compounds" (J., 1889, 55, 41). But he

had already contributed some original observations on analytical methods to the *Chemical News* and a paper on "Isodimorphism" (in relation to the specific volumes of arsenic and antimony trioxides in their octahedral and prismatic forms) to the *Berichte* of the German Chemical Society (1886, 19, 589).

In 1889, after having received the honour of election as a Fellow of his College, Rideal was appointed Lecturer on Chemistry in the Medical School of St. George's Hospital; and soon after, on his appointment as Public Analyst for Chelsea, he established himself as a chemical consultant at Westminster.

A communication from him to the German Chemical Society on "Organic Boron Compounds," dealing with the action of boron halides on ammonia and on organic bases, was published in the *Berichte* (1889, 22, 992). He gradually, however, turned his attention mainly to problems of a technical nature, his first memorable contribution in this direction being a paper, with S. G. Rosenblum as co-author, on the "Estimation of Chromium in Chrome Iron Ore, Ferro-chromium, and Chrome Steel," in which were communicated the results of a searching investigation into the method of fusion with sodium peroxide which had been put forward by Hempel in 1893 and adapted for quantitative purposes by Dr. John Clark as described in a communication by the latter to our own Society (J., 1893, 63, 1079): the subject was further pursued by Rideal and Rosenblum in a paper in the *Chemical News* (1896, 73, 1), to which was appended a very complete bibliography of other work on the same process.

Rideal's attention, however, became concentrated on matters connected with sanitation, mainly those bearing upon water supplies and, more especially, upon the disposal and purification of sewage and sewage effluents; on this subject he became a generally acknowledged authority, his assistance being constantly requisitioned by engineers and by local authorities, and he was frequently called upon to give evidence before Royal Commissions, Departmental Committees, and Local Government enquiries relating to sewage disposal or public water supplies.

Rideal also gave a good deal of attention to disinfectants and his name has for many years been familiar in connexion with the Rideal-Walker method for assessing the value of disinfectants on the basis of comparison with pure phenol by ascertaining their relative effect on cultivations of *Bacillus typhosus*.

He was the author of a book entitled "An Introduction to the Study of Disinfection and Disinfectants," first published in 1895, with subsequent editions in 1898 and 1904, which work, however, was superseded by a later edition by himself and his son, Dr. Eric

K. Rideal, on "Chemical Disinfection and Sterilisation" published in 1921.

He was also the author of a book on "Sewage and the Bacterial Purification of Sewage," first published in 1900 and re-published in 1901 and 1906; and in 1914, again jointly with his son, he published what has come to be regarded as a standard work on "Water Supplies, their Purification, Filtration, and Sterilisation."

The application of electrolytic chlorine to sewage purification and deodorisation engaged Rideal's attention over several years, and he was the author of two papers on the subject (*J. Roy. Sanit. Inst.*, 1905, 26, 378; *J. Soc. Chem. Ind.*, 1909, 215).

He was also the author of a book on "Glue and Glue Testing"; and made several communications to the Society of Public Analysts recorded from time to time in the *Analyst*. Amongst these were papers on "The Sulphuric Acid Hydrolysis of Butter-Fats" (1893, 18, 165); on "Formalin as a Milk-Preservative" (1895, 20, 157); on "Determination of Dissolved Oxygen in Waters in Presence of Nitrites and of Organic Matter" (1901, 26, 141); (jointly with H. G. Harrison) on the "Polenske Method for the Detection of Cocoanut Oil in Butter" (1906, 31, 254); (jointly with W. T. Burgess) on the "New Standards for Sewage Effluents" (1909, 34, 193); (jointly with L. H. D. Acland) on "Examination of the Oils from Manihot Ceara and Funtumia Elastica and a Comparison of their Properties with those of Linseed and Hevea Oils" (1913, 38, 259).

Rideal was chosen as Cantor Lecturer to the Royal Society of Arts in 1902, taking as his subject "Water Purification" (*J. Soc. Arts*, 1902, 50, 717, 729, 741, 755).

He was President of the Association of Sewage Works Managers in 1902, and President of the Society of Public Analysts in 1918; and he served a period as Examiner in Chemistry to the Royal Colleges of Physicians and Surgeons.

During recent years Rideal's health gradually failed, compelling him to give up—it was hoped only for a time—active work, and on medical advice he sought change of scene abroad; but the hoped-for recovery did not ensue and he died with unexpected suddenness in South Africa, leaving a widow (Lilla, daughter of the late Samuel Keightley, of Bangor, Co. Down), one daughter, and three sons, including Dr. Eric K. Rideal, Owen Jones Lecturer in Physical Chemistry in the University of Cambridge, already referred to in connexion with two books of which, with his father, he was joint author.

The writer deplores the termination of an intimate personal friendship which had lasted unbroken through more than forty years.

BERNARD DYER.

## SAMUEL BARNETT SCHRYVER.

BORN, 1869; DIED AUGUST 21st, 1929.

SAMUEL BARNETT SCHRYVER was born in London in 1869 and was educated at University College School, University College, and the University of Leipzig, where he graduated Ph.D. After his return to England he was appointed in 1893 Demonstrator in Chemistry under Campbell Brown at University College, Liverpool, where he remained until 1897. Early in 1898 he joined the staff of the Wellcome Research Laboratory and retained this position until March 1901, when he was appointed Lecturer in Physiological Chemistry at University College, London. Up to this time he had been engaged in research on a variety of subjects in Organic Chemistry, but here for the first time he came into direct contact with biochemical problems and henceforward until his death he was continuously engaged in biochemical and physiological research. He left University College in 1907, on his appointment as Physiological Chemist to the Research Institute of the Cancer Hospital, and in 1913 joined the Staff of the Imperial College of Science at South Kensington as Assistant Professor, becoming full Professor of Biochemistry in 1920. Schryver was elected to the Fellowship of the Royal Society in 1928. He died on August 21st, 1929 after an illness of several months' duration.

Trained as an organic chemist, Schryver developed into a biochemist whose chief interest lay in the chemical and physical behaviour of the proteins and other colloidal constituents of the cell. Gifted with a fertile imagination, he was never lacking in ideas for new lines of research, many of which he himself began to develop. He leaves behind him a band of workers trained in his laboratory, many of whom are continuing the work commenced under his inspiration.

In 1910 Schryver married Miss E. Davies, who, with their two daughters, survives him.

Schryver's first paper (1890) was published in conjunction with Norman Collie, under whom he studied, on the effect of heat on quaternary ammonium compounds and the nature of the tertiary amine thus formed when the radicals of the quaternary compound were varied. This led to an attempt (1891) to prepare stereoisomeric compounds of the quaternary ammonium salt type (methyldiethyl-isoamylammonium iodide). Certain differences in crystallisation (probably due to dimorphism) were regarded as possibly due to the effect of asymmetry of the nitrogen atom.

At Liverpool he commenced the study of the oxidation of oil of turpentine, from which he obtained a new acid (terpylonic acid).

The heptolactone formed by distillation of terpenylic acid and an isomeric lactone were synthesised and their constitutions thus established. He next turned to researches on the derivatives of camphor, effecting the synthesis of an isomeride of camphoric acid and studying the oxidation products of lauronic acid.

From the Wellcome Research Laboratories he published papers on acid phenyl salts of dibasic acids, which were obtained by acting on the anhydrides of such dibasic acids as camphoric, succinic and phthalic acids with the sodium salt of a phenol. Here too he commenced (with F. H. Lees) an investigation on morphine and published two papers on this subject, dealing with *iso*- and  $\beta$ -*iso*-morphine. He also devised a method for the estimation of phenols, depending on the production of ammonia from sodamide by the action of the dry phenol dissolved in anhydrous benzene.

At University College, in the course of unsuccessful attempts to effect the synthesis of proteins from peptones in presence of intestinal mucous membrane, his attention was drawn to the phenomenon of autolysis, which was investigated (partly in collaboration with Miss Lane Claypon) in some detail (1904, 1905, 1906). He finally reached the conclusion that the autolysis of the organs *in vivo* was regulated by chemical means and that the normal supply of nitrogenous food yielded by its breakdown sufficient ammonia to prevent the tissues from becoming acid and then undergoing autolysis.

Whilst at University College he also made experiments (with Hamill) on the excretion of nitrogen by normal individuals, finding that it corresponded to a daily intake of 93 g. of protein. In the course of investigations carried out for the Local Government Board he devised new and delicate methods for the detection of tin and of formaldehyde in foodstuffs. The application of the latter test enabled him to show the production of formaldehyde when chlorophyll was exposed to sunlight in the presence of moist carbon dioxide.

At the Cancer Hospital he carried out with Dr. C. Singer investigations on the gastric juice in malignant and non-malignant diseases of the stomach and duodenum (1913) in which chemical methods (*e.g.*, determination of the peptic index and of the ratio of acid combined with amino-acids to total nitrogen) were applied to diagnosis. To the last he retained an intense interest in the biochemistry of cancer. Here he also began work on the state of aggregation of matter, which led directly to the study of clot formation, the results of which formed the subject of a series of seven papers published between 1910 and 1919. These included useful

studies of the relation between the viscosity and surface tension of salt solutions and the effect of these salts on clotting and gel formation and an intensive examination of the clotting of milk by rennin, in the course of which he showed that caseinogen is converted into a less soluble "metacaseinogen" by treatment with hot water but that this substance differs in properties from the casein produced by rennin. He also (1912) made a study of the unconjugated acids of ox-bile and devised a method of separation of cholalic, choleic and deoxycholeic acids, depending on the solubilities of their magnesium and barium salts.

Schryver's deep interest in gel formation was maintained in the investigations which he carried out at the Imperial College. These followed two main lines. In the first place he attacked the constituents of plant cells, preparing and studying the proteins of leaves and also studying the cell wall, from which he isolated the pectins and hemicelluloses which take a part in its structure. He came to the conclusion that pectinogen is a trimethyl ester of pectic acid combined loosely with metallic ions, such as  $\text{Ca}^{++}$ , and that pectic acid and the hemicelluloses, a number of which were isolated from various materials, were both complexes of "uronic acids" and sugars, as suggested by Ehrlich and Ling. For such complexes he suggested the name "polyuronides." Lignification of tissue he found (1928) to be accompanied by the disappearance of pectins.

The second group of researches arose from work done under the auspices of the Adhesives Research Committee, of which he was made a member. This Committee was appointed by the Department of Scientific and Industrial Research in 1919 to take over the work of the Adhesives Committee originally appointed by the Conjoint Board of Scientific Societies in the latter part of 1917. This work, carried out largely in conjunction with his students, resulted in two series of papers, on the preparation, purification and properties of gelatin and on the separation of the products of protein hydrolysis. Many of these results are also contained in the First and Second Reports of the Adhesives Research Committee (1922, 1926): a Third Report, also containing much of his work, is in course of preparation.

The formation of gelatin from its precursors collagen and ossein was studied from the physico-chemical standpoint. Elaborate attempts were made to "purify" gelatin and obtain a material which could be regarded as a chemical entity, but without complete success. He found that a large degree of purification could be effected by electrolysis and by flocculation in an electric field. The resulting material, however, is probably always to some degree

contaminated by products formed by the action of water, which produces an irreversible change, measurable in a few hours, even at 37°. Such "purified" gelatin is almost insoluble in water at 15° and is very similar in properties to the globulins, from which it differs by its power of readily forming gels when dispersed in acids, alkalis or salts.

In the course of these researches the important observation was made (Knaggs, 1923) that the composition of gelatin was not constant, but varied with the treatment to which either the gelatin itself or its precursor had been subjected. This was detected by a variation in the percentage of the total nitrogen of the hydrolysis products which were precipitated by phosphotungstic acid (diamino-nitrogen). For instance, the hydrolysis products of gelatin from a precursor which had been treated with dilute alkali yielded 29.5%, whereas those of gelatin from the same precursor treated with dilute acid gave only 26.0% of diamino-nitrogen; gelatin itself showed similar changes, but of even greater magnitude.

These results have been criticised by Daft, working in the Carlsberg Laboratory, but the criticism has been refuted by Thimann (1930), one of Schryver's students, who has explained the apparent divergence of experimental results. The investigation of this phenomenon led to the work on the separation of the products of protein hydrolysis. In this pioneering work, which must be regarded as preliminary and awaiting further extension and confirmation, Schryver developed a method of separation of the products of protein hydrolysis which depended on the use of Siegfried's barium carbamate compounds of the amino-acids. In this way he obtained from the hydrolysis products of isinglass (and of edestin, but not of caseinogen or egg-albumin) hydroxylysine, in the form of a barium carbamate soluble in 70% alcohol but insoluble in cold water, whilst from the glutelin which he isolated from oats he obtained two new aminohydroxy-acids, aminohydroxybutyric acid, which forms an insoluble copper salt, and aminohydroxyvaleric acid, which forms a soluble copper salt.

In addition to this he obtained a new eight-carbon acid,  $C_8H_{15}O_3N_3$ , which he termed protoctin, from the phosphotungstic acid precipitate obtained from the soluble carbamate from glutelin and the protein of castor bean. Finally, *DL*-lysine was obtained from gelatin which had been treated with acid before being hydrolysed and to this the increased percentage of diamino-nitrogen found in such gelatin was traced. No clue was, however, found to the origin of this extra lysine.

Schryver (with Chibnall) also initiated an investigation into the

proteins of leaves, which has been continued with great success by Chibnall. He, moreover, isolated a crystalline substance,  $C_3H_8O_4$ , from cabbage leaves, which he regarded as a disaccharide derived from glycollaldehyde and formaldehyde.

From 1918 up to the time of his death he was also engaged in researches on the autolysis and nutrition of yeast in connexion with the Research Scheme of the Institute of Brewing. The interesting fact was observed that when yeast is washed it is only autolysed very slowly, and much work was expended in endeavouring to trace the presumed agent removed by washing, but without any definite result. The work on yeast nutrition had only reached a preliminary stage at the time of Schryver's death.

He was the author of two books. "An Introduction to the Study of Biological Chemistry" (1918) provided a general introduction to Organic Chemistry, followed by special chapters on the chief chemical constituents of the animal body (fats and lipoids, carbohydrates, proteins); the methods employed for the investigation of chemical changes within the animal organism (metabolism, total and intermediary); and the chemical processes taking place in plants (including enzyme actions). This was also the plan he adopted in his lectures. He also contributed in 1909 an early volume to Longman's Series of Monographs on Biochemistry on the general characteristics of the proteins.

A. HARDEN.

---

## CXII.—*The Isomerism of the Butylideneacetones.*

By EUSTACE NEVILL ECCOTT and REGINALD PATRICK Linstead.

THE movement of the double bond in unsaturated ketones containing an unbranched carbon chain has been but little investigated, although a considerable number of allied substances with a  $\beta$ -substituent, of the type of mesityl oxide, have been studied. The only direct investigation of the normal ketones is that of Blaise (*Bull. Soc. chim.*, 1905, **33**, 40), who showed that allyl alkyl ketones were readily converted into their  $\Delta^{\alpha}$ -propenyl isomerides by both acid and alkaline catalysts, a process involving an apparently irreversible movement of the double bond from the  $\beta\gamma$ - to the  $\alpha\beta$ -position. In attempting to correlate these earlier observations with the recent work on three-carbon tautomerism, we were led to examine the related pentenyl methyl ketones. At the outset, however, certain unexpected features were encountered in the preparation of the  $\alpha\beta$ -ketone, *n*-butylideneacetone, from *n*-butaldehyde and acetone, and this reaction was systematically reinvestigated.

The condensation of aldehydes with ketones, and more particularly acetone, originally examined by Schmidt and by Claisen and extended to aliphatic aldehydes by Barbier and Bouveault (*Compt. rend.*, 1895, **120**, 1270), was first applied to *n*-butaldehyde by Weizmann and Garrard (J., 1920, **117**, 324), who isolated an unsaturated ketone to which the formula (I) was given.

Under milder conditions, Grignard and Dubien (*Ann. Chim.*, 1924, **2**, 287) were able to isolate the ketol (II), a type of compound already recognised as an intermediate in such reactions (Claisen, *Ber.*, 1892, **25**, 3164; Francke and Kohn, *Monatsh.*, 1899, **20**, 876). Dehydration of (II) with iodine yielded a ketone (semicarbazone, m. p. 118°) identical with that of Weizmann and Garrard.

As a result of a large number of experiments on this condensation, using aqueous alkali as catalyst, we find that under most conditions mixtures of unsaturated ketones and ketol are produced. It has, however, been possible to develop one method by which an unsaturated ketone is obtained direct in a state of considerable purity, and one, similar to that of Grignard and Dubien, for preparing the pure ketol (II). Dehydration of this has been investigated with iodine, acetic anhydride, and anhydrous oxalic acid, all of which produce an unsaturated ketone giving a semicarbazone melting at 124° after repeated crystallisation, the purest material being that obtained with oxalic acid as dehydrating agent. The butylideneacetone of previous workers is believed to be essentially this substance. If the original condensation is carried out rapidly and no attempt is made to check the development of heat, the product is composed of unsaturated ketone almost free from ketol. This ketone is, however, not identical with that obtained by dehydration of the ketol. It is higher-boiling, denser, and more refractive and readily gives a semicarbazone, m. p. 152°. Both ketones give the analytical figures required for  $\text{C}_7\text{H}_{12}\text{O}$  and the semicarbazones also give the correct analytical values and depress each other's melting point. It is clear that these are two distinct substances, which may represent either structural isomerides differing in the position of the double bond or geometrical isomerides with the same position of the double bond.

Both ketones showed exaltations in the molecular refractivity (1.11 and 1.15 units) and had low iodine addition values (8 and 2%) (Linstead and May, J., 1927, 2565). Again, both resisted the action of ozone but yielded acetic and *n*-butyric acids on complete oxidation with alkaline permanganate. All doubt as to their

constitution was finally removed by the synthesis of the compound with the only possible alternative formula, the  $\beta\gamma$ -isomeride (III), from the acid chloride of  $\Delta^{\beta}$ -*n*-hexenoic acid (Eccott and Linstead, J., 1929, 2153) and zinc methyl iodide. The ketone so prepared,  $\text{CH}_3\text{Me}\cdot\text{CH}\cdot\text{CH}\cdot\text{CH}_2\cdot\text{COMe}$  (III), was a different substance. It had a high iodine addition value (70%), readily yielded propaldehyde on ozonisation, and gave a *semicarbazone*, m. p. 109–110°. No solid compound was formed when it was treated with ethyl sodio-malonate, whereas the other two ketones yielded the same 5-*n*-propyldihydroresorcinol,  $\text{CHPr}\cdot\begin{array}{c} \text{CH}_2-\text{CO} \\ \text{CH}_2-\text{C}(\text{OH}) \end{array}\cdot\text{CH}$  (IV), by this reaction and subsequent hydrolysis. The first two ketones must therefore be regarded as *cis*- and *trans*-modifications of *n*-butylideneacetone about the  $\alpha\beta$ -double bond.

Geometrical isomerism of this type in ketones has only recently been observed and has received no systematic study. Locquin and Heilmann (*Compt. rend.*, 1928, **186**, 705) have isolated two forms of two  $\alpha$ -alkyl unsaturated ketones, and the presence of a similar isomerism in the homomesitones is suggested by certain properties of these substances (Abbott, Kon, and Satchell, J., 1928, 2514). In addition, a number of styryl ketones containing the skeleton  $\text{CHPh}\cdot\text{CH}\cdot\text{COR}$  have been found to exist in coloured and colourless modifications (Haber, *Ber.*, 1891, **24**, 618; McGookin and Heilbron, J., 1924, **125**, 2099, and subsequent papers; Dilthey and Radmacher, *Ber.*, 1925, **58**, 361, *et cet.*). The isomerism shown by these compounds differs materially from that of the butylideneacetones. The isomeric styryl ketones have the same melting points and give identical derivatives (Wilson, Heilbron, and Sutherland, J., 1914, **105**, 2892). They are also noteworthy for the ease with which the less stable pass into the more stable forms.

In determining the configuration of the *n*-butylideneacetones, advantage was taken of their close relationship with  $\Delta^{\alpha}$ -*n*-hexenoic acid. Von Auwers and Wissebach have shown (*Ber.*, 1923, **56**, 715) that solid crotonic acid is almost unquestionably the *trans*-isomeride and von Auwers (*Annalen*, 1923, **431**, 46) found that it is this form of the acid which is produced from acetaldehyde by the Döbner reaction. It is reasonable to suppose that  $\Delta^{\alpha}$ -*n*-hexenoic acid (m. p. 33°), which is the almost exclusive product from *n*-butaldehyde in the Döbner reaction, also has the *trans*-configuration. When its acid chloride was condensed with zinc methyl iodide, the lower-boiling butylideneacetone was obtained, yielding the *semicarbazone* of m. p. 124° in a state of purity. The connexion indicated by this reaction was confirmed by the oxidation of this modification of the ketone with sodium hypochlorite, pure solid  $\Delta^{\alpha}$ -*n*-hexenoic acid

being obtained. As a first assumption, therefore, this butylideneacetone is the *trans*-isomeride and the *cis*-configuration must be assigned to the ketone with semicarbazone of m. p. 152°, prepared by direct condensation. We endeavoured to confirm this view by studying the relative ease of cyclisation of the two ketones, e.g., with concentrated sulphuric acid, to dihydrotoluenes, but deep-seated changes invariably occurred. When the *cis*-ketone was oxidised with sodium hypochlorite, a liquid acid was obtained giving long needles of m. p. 3°. This acid yielded the dibromide and anilide of solid (*trans*-)*n*-hexenoic acid and is regarded as a mixture of this acid with its as yet unknown *cis*-isomeride. It will be further investigated.

The isomeric *n*-butylideneacetones strongly resist configurational changes: for instance, the ketones regenerated from the semicarbazones by dilute acid re-form these derivatives in a state of purity. Bromine in an inert solvent, which has so marked an effect on configurational changes in acids, is rapidly absorbed with no apparent change in the unattacked ketone. Boiling dilute sulphuric acid has no pronounced effect, although it somewhat diminishes the purity of the ketones as measured by the readiness with which they yield pure semicarbazones. Hydrobromic acid, however, combines additively with both isomerides, giving a bromo-ketone which, when decomposed with aqueous potassium bicarbonate, yields the *trans*-ketone. In this way it is possible to convert the *cis*-form into its isomeride.

It was hoped to study the tautomeric change between the  $\beta\gamma$ - and the two  $\alpha\beta$ -ketones under the conditions previously used for such determinations. Unfortunately, all these ketones were readily converted into high-boiling products by the action of alkaline catalysts such as piperidine, sodium ethoxide and even sodium isopropoxide (Kon and Linstead, J., 1929, 1269). The  $\beta\gamma$ -ketone was, however, converted into the *trans*- $\alpha\beta$ -ketone with boiling 20% sulphuric acid (compare Blaise, *loc. cit.*; Kon and Linstead, J., 1925, 127, 815). Treatment in this way for 9 hours yielded a mixture of ketones with an iodine addition value of 32% (equivalent to about 75% of  $\alpha\beta$ -ketone), giving the *trans*- $\alpha\beta$ -semicarbazone, and further treatment did not appreciably affect this. It is remarkable that it was not found possible to produce the  $\beta\gamma$ -ketone—as shown by an increase in iodine addition—from either form of the  $\alpha\beta$ -ketone under these conditions. In any case, it is clear that the  $\alpha\beta$ -position of the double bond is the more stable as in the corresponding acids (Fittig, *Annalen*, 1894, 283, 47; Goldberg and Linstead, J., 1928, 2343). The  $\beta\gamma$ -ketone could also be converted into the  $\alpha\beta$ - by addition and elimination of hydrogen bromide. Here the product had an

iodine addition value of 32% and yielded the semicarbazone of the *trans*- $\alpha\beta$ -ketone. In view of the proved "abnormal" addition of hydrogen bromide to many  $\beta\gamma$ -unsaturated compounds, for example, to  $\Delta^1$ -cyclohexenylacetic acid (Wallach, *Annalen*, 1907, **353**, 289), the bromine entering the  $\beta$ - and the hydrogen the  $\gamma$ -position, it is unnecessary to assume with Blaise (*loc. cit.*) that the first stage in such a process is an isomeric change to the  $\alpha\beta$ -form, followed by a "normal" addition.

Attention was next directed to the isomeric ketones derived from isobutaldehyde. The condensation of this with acetone has been studied by Barbier and Bouveault (*loc. cit.*), who appear to have isolated only a crude product, and by Francke and Kohn (*loc. cit.*), who isolated both a ketol (V), the dehydration of which was not studied, and an unsaturated ketone (VI), b. p. 157°/750 mm.

Kishner (*J. Russ. Phys. Chem. Soc.*, 1913, **45**, 987) records the formation of an isobutylideneacetone (semicarbazone, m. p. 162—163°).

Using the method of Francke and Kohn, we isolated an unsaturated ketone which readily yielded a pure semicarbazone of m. p. 126°. The ketol (V) was prepared by a method similar to that used in the *n*-series and was dehydrated by iodine to yield an unsaturated ketone very similar to the first but giving a semicarbazone, m. p. 160°, which depressed the m. p. of the derivative already prepared. Francke and Kohn oxidised their ketone to  $\Delta^{\alpha}$ -isohexenoic acid, and we have confirmed this relationship by synthesising this form of the ketone (semicarbazone, m. p. 126°) from  $\Delta^{\alpha}$ -isohexenoyl chloride and zinc methyl iodide. As before, therefore, the ketone with the lower-melting semicarbazone is taken to be the *trans*-form. To show conclusively that neither form had the  $\beta\gamma$ -structure (VII), this ketone was independently prepared from pyroterebyl chloride (VIII) and zinc methyl iodide.

It is of interest that, although the action of thionyl chloride on pyroterebic acid fails to yield a pure product owing to the addition of hydrogen chloride to the double bond (Linstead, *J.*, 1929, 2498), the action of phosphorus trichloride in benzene gives the unsaturated acid chloride (VIII) in a state of purity. The new ketone (VII) has a high affinity for iodine, whereas the isobutylideneacetones have practically none, and moreover yields a distinct semicarbazone.

It has been shown that the presence of two  $\gamma$ -methyl groups in a three-carbon system is accompanied by great stability of the

$\beta\gamma$ -double bond; for example, in pyroterebic acid (Goldberg and Linstead, *loc. cit.*) and its ethyl ester (Linstead, *loc. cit.*). It was therefore of great interest to find that the ketones in the *iso*-series differed abruptly from those of the normal series in that the  $\beta\gamma$ -were the more stable forms. The *trans*- $\alpha\beta$ -ketone was converted to the extent of some 80% into its  $\beta\gamma$ -isomeride on being boiled with dilute sulphuric acid, and the same change could be effected by the addition and elimination of hydrogen bromide. In some respects these ketones resemble those investigated by Kon (J., 1926, 1792) with a *cyclohexane* ring in place of the  $\gamma$ -gem-dimethyl group.

Another difference between the two series is that on dehydration the *n*-ketol yields the *trans*-, and the *iso*-ketol the *cis*-, form of the unsaturated ketone. Direct condensation under vigorous conditions proceeds differently in the two cases, for the *n*-aldehyde gives a *cis*-ketone, and the *iso*-aldehyde the *trans*-, but this difference appears to depend largely upon the experimental conditions. For instance, Weizmann and Garrard (*loc. cit.*) obtained a fairly pure *trans*-*n*-butylideneacetone by direct condensation, whereas Kishner's ketone (*loc. cit.*) seems to have been the *cis*-form of isobutylideneacetone. In many condensations in the early stages of the present work mixtures of  $\alpha\beta$ -ketones were obtained and it is probably largely a matter of chance that the methods eventually developed to give individual products yielded a *trans*-form in one series and a *cis*-form in the other. In any case, it must be assumed that, whatever the configuration of the final product, the reaction first proceeds through the ketol, which subsequently loses water under the conditions used in the "direct condensation." This being so, it is a matter of interest that the pure *isolated* ketol is not dehydrated when treated with alkali under these conditions.

The investigation of these and related compounds will be continued.

[*Added to proof.*].—The publication of an abstract (A., 1930, 325) has directed our attention to a paper of Locquin and Heilmann (*Bull. Soc. chim.*, 1929, 45, 1126). These authors obtained an *iso*-butylideneacetone of indefinite b. p. which failed to yield a pure semicarbazone. This they regard as indicating the existence of stereoisomeric forms of the ketone and semicarbazone, a view which is amply confirmed by the isolation in the present work of the two individual ketones and their derivatives. There seems little doubt that the  $\beta\gamma$ -ketone of Locquin and Heilmann is identical with ours, but we consider Kishner's ketone, produced by direct condensation (*loc. cit.*), to be the *cis*- $\alpha\beta$ -form and not the  $\beta\gamma$ - as suggested by Locquin and Heilmann. The semicarbazones provide no useful

evidence, but the physical properties of Kishner's ketone agree with those of our  $\alpha\beta$ -forms rather than with those found for the  $\beta\gamma$ - by Locquin and Heilmann and in the present work. Further, Kishner prepared 3-methyl-5-isopropylpyrazoline in 90% yield from his ketone by a reaction which Locquin and Heilmann themselves use as being selective for  $\alpha\beta$ -ketones (*loc. cit.*, p. 1118).

#### EXPERIMENTAL.

##### *Normal Series.*

*Condensation of n-Butaldehyde with Acetone.*—(a) *Production of the ketol.* Grignard and Dubien's method gave good yields of total condensation product, but this always contained a considerable proportion of dehydrated material. The following process caused less dehydration than any other used. To a mechanically stirred mixture of caustic soda (20 g.) in water (40 c.c.) and acetone (116 g.) kept between 5° and 10°, *n*-butaldehyde (72 g.), diluted with acetone (58 g.), was added during 3 hours. After an hour's stirring, the aqueous layer was separated and extracted with ether, and the extract added to the oil. The combined product was neutralised with dilute acetic acid, washed with sodium bicarbonate solution and a little water, and dried over anhydrous potassium carbonate. The acetone and ether were removed by suction and the residue was distilled under reduced pressure. A little water and then a fraction (b. p. 68—92°/12 mm.; 30 g.) containing some unsaturated material distilled over, followed by the ketol (40 g.), b. p. 95°/12 mm.

Reducing the *amount* of caustic soda lowers the yield and reducing its *concentration* by the addition of water has the same effect and results in the formation of high-boiling material derived from the aldehyde.

Heptan-8-ol- $\beta$ -one (II) (Grignard and Dubien, *loc. cit.*) is a pale yellow liquid with a faint odour,  $d_4^{20}$  0.9296,  $n_D^{20}$  1.4357 (Found: C, 64.8; H, 10.7. Calc.: C, 64.6; H, 10.8%). Treatment of the ketol with 25% aqueous caustic soda (8 vols.) at the b. p. or with shaking in the cold for 3 hours gave only unchanged ketol and high-boiling material.

(b) *Production of cis-n-butylideneacetone* (I). To a mixture of acetone (145 c.c.) and 15% aqueous caustic soda (320 c.c.), *n*-butaldehyde (178 c.c.) was added in a slow stream. The vigorous reaction was at first allowed to proceed under reflux and finished by mechanical shaking for 2—3 days. The aqueous layer was extracted with ether and the extract was added to the organic portion, which was then washed with water and dried with calcium chloride. After removal of the low-boiling material, the residue was fractionated under reduced pressure. The crude ketone had b. p. 70°/12 mm.,

but contained water which could not be removed by ordinary drying agents. An equal volume of dry benzene was added which was then distilled off at ordinary pressure through a column (compare Grignard and Dubien, *loc. cit.*). The dry ketone obtained by fractionation of the residue (50 g.) had b. p.  $67-70^{\circ}/12$  mm.,  $d_4^{25}$  0.8507,  $n_D^{25}$  1.4470,  $[R_L]_D$  35.22. The iodine addition value was 4%. This and all other iodine addition values referred to in this paper were obtained by using 10-minute reactions in chloroform solution (Linstead and May, *loc. cit.*). If the amount of alkali and water used in the condensation was similar to that used in the preparation of the ketol, and the reaction was allowed to proceed vigorously, mixtures of ketol and ketone were obtained.

The *cis*-ketone so prepared was nearly free from its isomeride, as shown by the purity of the semicarbazone, which could only be obtained in quantity when the following precautions were observed. The ketone (20 g.) was added to a cold solution of semicarbazide hydrochloride (20 g.) in the minimum quantity of saturated aqueous sodium acetate. Miscibility was established with alcohol, and a seeding crystal introduced together with enough water to prevent its solution. Precipitation of the semicarbazone was allowed to occur at room temperature, the product being cooled in a freezing mixture before filtration. The material so obtained was micro-crystalline, melting at  $143^{\circ}$ , and at  $152^{\circ}$  after one crystallisation. The m. p. could not be further raised (Found: C, 57.1; H, 9.1.  $C_8H_{15}ON_3$  requires C, 56.8; H, 8.9%). The semicarbazone (22 g., m. p.  $152^{\circ}$ ) was intimately mixed with 25 g. of crystallised oxalic acid and the very volatile ketone was distilled in a current of steam, isolated by means of ether, and dried in the manner already described. Yield, 80%.

*cis*-Butylideneacetone so obtained is a colourless pleasant-smelling liquid, b. p.  $70^{\circ}/15$  mm.,  $d_4^{25}$  0.8555,  $n_D^{25}$  1.4505,  $[R_L]_D$  35.22 (calc., 34.07) (Found: C, 74.7; H, 10.7.  $C_7H_{12}O_2$  requires C, 74.9; H, 10.8%). The pure ketone has an iodine addition value of 2.3% and immediately yields the semicarbazone, m. p.  $152^{\circ}$ , in a state of purity.

*Dehydration of the Ketol.*—(i) *With iodine.* By the method of Grignard and Dubien, 40 g. of the ketol yielded 24 g. of ketone, b. p.  $58-62^{\circ}/16$  mm.,  $d_4^{25}$  0.8493,  $n_D^{25}$  1.4408,  $[R_L]_D$  34.8, iodine addition value 23.4%.

(ii) *With acetic anhydride* (Claisen, *Annalen*, 1899, 306, 326). The ketol (42 g.) was refluxed with acetic anhydride (50 g.) for 3 hours. Direct distillation of the product under reduced pressure yielded no evidence of acetylation, the material boiling between  $50^{\circ}$  and  $71^{\circ}/5$  mm. After the addition of an excess of sodium carbonate

the product was distilled in steam and the ketone was isolated in the usual way and redistilled. The product (28 g.) had b. p.  $60^{\circ}/10$  mm.,  $d_4^{25}$  0.8507,  $n_D^{25}$  1.4449,  $[R_L]_D$  35.06, iodine addition 11.2%.

(iii) *With oxalic acid* (Pauly and von Berg, *Ber.*, 1901, **34**, 2092). 32 G. of the ketol were heated on the water-bath for 2 hours with 46 g. of anhydrous oxalic acid. Hydrated oxalic acid crystallised from the reddish-brown syrupy residue, which was distilled in a current of steam. The ketone, isolated in the usual way (19 g.), had b. p.  $62-64^{\circ}/12$  mm.,  $d_4^{25}$  0.8450,  $n_D^{25}$  1.4432,  $[R_L]_D$  35.18, iodine addition 8.2%.

The products obtained by all these methods yielded a *semicarbazone* which crystallised from dilute alcohol in white silvery plates, m. p.  $128^{\circ}$  (Found: C, 56.9; H, 9.2.  $C_8H_{15}ON_3$  requires C, 56.8; H, 8.9%). The product from the iodine dehydration yields this with comparative difficulty, and the oxalic acid method is the most satisfactory for preparing a homogeneous ketone. The ketone from each method contains water which cannot be removed by ordinary drying agents (compare Grignard and Dubien, *loc. cit.*) (Found: C, 72.9; H, 10.4%). Dried by distillation with benzene in the manner already described, *trans-n*-butylideneacetone was obtained as a colourless liquid with a pleasant odour differing somewhat from that of the *cis*-isomeride. It had b. p.  $62^{\circ}/15$  mm.,  $d_4^{25}$  0.8445,  $n_D^{25}$  1.4430,  $[R_L]_D$  35.18, iodine addition 9.0%. Ultimate analysis is difficult and tends to give low results for this type of ketone, as has been noticed by other workers (Claisen, Francke and Kohn, Weizmann and Garrard, *loc. cit.*) (Found: C, 74.3; H, 10.5. Calc.: C, 74.9; H, 10.8%). Unlike the *cis*-ketone, the *trans*-ketone was regenerated from its semicarbazone with considerable loss. In one experiment 16 g. of semicarbazone gave 2 g. of ketone having b. p.  $62^{\circ}/10$  mm.,  $d_4^{25}$  0.8483,  $n_D^{25}$  1.4423, iodine addition 8.1%; and in another, 12 g. yielded 2 g., b. p.  $64^{\circ}/10$  mm.,  $d_4^{25}$  0.8454,  $n_D^{25}$  1.4424. The ketone prepared by the oxalic acid method and purified by distillation with benzene and under reduced pressure was used as *trans*-ketone in the experiments described later.

*trans-Ketone from  $\Delta^2$ -n-Hexenoyl Chloride.*—36 G. of the acid chloride (Goldberg and Linstead, *loc. cit.*) were added to zinc methyl iodide, prepared in the usual way from 41.6 c.c. of methyl iodide and 43 g. of zinc-copper couple in 21.6 c.c. of ethyl acetate and 50 c.c. of benzene (Blaise and Maire, *Ann. Chim. Phys.*, 1908, **15**, 556). A typical product, isolated in the usual way (*loc. cit.*), had b. p.  $69-71^{\circ}/20$  mm., iodine addition 8% (16 g.). This synthesis was carried out many times in the present work, but the physical constants of the products agreed neither among themselves nor

with those already found for the two isomeric ketones, as may be seen from the following table :

	B. p.	$d_{20}^{20}$ .	$n_D^{20}$ .
<i>trans</i> -Ketone .....	62°/15 mm.	0.8445	1.4430
<i>cis</i> -Ketone .....	70/15	0.8571	1.4513
Ketone from acid chloride .....	69—71/20	0.8672	1.4404
" " " .....	69/15	0.8603	1.4420
" " " .....	63/10	0.8786	1.4387
" " " .....	66/10	0.8723	1.4407
" " " .....	62—63/12	0.8658	1.4414

The high density and low refractivity of the material prepared from the acid chloride point to the presence of traces of ester (such as is often produced in these reactions) which cannot be completely removed by fractionation. This impurity somewhat inhibits the formation of the semicarbazone, which is best prepared by mixing the components in a freezing mixture and keeping the mixture ice-cold until crystallisation is at an end. The derivative then separates almost pure, m. p. 124° alone or when mixed with the *trans*-semicarbazone. A mixture with equal parts of the *cis*-semicarbazone melts at 110°.

*Preparation of  $\Delta^8$ -Hepten- $\beta$ -one (III).*— $\Delta^8$ -Hexenoyl chloride was prepared from  $\Delta^8$ -*n*-hexenoic acid which had been purified by one partial esterification (followed by fractionation) (Eccott and Linstead, *loc. cit.*). The purity of this acid chloride was checked by conversion of a small portion into the *p*-toluidide, m. p. 90° (crude), 95—96° after one crystallisation (mixed m. p. 96°). The acid chloride (25 g.), treated exactly as its  $\alpha\beta$ -isomeride, yielded the ketone (12 g.) as a sweet-smelling liquid, b. p. 61—62°/20 mm.,  $d_{20}^{20}$  0.8618,  $n_D^{20}$  1.4290, iodine addition, 71%. The *semicarbazone* crystallised in small white plates, m. p. 109—110° (Found : C, 57.0; H, 8.7.  $C_8H_{15}ON_3$  requires C, 56.8; H, 8.9%). Satisfactory analytical figures could not be obtained for the ketone itself.

*Oxidation of the Ketones.*—*trans*-Butylideneacetone (5 g.) was mixed with saturated sodium carbonate solution (10 g.-mols. per g.-mol. of ketone), and 3% aqueous potassium permanganate added until no more was reduced. The product, worked up in the usual way, yielded 5 g. of total oxidation product: this had a strong odour of acetic acid, which was separated by distillation and converted into acetanilide (m. p. and mixed m. p. 115°). The higher-boiling material was converted into chloride, and butyryl chloride separated by fractionation and identified by conversion into *n*-butyramide (m. p. and mixed m. p. 115°). The *cis*-ketone was treated in the same way and yielded the same products.

Both *cis*- and *trans*-ketones were recovered unchanged after treatment with ozonised oxygen for 20 hours. The  $\beta\gamma$ -ketone (III), however, readily yielded an ozonide. This was decomposed with

water, and the product, after being made alkaline, distilled. The first fraction contained propaldehyde, which was identified as the *p*-nitrophenylhydrazone, m. p. and mixed m. p. 120°.

The *trans*-ketone (11 g.) was added slowly to excess of an ice-cold, freshly prepared solution of sodium hypochlorite. The mixture was removed from the ice and shaken thoroughly for an hour; the temperature then rose sharply. The cold product was extracted with ether to remove unchanged ketone, treated with an excess of sodium sulphite, acidified, and extracted with ether. The residue from the ether yielded an acid (3 g.), b. p. 116—120°/15 mm., which solidified at room temperature and melted after crystallisation at 33°, alone or when mixed with authentic  $\Delta^{\alpha}$ -*n*-hexenoic acid. The anilide had m. p. and mixed m. p. 109—110°.

The *cis*-ketone (11 g.) was oxidised exactly as above and yielded 3 g. of an acid, b. p. 120—126°/14 mm., m. p. 3°,  $d_4^{25}$  1.00,  $n_D^{25}$  1.4520, iodine addition 0.9% (Linstead and May, *loc. cit.*). A mixture of this acid with a quarter of its weight of the acid of m. p. 33° melted at 6° and the m. p. was further raised by the addition of more 33°-acid. The acid slowly yielded the dibromide of the 33°-acid (m. p. and mixed m. p. 68—70°) and readily gave the anilide through the acid chloride (m. p. and mixed m. p. 109°).

5-*n*-Propyldihydroresorcinol (IV).—(a) From the *trans*-ketone. 4.5 G. of the ketone were added to ethyl sodiomalonate made from 0.92 g. of sodium, 18 c.c. of alcohol, and 6.2 g. of the ester, and the mixture was heated on the water-bath under reflux for 3 hours. The solid sodio-compound of the intermediate ester (6 g.) was collected, washed with a little alcohol, and hydrolysed with crystallised sodium carbonate (10 g.) in water (12 c.c.). The product was worked up in the usual way, and the 5-*n*-propyldihydroresorcinol purified by treatment with sodium bicarbonate. From this it was obtained by acidification and extraction as a viscous oil, which gradually solidified (1 g.). On recrystallisation this melted at 107° (Found: C, 69.8; H, 8.9.  $C_9H_{14}O_2$  requires C, 70.1; H, 9.1%). If the solid sodio-compound was not hydrolysed as such but was acidified and the dihydroresorcinol ester itself was extracted before hydrolysis, the solidification of the final product was much delayed. Hydrolysis with baryta yielded gummy products.

(b) Under similar conditions the *cis*-ketone (5 g.) yielded the same product (1 g.), m. p. and mixed m. p. 107°.

Interconversion of the Isomeric Ketones.—Reference data. Mixtures of the  $\beta\gamma$ - and the *trans*- $\alpha\beta$ -ketone reacted with iodine as follows:

% $\alpha\beta$ -ketone	100	90	80	75	66.6	50	33.0	20	0
% Iodine addition .....	8.1	17.5	28.0	30.4	37.6	48.2	58.0	64.6	71.0

(a) *Sodium ethoxide*. The *trans*- $\alpha\beta$ -ketone (7.4 g.) was treated with 1 equiv. of anhydrous *N*-sodium ethoxide (Kon and Linstead, *loc. cit.*, 1929). The entire product boiled above 170°/20 mm. The  $\beta\gamma$ -ketone was also converted into high-boiling material.

(b) *Sodium isopropoxide* gave the same result.

(c) *Barium hydroxide* (compare Hugh, Kon, and Linstead, J., 1927, 2585). The *trans*- $\alpha\beta$ -ketone (2 g.) was mixed with 10 c.c. of 0.17*N*-barium hydroxide, and miscibility established by addition of alcohol. After 4 hours' boiling, the ketone was isolated unchanged ( $d_4^{20}$  0.8757,  $n_D^{19}$  1.4376, iodine addition 2.5%; semicarbazone, m. p. 124°).

(d) *Piperidine*. A mixture of *trans*- $\alpha\beta$ -ketone (4 g.) and piperidine (6.1 g.) was heated under reflux for 2 days on the water-bath and was finally boiled for 2 hours. Only high-boiling material was recovered. The *cis*- $\alpha\beta$ - and the  $\beta\gamma$ -ketone were similarly affected.

(e) *Dilute sulphuric acid*. The *trans*- $\alpha\beta$ -ketone (3 g.) was refluxed with 9 g. of 20% (by weight) sulphuric acid for 8 hours. The ketonic product (1 g.) had b. p. 70°/15 mm., iodine addition 10%, and gave a semicarbazone, m. p. 100° (crude), which yielded the pure *trans*-derivative on recrystallisation (m. p. and mixed m. p. 124°). Similarly treated, the *cis*- $\alpha\beta$ -ketone (3 g.) gave 1 g. of product, b. p. 70°/15 mm., with unchanged iodine addition. After one crystallisation the semicarbazone gave the almost pure *cis*-derivative (m. p. 148°).

The  $\beta\gamma$ -ketone (3 g.), mixed with 6 g. of 20% sulphuric acid, was heated under reflux for 1 hour. The recovered ketone (1.8 g.) had b. p. 63—68°/18 mm.,  $d_4^{20}$  0.8654,  $n_D^{19}$  1.4332, iodine addition 51%. The semicarbazone was a mixture, m. p. 78°, which could not be separated into its constituents. A similar experiment was carried out for 9 hours. The recovered ketone (1.0 g.) had  $d_4^{20}$  0.8680,  $n_D^{19}$  1.4390, iodine addition 32.4%. The semicarbazone melted (crude) at 95—96° and after recrystallisation gave the white plates of the *trans*- $\alpha\beta$ -semicarbazone, m. p. 122°, mixed m. p. 123—124°. In a further experiment, the  $\beta\gamma$ -ketone (5 g.) was treated as before for 9 hours; the product was then isolated and given a further 9 hours' treatment. The final product (2 g.) had  $d_4^{20}$  0.8539, iodine addition 29.4% (equivalent to 77% of *trans*- $\alpha\beta$ -ketone) and yielded the *trans*- $\alpha\beta$ -semicarbazone.

(f) *Hydrobromic acid* (compare Blaise, *loc. cit.*). The *trans*- $\alpha\beta$ -ketone (5 g.) was added slowly to 12 g. of ice-cold hydrobromic acid, saturated at 0°. The black liquid was kept at 0° for  $\frac{1}{2}$  hour and then poured into water and extracted with ether. The extract was washed with sodium bicarbonate solution and dried over anhydrous sodium sulphate. After removal of the solvent the

residue was distilled; the bromo-ketone (4 g.) then came over at  $70^{\circ}/3$  mm. as a colourless liquid, which quickly darkened in light and had a faint characteristic odour distinct from that of the unsaturated ketone. It was boiled with potassium bicarbonate (5 g.) in water (30 c.c.) for 2 hours. The ketone obtained had b. p.  $70^{\circ}/15$  mm.,  $d_4^{25}$  0.8460, and iodine addition 17.3% (an increase of 8.0%). The semicarbazone melted at  $100^{\circ}$  (crude) and yielded the pure *trans*-derivative after recrystallisation (m. p. and mixed m. p.).

Similarly treated, the *cis*-ketone reacted less completely and the crude bromo-ketone was accordingly mixed with a further 12 g. of hydrobromic acid. The bromo-ketone isolated from the product had b. p.  $80^{\circ}/5$  mm. and gave with bicarbonate a ketone the semicarbazone of which melted (crude) at  $100^{\circ}$  and after recrystallisation at  $124^{\circ}$ . Its identity with the *trans*-derivative was confirmed by a mixed melting-point determination.

The  $\beta\gamma$ -ketone (3.5 g.), treated in the same way with hydrobromic acid (8.4 g.), yielded a bromo-ketone, b. p.  $80^{\circ}/5$  mm. The ketone obtained from this by treatment with bicarbonate had b. p.  $72^{\circ}/15$  mm.,  $d_4^{25}$  0.8835,  $n_D^{20}$  1.4337, iodine addition 32%. The crude semicarbazone melted at  $103^{\circ}$  and furnished the pure *trans*- $\alpha\beta$ -derivative on recrystallisation.

#### iso-Series.

*Condensation of isoButaldehyde with Acetone.*—(a) *Production of ketol.* The isobutaldehyde was partly prepared by Fossek's method (*Monatsh.*, 1881, 2, 614) and partly purchased from Messrs. Poulenc Frères. The aldehyde (50 g.) was added during 5 hours with mechanical stirring to a mixture of acetone (100 g.), aqueous caustic soda (50 c.c. of 12%), and ether (20 g.) maintained at  $10^{\circ}$ . The product was isolated as in the *n*-series and yielded 32 g. of the pure ketol and a considerable quantity of dehydrated material.  $\epsilon$ -Methylhexan-8-ol- $\beta$ -one (V) (Francke and Kohn, *loc. cit.*) was thus obtained as a colourless liquid, b. p.  $92^{\circ}/23$  mm.,  $d_4^{25}$  0.9432,  $n_D^{25}$  1.4357 (Found : C, 64.7; H, 10.5. Calc. : C, 64.6; H, 10.8%).

(b) *Production of *trans*-isobutylideneacetone (VI)* (compare Francke and Kohn, *loc. cit.*). *iso*Butaldehyde (50 g.) was added in a slow stream to a mixture of acetone (52 c.c.) and aqueous caustic soda (120 c.c. of 10%). The mixture was subsequently shaken for 2 days and worked up in the usual way. The ketone obtained (20 g.) had b. p.  $63$ — $65^{\circ}/20$  mm.,  $d_4^{25}$  0.8407,  $n_D^{25}$  1.4395,  $[R_L]_D$  35.06 (calc., 34.07), iodine addition 4.5%. The semicarbazone melted in the crude state at  $120^{\circ}$  and formed white silvery plates, m. p.  $126^{\circ}$ , from dilute alcohol (Found : C, 56.7; H, 9.1.  $C_8H_{15}ON_3$  requires C, 56.8; H, 8.9%).

*Dehydration of the Ketol.*—Anhydrous oxalic acid caused considerable charring and only a few drops of material, b. p. 62°/12 mm., could be obtained. This yielded a mixture of semicarbazones.

Dehydration with iodine in the usual manner gave a 70% yield of *cis*-isobutylideneacetone, b. p. 64°/18 mm.,  $d_4^{20}$  0.8558,  $n_D^{20}$  1.4374,  $[R_L]_D$  34.32 (calc., 34.07), iodine addition 8%. The *semicarbazone* crystallised in small plates, m. p. 160° (Found: C, 57.0; H, 9.2.  $C_8H_{15}ON_3$  requires C, 56.8; H, 8.9%). A mixture of equal parts of this and the *trans*-semicarbazone (m. p. 126°) melted at 110°.

$\Delta^{\alpha}$ -isoHexenoyl chloride (Goldberg and Linstead, *loc. cit.*), treated with zinc methyl iodide in the usual way, yielded *trans*-isobutylideneacetone in 45% yield. This had b. p. 64°/23 mm.,  $d_4^{20}$  0.8549,  $n_D^{20}$  1.4357,  $[R_L]_D$  34.22 (calc., 34.07), iodine addition 1%, and was identified with that prepared by direct condensation by the formation of the semicarbazone, m. p. and mixed m. p. 126°.

$\beta\gamma$ -Ketone.—Pyroterebic acid prepared by equilibration of  $\Delta^{\alpha}$ -isohexenoic acid (Goldberg and Linstead, *loc. cit.*) had b. p. 103°/14 mm.,  $d_4^{25}$  0.9694,  $n_D^{25}$  1.4442. It was dissolved (18 g.) in an equal volume of dry benzene, and phosphorus trichloride (10% excess) was cautiously added. The mixture was heated on the water-bath for  $\frac{3}{4}$  hour and then yielded 15 g. of pyroterebyl chloride (VIII), b. p. 54°/15 mm. The *anilide* prepared from this formed flattened needles, m. p. 98°, from benzene and light petroleum (Found: C, 76.1; H, 7.9.  $C_{12}H_{15}ON$  requires C, 76.2; H, 8.0%). Repeated crystallisation failed to raise the melting point: the derivative, m. p. 106°, of Goldberg and Linstead (*loc. cit.*) probably contained some  $\gamma$ -chloroanilide.

Pyroterebyl chloride so prepared gave with zinc methyl iodide a 35% yield of  $\epsilon$ -methyl- $\Delta^{\delta}$ -hexen- $\beta$ -one (VII), b. p. 72–74°/30 mm., obviously contaminated with non-ketonic by-products. It had  $d_4^{25}$  0.9012,  $n_D^{25}$  1.4317, iodine addition 66%, and yielded a very pure *semicarbazone*, which crystallised from dilute alcohol in white silvery flakes, m. p. 158° (crude) and 159–160° (after recrystallisation) (Found: C, 57.0; H, 9.2.  $C_8H_{15}ON_3$  requires C, 56.8; H, 8.9%). A mixture with the *cis*- $\alpha\beta$ -semicarbazone melted at 154°.

*Conversion of the trans- $\alpha\beta$ - into the  $\beta\gamma$ -form.* (a) *With sulphuric acid.* The procedure used in the *n*-series was followed. Reaction for 16 hours almost completely destroyed the ketone, only 10% being recovered. This yielded the  $\beta\gamma$ -semicarbazone, m. p. and mixed m. p. 159–160°. Reaction for 3 hours left 40% of ketone, b. p. 64°/20 mm., iodine addition 51.3% (an increase of 46.8%), which gave the  $\beta\gamma$ -semicarbazone.

(b) *With hydrobromic acid.* This was carried out as in the *n*-series,

two treatments with the reagent being used. The bromo-ketone decomposed slightly on distillation, but a sample of b. p.  $90^{\circ}/5$  mm. was decomposed with bicarbonate in the usual way and yielded the  $\beta\gamma$ -ketone, identified in the form of its semicarbazone. In another experiment, only one treatment with the reagent was given and the bromo-ketone was treated with bicarbonate without distillation: 40% of ketone was recovered, b. p.  $64^{\circ}/20$  mm., iodine addition 52.4%, which readily yielded the  $\beta\gamma$ -semicarbazone, m. p. and mixed m. p.  $159-160^{\circ}$ .

All the unsaturated ketones described in the present communication deteriorate rapidly on keeping with the formation of high-boiling products (compare Weizmann and Garrard, *loc. cit.*). On one occasion an old sample of *cis*-isobutylideneacetone exploded on attempted distillation, which suggests that some type of oxidation occurs.

Our thanks are due to the Government Grant Committee of the Royal Society and to the Chemical Society for grants which have largely defrayed the cost of this work.

[Received, February 11th, 1930.]

### CXIII.—*The Action of Benzenediazonium Chloride on $\beta$ -Nitroethyl Alcohol and its Derivatives.*

By EDWARD CHARLES SNELL JONES and JAMES KENNER.

In a previous paper (J., 1928, 2697) it was pointed out that a large proportion of the reactions of nitroso-compounds can be referred to their tendency to pass into oximino-derivatives, and the perception of this, illuminating the nature of Piloty and Ruff's synthesis of glycerol, permitted the generalisation that compounds in which a nitroso- and a methylol group are attached to the same quaternary carbon atom will decompose immediately they are produced, with the formation of an oximino-compound and formaldehyde:

Considering now the methylol rather than the nitroso-group, the reaction in question corresponds to the loss of carbon dioxide undergone when, for example, methylacetoacetic and *isosuccinic* acids are treated with nitrous acid:

Similarly the familiar decomposition of the nitroacetate ion, and its homologues, into the nitro-compound and carbon dioxide corresponds to the elimination of formaldehyde from derivatives of  $\beta$ -nitroethyl alcohol under the influence of sodium methoxide (Schmidt and Wilkendorf, *Ber.*, 1919, 52, 389):

A similar correspondence was observed when the sodium salts of  $\beta$ -nitroethyl alcohol and its derivatives were treated with benzenediazonium chloride in place of nitrous acid. For instance, the  $\omega$ -nitroacetaldehydephenylhydrazone (I) resulting from the interaction of the sodium salt of nitroethane with benzenediazonium chloride was also obtained by the action of the same reagent on the sodium salt of  $\beta$ -nitropropyl alcohol:

The formaldehyde produced was identified as usual in the form of methylenebis- $\beta$ -naphthol.

Similarly,  $\beta$ -nitrotrimethylene glycol was converted into a compound corresponding in composition to  $\omega$ -nitroglycollaldehydephenylhydrazone (II):

In this instance, however, the product melted at  $117^\circ$ , whereas Demuth and Meyer record a melting point of  $104^\circ$  for the compound obtained from  $\beta$ -nitroethyl alcohol itself (*Annalen*, 1890, 256, 30) and a repetition of their work confirmed their result with the exception that the melting point was raised to  $108^\circ$ . Whereas the specimen of Demuth and Meyer's substance was orange-red and became discoloured after a day or two at the ordinary temperature, (II) was yellow and remained unchanged for a considerable period. Each compound exhibited the normal molecular weight in chloroform solution, and satisfied Bülow's reaction for hydrazones (*Annalen*, 1886, 236, 195). Furthermore, (II) was converted into its isomeride by treatment with aqueous sodium hydroxide or with methylalcoholic sodium methoxide, followed by acidification, whereas the isomeride was recovered unchanged after similar treatment. We therefore regard them as stereoisomerides, assigning the *cis*-configuration to the lower-melting isomeride, and thus relating its

instability to that of the nitrolic acids, which are also regarded as *cis*-compounds (Graul and Hantzsch, *Ber.*, 1898, **31**, 2863).

In no other of the cases investigated and referred to later, did we isolate definite stereoisomerides, although there was some evidence of their formation: for instance, the hydrazones (III) and (IV) were isolated in the first place as red oils, which crystallised only very slowly when inoculated with the pure material (compare also Lapworth, *J.*, 1903, **83**, 1114), but were at once obtained in the solid condition by solution in alkali and precipitation by acid:

Bamberger and Schmidt have described two forms of nitroformaldehydephenylhydrazone, melting respectively at  $74\cdot5^\circ$  and  $84\cdot5^\circ$  (*Ber.*, 1901, **34**, 2001), but since the two forms are interconvertible by treatment with solvents their relationship would seem to be of a physical rather than a chemical character. Moreover, in a repetition of the preparation of this compound from nitromethane we were able to raise the melting point to  $92^\circ$ .

Although the hydrazone formula for the products of coupling nitro- and other reactive compounds with benzenediazonium chloride has probably been universally accepted since it was put forward by V. Meyer (*Ber.*, 1888, **21**, 11), this would appear to be the first occasion on which the stereoisomerism it involves has received definite experimental verification. The slow mutarotation of menthyl benzeneazoacetoacetate (V) observed by Lapworth (*loc. cit.*) is an indication of isomerism which might, however, be structural rather than spatial. The possibility of structural isomerism in fact is indicated by the behaviour of the above stereoisomeride towards alkali. For the transition of (II) into its isomeride must be regarded as indicating the formation from each of an anion (VI), in which the double bond of the hydrazone group has given place to a single bond. Further evidence on this point is supplied by the behaviour of the hydrazones towards benzenediazonium ions. Thus the formula (VI) shows a negative centre available for coupling:

In the light of the foregoing considerations, however, it is clear that the first product (VII) of such a reaction would at once pass into nitroformazyl (VIII) by the loss of formaldehyde. Indeed this series

of changes was observed by Demuth and Meyer (*loc. cit.*) when they studied the interaction of the sodium salt of nitroethyl alcohol with benzenediazonium chloride, and, as we have found, occurs so readily that the nitroacetaldehydephenylhydrazone initially formed can be satisfactorily isolated only when the solution of sodium salt is added to that of the diazonium compound so that no opportunity is afforded for salt formation on the part of the hydrazone. Demuth and Meyer attributed their result to the presence in nitroethyl alcohol (prepared in the usual manner by means of silver nitrite) of a considerable proportion of nitroacetic acid, and suggested that it originated from the action of nitrous acid on the alcohol. This explanation was not challenged either by Bamberger (*Ber.*, 1892, 25, 3201, 3547; 1894, 27, 147, 155), who first assigned the correct constitution to nitroformazyl, or by von Pechmann (*Ber.*, 1892, 25, 3190), who, simultaneously with Bamberger, made an extensive study of the displacement of other groups by the benzeneazo-group, according to the scheme:

The course of this reaction is presumably analogous to that represented above by the formulæ (VI), (VII), and (VIII).

This property of the methylol group asserts itself in still another direction. For although  $\beta$ -hydroxy-acids in general readily undergo loss of water with formation of  $\alpha\beta$ -unsaturated acids,  $\beta$ -hydroxy- $\alpha\alpha$ -dimethylpropionic acid, lacking an  $\alpha$ -hydrogen atom, undergoes in part a thermal decomposition (Blaise, *Compt. rend.*, 1902, 134, 552; Marcilly, *Bull. Soc. chim.*, 1904, 31, 120) strictly analogous to that of the malonic acids and of various aldols:\*

Similarly, by analogy with the decomposition of nitroacetic acid into nitromethane and carbon dioxide, it might be expected that the thermal decomposition of the hydrazone (II) and its isomeride would, in part, follow the course:

In the case of the *trans*-isomeride, there is no difficulty in observing the production of formaldehyde, but careful regulation of the temperature is requisite in the case of the *cis*-compound to enable the

\* [Added to proof.] The thermal decomposition of ethyl di(hydroxymethyl)-malonate (Welch, *this vol.*, p. 257) is a further example of this reaction.

odour of formaldehyde to be detected before the main portion of the material undergoes a complete decomposition, doubtless analogous to that of the nitrolic acids into nitrogen peroxide, nitrogen, and carboxylic acids.

The thermal decomposition of  $\beta$ -hydroxy-acids already mentioned is also exhibited by higher acids, containing alkylol in place of methylol groups (compare, for example, Beilstein's "Handbuch der Organischen Chemie," 4th edition, III, pp. 330—353), and accordingly we have found that quite generally the saturated group  $X\cdot CH\cdot OH$  can be displaced from nitro-compounds in the same manner as the unsaturated groups already enumerated. Thus the reactions represented by the following scheme have been carried out in a number of cases, the ultimate product in each instance being nitroformazyl:

In each case the intermediate hydrazone was isolated and shown to be recovered unchanged from its solution in alkali.

A comparison of (IX), (X), and (XI) shows that the decomposition of the product initially formed from (IX) is formally analogous to the reversals of the aldol condensation (compare, for example, Houben-Weyl, "Methoden der Organischen Chemie," 2nd edition, 1922, 2, 466) and the Michael reaction (compare Knoevenagel, *Annalen*, 1894, 285, 27; Kohler and Conant, *J. Amer. Chem. Soc.*, 1917, 39, 1411):

This comparison assists in substantiating the view that in (X) and (XI), as well as in the thermal decomposition of malonic acids, the initiation of the decomposition is due to an effect transmitted from the carbonyl oxygen atom (compare Cooper, Ingold, and Ingold, *J.*, 1926, 1870), just as in the case of (IX) it is clearly determined by the nitrogen atom attached to the phenyl group. At the same time, however, it must not be overlooked that the cyanohydrins,  $\alpha$ -hydroxy-acids, and, quite generally, compounds of the type  $X\cdot CH(OH)Y$  tend to decompose into  $X\cdot CHO$  and  $HY$ , and that the reversal of the aldol change can be formulated in this manner.

There is also an evident analogy between the aldol condensation and that of aldehydes with nitro-compounds. Correspondingly, we

have found that with increase in complexity of the groups X and Y the stability of the compound  $X\cdot CH(OH)\cdot CHY\cdot NO_2$  towards alkali diminishes, as has been observed in the case of aldols. For instance, whereas the methylol derivatives prepared from nitroethane,  $\alpha$ -nitropropane, and  $\alpha$ -nitrobutane are convertible into their sodium salts, analysis of those prepared from the ethylol derivatives shows that  $\gamma$ -nitropentan- $\beta$ -ol (XII) and  $\gamma$ -nitrohexan- $\beta$ -ol (XIII) suffer decomposition by alkali:

Under the same conditions, however, the desired sodium salt was obtained from  $\beta$ -nitrobutyl alcohol (XIV).

These various salts, on treatment with benzenediazonium chloride, yielded hydrazones in accordance with the principles already discussed.

#### EXPERIMENTAL.

*$\omega$ -Nitroacetaldehydephenylhydrazone from  $\beta$ -Nitropropyl Alcohol.*—A solution of the sodium salt of  $\beta$ -nitropropyl alcohol (J., 1928, 2697) (12.7 g.) in water (125 c.c.) was gradually added to a solution prepared from aniline (9.3 g.), water (125 c.c.), hydrochloric acid ( $d$  1.17; 22 c.c.), and sodium nitrite (6.9 g.). The product (17 g.), isolated by extraction with ether, crystallised from methyl alcohol in yellow plates, m. p.  $149^\circ$  (Found: C, 53.5; H, 5.15. Calc. for  $C_8H_9O_2N_3$ : C, 53.6; H, 5.1%). By the procedure previously described (*loc. cit.*), formaldehyde in the aqueous liquor was identified in the form of methylenebis- $\beta$ -naphthol, m. p.  $205^\circ$ , which did not depress the melting point of an authentic specimen.

The phenylhydrazone was also directly prepared for purposes of comparison by gradual addition of a solution of nitroethane (7.5 g.) and sodium hydroxide (4 g.) in water (100 c.c.) to a diazonium solution prepared as above. The product (16.2 g.) also melted at  $149^\circ$  (Bamberger, *Ber.*, 1898, **31**, 2629, gives  $141$ – $142^\circ$ ) and did not depress the melting point of the above material. Each product was recovered unchanged from its solution in sodium hydroxide.

*$\omega$ -Nitroglycollaldehydephenylhydrazones.*—(1) When a solution of the sodium salt of  $\beta$ -nitrotrimethylene glycol (8.3 g.) in water (50 c.c.) was gradually added to a solution (50 c.c.) prepared from aniline (3.73 g.), hydrochloric acid ( $d$  1.17; 8 c.c.), and sodium nitrite (2.76 g.), a crystalline separation (7.6 g.) was soon produced. On recrystallisation from acetone, stout yellow prisms (II), m. p.  $117$ – $118^\circ$ , were obtained (Found: C, 49.0; H, 4.9; N, 21.6;

*M*, 187.  $C_8H_9O_3N_3$  requires C, 49.2; H, 4.65; N, 21.6%; *M*, 195). Methylenebis- $\beta$ -naphthol, prepared from the aqueous liquor as in the previous case, melted at 205—206°, as also did a sample prepared from the solution obtained by carefully heating the hydrazone in a water-bath at 85° under reduced pressure and absorbing the gases evolved in water. At 110°, oxides of nitrogen accompanied the formaldehyde. This decomposition of the hydrazone also asserted itself when its methyl-alcoholic solution was concentrated.

(2) A solution of the sodium salt of  $\beta$ -nitroethyl alcohol (3.9 g.) (compare *J.*, 1928, 269) was gradually added to a diazonium solution (70 c.c.) prepared from aniline (3.2 g.), hydrochloric acid (*d* 1.17; 7 c.c.), water and sodium nitrite (2.4 g.). The product (6.3 g.) melted at 108—109° after crystallisation from methyl alcohol (Found: C, 49.4; H, 4.7; N, 21.6%; *M*, 201, 189). Formaldehyde could not be detected as a product of treatment of the hydrazone with warm methyl-alcoholic sodium methoxide or aqueous sodium hydroxide, and the material was recovered unchanged. The same compound was obtained by acidifying a solution of the isomeride, m. p. 117—118°, in aqueous sodium hydroxide or in sodium methoxide. A mixture of the isomerides melted at 100—102°. When the hydrazone was very cautiously heated, the odour of formaldehyde was distinctly perceptible, but further decomposition supervened so closely that it was not possible to collect and identify the aldehyde as was done in the previous instance.

By treating the hydrazone (1.95 g.) with a solution of sodium hydroxide (0.4 g.) in water (20 c.c.) and mixing the whole with a diazonium solution (40 c.c.) prepared from aniline (0.93 g.), nitroformazyl (2.1 g.), m. p. 162—163°, was obtained; this did not depress the melting point of an authentic specimen prepared from nitromethane. The odour of formaldehyde was very noticeable in the concentrated ethereal extract, and it was identified as in previous cases. A similar experiment was performed with (II), and nitroformazyl was also produced when a diazonium solution was gradually added to an aqueous solution of the sodium salt of  $\beta$ -nitrotrimethylene glycol.

*Nitroformaldehydephenylhydrazone*.—When a diazonium solution from aniline (9.3 g.), hydrochloric acid (*d* 1.17; 24.4 c.c.), water (125 c.c.), and sodium nitrite (6.9 g.) was gradually added to a solution of nitromethane (6.1 g.) and sodium hydroxide (4 g.) in water (100 c.c.), a mixture of the desired hydrazone with nitroformazyl was produced. The latter was removed by repeated crystallisation from methyl alcohol and the hydrazone was ultimately obtained in orange prisms, m. p. 92° (Found: C, 50.7; H, 4.5; N, 25.7. Calc. for  $C_7H_8O_2N_3$ : C, 50.9; H, 4.3; N, 25.4%).

*Other Examples of the Elimination of Formaldehyde from Nitromethylol Derivatives.*— $\beta$ -Nitrobutyl alcohol, b. p. 122—125°/24 mm. (Pauwels, *Bull. Acad. Sci. Belg.*, 1897, **34**, 651), was converted into its sodium salt (Na, 15.8%), which was coupled with benzenediazonium chloride in the manner described for the case of  $\beta$ -nitropropyl alcohol. The oily phenylhydrazone had only partly crystallised after 4 days, but by precipitation of its solution in aqueous sodium hydroxide the solid hydrazone was at once obtained; it melted at 103—104° after crystallisation from methyl alcohol and did not depress the melting point of the product prepared from nitropropane in brilliant red needles, m. p. 103—104° (N, 21.9%). In the latter case no difficulty was experienced in regard to the solidification of the hydrazone. Bamberger (*Ber.*, 1898, **31**, 2631) gives m. p. 98—99°.

$\beta$ -Nitroamyl alcohol, prepared by adding a few grains of potassium carbonate to a mixture of nitrobutane (12 g.) and formaldehyde (40% solution; 8.75 c.c.) and leaving the mixture for 12 hours after the initial reaction was over, boiled at 130—136°/28 mm. (Found: N, 10.4.  $C_5H_{11}O_3N$  requires N, 10.5%). From its sodium salt (Found: Na, 15.1.  $C_5H_{10}O_3NNa$  requires Na, 14.8%), an oily phenylhydrazone was obtained which did not crystallise when inoculated with the solid material. This was, however, readily obtained by acidifying the solution of the oil in aqueous alkali, and separated from methyl alcohol in brilliant red needles, m. p. 63—66° (Found: N, 20.6.  $C_{10}H_{13}O_2N_3$  requires N, 20.3%). The same compound was obtained directly from the sodium salt of nitrobutane, the crude hydrazone solidifying as in the case of that prepared from nitropropane.

$\beta$ -Nitro- $\beta$ -hydroxymethylamyl alcohol, also formed in small amount in the preparation of the nitroamyl alcohol just described, was isolated as the non-volatile residue from the distillation of the nitroamyl alcohol. After crystallisation from alcohol it melted at 80—83° (Found: N, 8.9.  $C_6H_{13}O_4N$  requires N, 8.6%), and its constitution was established by treatment with sodium ethoxide, the sodium salt of the nitroamyl alcohol (Na, 15.0%), itself identified by conversion into the phenylhydrazone, m. p. 63—66°, just described, being produced.

*Displacement of Other Aldehydes as a Consequence of Coupling.*—The sodium salt of nitroisopropyl alcohol (Henry, *Bull. Acad. Roy. Belg.*, 1895, **15**, 999), on treatment with benzenediazonium chloride, was converted into a phenylhydrazone,  $CHMe(OH) \cdot C(NO_2) \cdot N \cdot NHPh$ , which formed felted orange needles, m. p. 126—127° (Found: C, 51.65; H, 5.5.  $C_9H_{11}O_3N$  requires C, 51.65; H, 5.3%). From  $\alpha$ -nitrobutan- $\beta$ -ol (Henry, *ibid.*, 1896, **15**, 1223) in the same

way, a *sodium* salt (Found: Na, 16.3.  $C_4H_8O_3NNa$  requires Na, 16.3%) and a *phenylhydrazone*,  $CH_3Et(OH) \cdot C(NO_2) : N \cdot NPh$ , bright red needles, m. p. 100—102° (Found: N, 18.9.  $C_{10}H_{13}O_3N_3$  requires N, 18.9%), were successively obtained.

$\alpha$ -Nitropentan- $\beta$ -ol was prepared by condensation of nitromethane (33 g.) with *n*-butaldehyde (39 g.) in presence of water (10 c.c.) and potassium carbonate (0.2 g.). Since no particular rise in temperature was observed, the mixture was heated for some time at 60°, until the aqueous layer (originally the lower) was displaced by the specifically heavier condensation product. After 12 hours, the mixture was worked up and the alcohol (44 g.) isolated as a viscous oil, b. p. 117°/17 mm. (Found: N, 10.8.  $C_5H_{11}O_3N$  requires N, 10.5%). From the *sodium* salt (Found: Na, 14.6.  $C_5H_{10}O_3NNa$  requires Na, 14.8%),  $\alpha$ -chloro- $\alpha$ -nitropentan- $\beta$ -ol was prepared by direct chlorination; it separated from a mixture of equal volumes of chloroform and ethyl acetate in fine needles, m. p. 38° (Found: N, 8.6.  $C_5H_{10}O_3NCl$  requires N, 8.4%). The *phenylhydrazone* obtained from the sodium salt crystallised from methyl alcohol in brilliant red needles, m. p. 92—94° (Found: N, 18.1.  $C_{11}H_{15}O_3N_3$  requires N, 17.7%).

$\alpha$ -Nitrohexan- $\beta$ -ol (Mousset, *Bull. Acad. Roy. Belg.*, 1901, 26, 622) yielded a *sodium* salt (Found: Na, 13.3.  $C_6H_{12}O_3NNa$  requires Na, 13.6%), and a *phenylhydrazone*, which separated from methyl alcohol in bright red needles, m. p. 108—111° (Found: N, 16.7.  $C_{12}H_{17}O_3N_3$  requires N, 16.7%). The chloro-derivative, analogous to that described above, was obtained as an oil which could not be induced to crystallise.

$\gamma\gamma\gamma$ -Trichloro- $\alpha$ -nitropropan- $\beta$ -ol, m. p. 48—49° (Henry, *Bull. Acad. Roy. Belg.*, 1896, 15, 1223, gives m. p. 42—43°), was for obvious reasons not converted into its sodium salt, but coupled in dilute aqueous solution immediately after addition of sodium hydroxide (1 mol.). The resulting *phenylhydrazone* crystallised from methyl alcohol in red prisms, m. p. 129° (Found: N, 13.6.  $C_9H_8O_3N_3Cl_3$  requires N, 13.5%).

The sodium salt of  $\beta$ -nitro- $\alpha$ -phenylethyl alcohol (Rosenmund, *Ber.*, 1913, 46, 1037) yielded a *phenylhydrazone*, which crystallised from methyl alcohol in fine red needles, m. p. 126° (Found: N, 15.8.  $C_{14}H_{13}O_3N_3$  requires N, 15.5%).

The following details are typical of the procedure followed in converting each of the above-mentioned phenylhydrazones into nitroformazyl: a diazonium solution (100 c.c.) prepared from aniline (0.93 g.), hydrochloric acid (*d* 1.12; 2.2 c.c.), water, and sodium nitrite (0.69 g.) was added to a cold solution of the phenylhydrazone from methylnitropentanol (2.5 g.) and sodium hydroxide (0.4 g.)

in water (100 c.c.), and the precipitate purified by crystallisation from methyl alcohol.

$\gamma$ -Nitrobutan- $\beta$ -ol (Henry, *Bull. Acad. Roy. Belg.*, 1896, **15**, 1224) yielded a *sodium* salt which was purified by addition of ether to its solution in methyl alcohol (Found: Na, 16.7.  $C_4H_8O_3NNa$  requires Na, 16.3%), from which a phenylhydrazone, m. p. 148—149°, was prepared (Found: N, 23.5%). The liquor from the coupling process exhibited reducing properties and responded to Simon's test for acetaldehyde, and the phenylhydrazone did not depress the melting point of the phenylhydrazone prepared from nitroethane.

*Decomposition of Derivatives of Nitroisopropyl Alcohol by Alkali.*—When a solution of  $\gamma$ -nitropentan- $\beta$ -ol (Henry, *Bull. Acad. Roy. Belg.*, 1896, **15**, 1223) (Found: N, 10.3%) (13.5 g.) in alcohol (25 c.c.) was treated with a solution of sodium (2.3 g.) in alcohol (42 c.c.), a *sodium* salt was precipitated (Found: Na, 19.9%), and the presence of acetaldehyde in the liquor was demonstrated by Simon's test. The salt was purified by addition of ether to its solution in methyl alcohol (Found: Na, 20.7.  $C_5H_{10}O_3NNa$  requires Na, 20.7%).

$\gamma$ -Nitrohexan- $\beta$ -ol (36.5 g.), b. p. 122.5°/17 mm. (Found: N, 10.0, 10.2.  $C_6H_{12}O_3N$  requires N, 9.5%), was prepared by addition of two drops of aqueous potassium hydroxide solution (50%) to a mixture of nitrobutane (50 g.), acetaldehyde (22 g.), and water (10 c.c.). A *sodium* salt was prepared in the same manner as in the previous instance (Found: Na, 18.2.  $C_4H_8O_3NNa$  requires Na, 18.4%), and the presence of acetaldehyde in the mother-liquor was again indicated by Simon's test.

#### CXIV.—*The Scission of Diaryl Ethers and Related Compounds by Means of Piperidine. Part III. The Nitration of 2:4-Dibromo-2':4'-dinitrodi-phenyl Ether and of 2:4-Dibromophenyl p-Toluenesulphonate and Benzoate. The Chlorination and Bromination of m-Nitrophenol.*

By ROSALIND VENETIA HENLEY and EUSTACE EBENEZER  
TURNER.

IN continuation of previous work (Part II, J., 1929, 512), the nitration of 2:4-dibromophenyl p-toluenesulphonate has been investigated. The sole product of dinitration was 2:4-dibromo-

5-nitrophenyl *o*-nitro-*p*-toluenesulphonate (I), the constitution of which was established by its conversion successively into 2:4-di-

bromo-5-aminophenyl *o*-amino-*p*-toluenesulphonate and 2:4:5-tribromophenyl *o*-bromo-*p*-toluenesulphonate (II). The latter substance was converted by piperidine at 100° into 2:4:5-tribromophenol, identical with the product obtained by the replacement of the amino-group by hydroxyl in 2:4:5-tribromoaniline.

When 2:4-dibromo-5-nitrophenyl *o*-nitro-*p*-toluenesulphonate was heated with piperidine, there were formed 1-*o*-nitro-*p*-toluenesulphonylpiperidine and 2:4-dibromo-5-nitrophenol (III), the constitution of which is determined by that of the above tribromophenol. After crystallisation from light petroleum, with subsequent normal drying, the dibromonitrophenol melted at 77–78°, and an identical product was obtained by nitrating 2:4-dibromophenyl benzoate, followed by hydrolysis. It seemed probable that the compound obtained by Garzino (*Atti R. Accad. Sci. Torino*, 1889, 25, 250) by nitrating 2:4-dibromophenyl propionate should also be 2:4-dibromo-5-nitrophenol, but he gave the m. p. as 90–91°. Crystallisation of our compound from dilute acetone gave a *monohydrate*, m. p. 92–94°, which is probably the product obtained by Garzino.

Another dibromonitrophenol, m. p. 91°, was described by Lindner (*Ber.*, 1885, 18, 612) as resulting from the dibromination of *m*-nitrophenol, and in Beilstein's "Handbuch" (4th Edn., Vol. VI, 246, 248) it is suggested that this compound is possibly identical with Garzino's dibromonitrophenol. In view of the fact (Part II) that *m*-nitrophenol is dichlorinated in the 2- and 4-positions, it at first seemed unlikely that the dibromination would proceed so differently, and we have accordingly investigated the bromination of *m*-nitrophenol afresh.

Attempts to prepare the dibromo-compound according to Lindner's directions did not yield any chemically pure substance. When, however, bromine, diluted with carbon dioxide, was passed through *m*-nitrophenol at 120–140°, until the latter acquired the correct increase in weight, and the product was worked up exactly in accordance with Lindner's instructions, material was obtained which behaved as regards crystallisation as an individual, melted at 82–98°, and appeared to be a mixture of 4-bromo- and 2:4:6-tribromo-3-nitrophenol.

When an attempt was made to dibrominate *m*-nitrophenol in glacial acetic acid in presence of anhydrous sodium acetate, the tribromo-compound, m. p. 89—90°, was alone isolated. This substance, m. p. 85°, was obtained by Lindner (*loc. cit.*) by brominating *m*-nitrophenol, and by Daccomo (*Ber.*, 1885, **18**, 1167) by nitrating 2:4:6-tribromophenyl benzoate. Its constitution has now been definitely proved by converting it in stages into 2:3:4:6-tetrabromophenol. Monobromination of 4-bromo-3-nitrophenol also failed to give a dibromo-3-nitrophenol.

In preparing the monobromo-derivatives of *m*-nitrophenol, we again encountered conflicting results. Pfaff (*Ber.*, 1883, **17**, 612) treated *m*-nitrophenol with bromine in the cold, and described his monobromo-compound as bright yellow needles melting at 110°. Lindner (*loc. cit.*) and Schlieper (*Ber.*, 1892, **25**, 552), using similar methods, obtained what they took to be Pfaff's substance, but they gave the m. p. as 147—148°. Schlieper (*Ber.*, 1893, **26**, 2469) regarded this substance as 2-bromo-3-nitrophenol, since he had obtained the following evidence that the analogous chloro-compound was 2-chloro-3-nitrophenol (IV): the chloro-compound was methylated, and the ether reduced and then deaminated. The product obtained was thought by Schlieper to be *o*-chloroanisole for two reasons: (1) it had the correct b. p., and (2) nitration gave a chloro-nitroanisole, m. p. 93—94°, which he took to be (V), because a substance having this constitution and this m. p. had been described by Fischli (*Ber.*, 1878, **11**, 1463). It seemed possible, however, that Schlieper's chloronitrophenol was the 4-compound, in which

(IV.)

(V.)

(VI.)

case his chloronitroanisole would be (VI), which melts at 97.5° (Reverdin, *Ber.*, 1893, **26**, 1689).

We have found that the monobromination of *m*-nitrophenol at 120—140° (the lowest temperature at which bromination is practicable) gives a mixture of products, at least 50% of which is 4-bromo-3-nitrophenol, m. p. 146.5—147.5°, the constitution of which has been established by its synthesis from *ON*-diacetyl-3-nitro-*p*-aminophenol. Schlieper's supposed 2-bromo-compound is therefore 4-bromo-3-nitrophenol, which substance has indeed already been prepared (Heller and Kammann, *Ber.*, 1909, **42**, 2179) from 3-nitro-*p*-aminophenol.

Monobromination of *m*-nitrophenol in glacial acetic acid in

presence of sodium acetate gave indefinite results, but in absence of sodium acetate the product was a monobromo-compound, m. p. 118.5—121°. This we at first thought to be 2-bromo-3-nitrophenol, and in order to prove its constitution, we converted it into the *p*-toluenesulphonyl derivative, reduced the latter, and replaced the amino-group by bromine. During the last stage, the *p*-toluenesulphonyl group was removed by hydrolysis and a dibromophenol, m. p. 73—74°, was formed. At the same time we performed an analogous synthesis, starting from 3-bromo-2-nitrophenol. The dibromophenol obtained in the second synthesis melted at 68—69°, was different from the first, and was clearly the hitherto unknown 2:3-dibromophenol. It therefore seemed certain that the isomeric compound was 2:5-dibromophenol. Raiford and Bren (*J. Amer. Chem. Soc.*, 1929, 51, 2539) recently attempted the preparation of this substance from 2:5-dibromoaniline. It has now been obtained in excellent yield by applying the method of Noetting and Kopp (*Ber.*, 1905, 38, 3506) to this base, and was found to be identical with the product from the bromo-3-nitrophenol, which is therefore the 6-derivative (2-bromo-5-nitrophenol) already described by Heller and Kammann (*loc. cit.*), who obtained it from 5-nitro-2-aminophenol.

Although it has already been shown (Part II) that *m*-nitrophenol is readily converted into 2:4-dichloro-3-nitrophenol, the above results made it desirable to investigate the monochlorination. Schlieper (*Ber.*, 1893, 26, 2466), by direct chlorination of *m*-nitrophenol, obtained a compound, m. p. 120°, which, as is shown above, may be either the 2- or the 4-chloro-compound. Meldola and Eyre (*J.*, 1902, 81, 996) agreed with Schlieper's conclusion that this was the 2-chloro-compound; they obtained 4-chloro-3-nitrophenol, m. p. 126—127°, by synthesis from 3-nitro-*p*-aminophenol.

We find that monochlorination of *m*-nitrophenol at 120—140° gives approximately equal amounts of 4-chloro-3-nitrophenol (A), m. p. 127—128°, and 2-chloro-3-nitrophenol (B), m. p. 120°. A was identical with a specimen prepared from *ON*-diacetyl-3-nitro-*p*-aminophenol, and the constitution of B follows from two facts: (1) dichlorination of *m*-nitrophenol under similar conditions gives the 2:4-dichloro-compound in good yield, and (2) reduction of B, followed by replacement of the amino-group by chlorine, gives 2:3-dichlorophenol. Although the first of these appears to be sufficient proof, it was desired to prove beyond doubt that B was not 6-chloro-3-nitrophenol (m. p. 118—119°; prepared synthetically by Meldola, Woolcott, and Wray, *J.*, 1896, 69, 1322).

It is therefore possible that, in this case, Schlieper actually had a 2-chloro-compound, but it is difficult to believe this, since the

4-chloro-compound, which was presumably present, is so readily isolated.

We have not investigated the iodination of *m*-nitrophenol, as the statements in the literature seem to be accurate. Schlieper (1893, *loc. cit.*) described the monoiodo-compound as the 2-iodo-derivative, m. p. 134°, and Datta and Prosad (*J. Amer. Chem. Soc.*, 1917, 39, 441) state that iodination in the 2-position proceeds quantitatively. There seems little doubt that this substance is different from the 4- and the 6-iodo-derivative, m. p. 156° and 146–147° respectively (Hähle, *J. pr. Chem.*, 1891, 43, 72; Meldola and Eyre, P., 1901, 238).

In endeavouring to prepare 4-bromo-3-nitrophenol by a different method, we nitrated *N*-*p*-bromophenylphthalimide in presence of excess of concentrated sulphuric acid, expecting to obtain a considerable proportion of the *m*-nitro-derivative (compare Brady, Quick, and Welling, J., 1925, 127, 2264). The main product, however, was the *o*-nitro-derivative. This result is interesting, since nitration of *p*-bromoaniline in presence of excess of sulphuric acid gives almost entirely the *m*-nitro-compound (Noelting and Collin, *Ber.*, 1884, 17, 261) (see Experimental).

The nitration of 2:4-dibromo-2':4'-dinitrodiphenyl ether proceeds similarly to that of the analogous dichloro-compound and gives 2:4-dibromo-5:2':4'-trinitrodiphenyl ether. This ether readily undergoes scission by piperidine into 2:4-dibromo-5-nitrophenol and *N*-2':4'-dinitrophenylpiperidine.

#### EXPERIMENTAL.

2:4-Dibromophenyl *p*-toluenesulphonate, readily obtained by the usual type of process, crystallised from glacial acetic acid in colourless plates, m. p. 120° (Found: Br, 39.8.  $C_{13}H_{10}O_3Br_2S$  requires Br, 39.4%).

*Dinitration of 2:4-Dibromophenyl p-Toluenesulphonate.*—The compound was added to 10 parts of nitric acid (*d* 1.5), the resulting solution being left for an hour and then poured into a large bulk of water. Filtration, followed by crystallisation from glacial acetic acid, gave 2:4-dibromo-5-nitrophenyl *o*-nitro-*p*-toluenesulphonate in pale greenish-yellow leaflets, m. p. 122–123° (Found: Br, 32.6.  $C_{13}H_8O_7N_2Br_2S$  requires Br, 32.3%).

2:4-Dibromo-5-nitrophenol.—The last-mentioned compound was heated for 1 hour at 100° with 2 parts of piperidine. No piperidine hydrobromide separated. Excess of dilute alkali was added, and the solution shaken with benzene; this extracted the 1-*o*-nitro-*p*-toluenesulphonylpiperidine, but, contrary to expectation, it also extracted the piperidine salt of the phenol. It was therefore shaken

with dilute hydrochloric acid and then with alkali. Acidification of the alkaline solution precipitated 2:4-dibromo-5-nitrophenol. This crystallised from light petroleum (b. p. 80—100°) in long yellow needles, m. p. (after being dried over-night in a vacuum over concentrated sulphuric acid) 77—78° (Found: Br, 53.5.  $C_6H_3O_3NBr_2$  requires Br, 53.9%), and from very dilute acetone as the hydrate,  $C_6H_3O_3NBr_2 \cdot H_2O$ , in long yellow needles, m. p. 92—94° (with previous softening), the m. p. depending on the rate of heating (0.5236 g. lost 0.0309 g. in 14 days in a vacuum over phosphoric oxide. Loss of  $1H_2O$  requires 0.0299 g. The specially dry material so obtained melted at 84—86°).

2:4-Dibromo-5-aminophenyl *o*-Amino-*p*-toluenesulphonate.—The corresponding dinitro-compound was added with shaking to a hot solution of stannous chloride (1.5 times the calculated quantity) in a mixture of glacial acetic acid and concentrated hydrochloric acid. After the mixture had been heated at 100° for a few minutes, vigorous reduction set in, and was allowed to become complete during an hour at 100°. The resulting solution was poured into excess of 20% potassium hydroxide solution, and the suspension was cooled and filtered (asbestos). The washed and dried precipitate crystallised from dilute acetone in colourless leaflets, m. p. 174—175° (Found: Br, 37.5.  $C_{13}H_{12}O_3N_2Br_2S$  requires Br, 36.7%).

2:4:5-Tribromophenyl *o*-Bromo-*p*-toluenesulphonate.—The di-amino-compound was diazotised at 20—25°, in a mixture of equal parts of concentrated hydrochloric acid and water, with a solution of sodium nitrite. The diazo-perbromide was precipitated by means of a solution of bromine in aqueous potassium bromide, collected, washed, and decomposed in glacial acetic acid, the temperature of the latter being slowly raised until the b. p. was reached. Water was added, and the precipitate crystallised from alcohol, colourless leaflets, m. p. 107—108°, being obtained (Found: Br, 56.9.  $C_{13}H_8O_3Br_4S$  requires Br, 56.7%).

2:4:5-Tribromophenol.—(a) A solution of the preceding compound in excess of piperidine was boiled under reflux for an hour; the solution was then strongly acidified and submitted to steam distillation. The tribromophenol passed over rapidly, and crystallised from light petroleum (b. p. 40—60°) in long colourless needles, m. p. 85—86° (Found: Br, 73.0.  $C_6H_3OBr_3$  requires Br, 72.5%).

(b) 2:4:5-Tribromoaniline, prepared for the purpose from *p*-dibromobenzene, was converted into the corresponding phenol by adapting the method of Noelting and Kopp (*loc. cit.*). The product was identical with that from process (a).

Kohn and Pfeifer (*Monatsh.*, 1927, 48, 211) obtained what was

evidently mainly 2:4:5-tribromophenol, m. p. 79°, by heating pentabromophenol with zinc dust and glacial acetic acid. We failed to trace this work for some time, since in the original paper and in the British abstracts the substance was incorrectly called 3:4:6-tribromophenol.

*Nitration of 2:4-Dibromo-2':4'-dinitrodiphenyl Ether.*—The ether, described by Le Fèvre, Saunders, and Turner (J., 1927, 1168), is more conveniently obtained as follows: 21 g. of 2:4-dibromophenol were added to 4.6 g. of potassium hydroxide previously fused with 0.5 c.c. of water. To the still hot mixture were added 17.5 g. of 1-chloro-2:4-dinitrobenzene. After a few minutes' shaking, potassium chloride began to separate, and after an hour's heating at 100°, interaction was complete. Excess of dilute alkali was added, and the mixture cooled and shaken. The solid mealy product was collected, washed with water, and crystallised from glacial acetic acid (23 g., m. p. 133°).

The ether was added rapidly to 10 parts of nitric acid (*d* 1.5). After 0.5 hour, the solution was poured into water. The precipitated solid was collected, washed, and crystallised from glacial acetic acid, 2:4-dibromo-5:2':4'-trinitrodiphenyl ether being obtained in very pale yellow needles, m. p. 142° (Found: Br, 35.1.  $C_{12}H_5O_7N_3Br_2$  requires Br, 34.9%).

*Scission of 2:4-Dibromo-5:2':4'-trinitrodiphenyl Ether.*—(a) *With piperidine.* The trinitro-compound was heated with twice its weight of piperidine at 100° for an hour. The solution was treated with alkali and extracted several times with benzene. The benzene layer was extracted first with hydrochloric acid and then with alkali. Acidification of the alkaline solution gave 2:4-dibromo-5-nitrophenol, identical with the above product, and the benzene layer yielded 2:4-dinitrophenylpiperidine.

(b) *With aniline.* The trinitro-compound was heated for an hour at 100° with excess of aniline. On addition of much dilute hydrochloric acid, 2:4-dinitrodiphenylamine separated in almost quantitative yield.

*Nitration of 2:4-Dibromophenyl Benzoate.*—The benzoate was added slowly to 10 parts of nitric acid (*d* 1.5), kept below 30°. After a further 15 minutes, the solution was poured into excess of cold water. The gummy precipitate was separated, and heated with water until it became hard. It crystallised from alcohol in colourless needles, m. p. 155–156° (Found: Br, 36.2.  $C_{13}H_6O_6N_2Br_2$  requires Br, 35.9%). The nitro-compound was heated for an hour at 100° with excess of piperidine. The excess of piperidine was removed by extraction with benzene in presence of alkali. The 2:4-dibromo-5-nitrophenol obtained, after crystallisation from

light petroleum, had m. p. 77—78°, and did not depress the m. p. of the dibromo-compound described above.

The *m*-nitrophenol used in these experiments was prepared as described in Adams's "Organic Syntheses," Vol. VIII, p. 80, but it was found advisable to remove all traces of sulphuric acid from the crude product by dissolving it in alkali and reprecipitating it with hydrochloric acid before distilling it under reduced pressure; otherwise, towards the end of the distillation, explosive decomposition set in. From 212 g. of *m*-nitroaniline, 135—140 g. of pure *m*-nitrophenol were consistently obtained.

*m*-Nitrophenyl *p*-toluenesulphonate, obtained in the usual way, separated from alcohol in prisms, m. p. 112—113° (Found: S, 10.7.  $C_{13}H_{11}O_5NS$  requires S, 10.9%).

*Experiments on the Dibromination of m-Nitrophenol.*—(A) *Dry*. (1) The method described by Lindner (*loc. cit.*) led to mixtures, the examination of which proved unprofitable.

(2) A current of carbon dioxide laden with bromine vapour was passed through *m*-nitrophenol in a bath at 120—140° until the desired increase in weight had occurred. The product was worked up by Lindner's method. Precipitation of the barium-salt fraction gave a solid, m. p. 82—98°. A mixture of this with 2 : 4 : 6-tribromo-3-nitrophenol melted below 75°, and one with 4-bromo-3-nitrophenol melted at 76—135°. On the assumptions that the product, m. p. 82—98°, is approximately 50% of 4-bromo- and 50% of tribromo-3-nitrophenol, and that the mixed melting-point curve is of the simplest type, these results are explicable, as is also the bromine content of the bromination product (51.3%; a 1 : 1 mixture of mono- and tri-bromo-compounds requires Br, 53.9%).

(3) On one occasion, by Schlieper's method of monobromination, a product was obtained corresponding very closely to that just described. It had m. p. 85—95°, and Br, 51.2%.

(B) *Wet*. (1) A solution of *m*-nitrophenol (1 mol.) and bromine (2 mols.) in 90% acetic acid was left in the cold for an hour. Since bromination did not begin, the solution was heated at 100° for 0.5 hour and then boiled for 0.5 hour. The product was worked up by Lindner's method and gave no substance corresponding to his dibromo-derivative.

(2) A solution of *m*-nitrophenol (1 mol.) and anhydrous sodium acetate (2 mols.) in glacial acetic acid was treated with a solution of bromine (2 mols.) in glacial acetic acid. A number of experiments were carried out, with variation of concentrations, temperature, and time of mixing. In every case the main product was 2 : 4 : 6-tribromo-3-nitrophenol, m. p. 89—90° (Found: Br, 63.4. Calc.: Br, 63.8%).

**2 : 4 : 6-Tribromo-3-nitrophenyl p-Toluenesulphonate.**—The tribromo-compound was readily converted into the *p*-toluenesulphonyl derivative, which crystallised from alcohol in colourless needles, m. p. 146—147° (Found : Br, 45·2; S, 6·0.  $C_{13}H_8O_5NBr_3S$  requires Br, 45·3; S, 6·0%).

**2 : 4 : 6-Tribromo-3-aminophenyl p-Toluenesulphonate.**—Reduction of the preceding compound was effected by West's method (J., 1925, 127, 494). The amino-compound separated from alcohol or dilute acetic acid in colourless prisms, m. p. 146—147° (mixture with the nitro-compound, m. p. 120—125°) (Found : Br, 47·9.  $C_{13}H_{10}O_3NBr_3S$  requires Br, 48·0%).

**2 : 3 : 4 : 6-Tetrabromophenol.**—A solution of the preceding amino-compound in concentrated sulphuric acid was diazotised at 15° with a solution of sodium nitrite in concentrated sulphuric acid (made at -10°). When the resulting solution was poured on ice, a yellow crystalline precipitate of the diazo-compound separated. Addition of water produced a clear solution, to which was added a solution of bromine in potassium bromide until no further precipitate was obtained. The diazo-perbromide was collected, washed with water, and decomposed in hot glacial acetic acid. On cooling, a crystalline product separated, which was washed with water and then heated with excess of piperidine at 100° for 4 hours. Addition of water precipitated 2 : 3 : 4 : 6-tetrabromophenol, which soon became solid and crystallised from dilute alcohol in colourless needles, m. p. 113—114°. An identical specimen was obtained by using the Sandmeyer instead of the perbromide process (Found : Br, 76·8. Calc. : Br, 78·0%).

**N-*p*-Bromophenylphthalimide.**—A mixture of *p*-bromoaniline (1 mol.) with finely ground phthalic anhydride (1 mol.) was heated at 250—300° for 2 hours. The molten mass was poured into cold alcohol and the solid product was ground and extracted with a large volume of boiling alcohol. The residual solid and the long silky needles that separated from the extract both melted at 204° (Found : Br, 26·8.  $C_{14}H_8O_2NBr$  requires Br, 26·5%). Yield, 88%.

**Nitration of N-*p*-Bromophenylphthalimide.**—The imide (1 mol.) was dissolved in 10 parts of warm concentrated sulphuric acid. To the solution, cooled in running water, 1 mol. of nitric acid (*d* 1·5), dissolved in 5 vols. of concentrated sulphuric acid, was added slowly, with stirring. After an hour, the solution was poured on ice, and the resulting gummy precipitate collected. It was heated for an hour at 130° with 90% sulphuric acid, and the resulting solution was much diluted and then basified. The product was mainly 4-bromo-2-nitroaniline, and did not contain more than 20% of 4-bromo-3-nitroaniline (fractional crystallisation of the mixed sulphates).

Nitration of *p*-bromoaniline in excess of sulphuric acid as described by Noelting and Collin (*loc. cit.*) gave 4-bromo-3-nitroaniline in good yield, but an attempt to effect replacement of the amino-group by hydroxyl by the diazo-method proved unsuccessful.

*Mononitration of ON-Diacetyl-p-aminophenol.*—Hähle (*loc. cit.*) recommends nitration at 0° with fuming nitric acid. We have found that the best results are obtained when 50 g. of the diacetyl compound are added gradually to 75 c.c. of nitric acid (*d* 1.5) kept at about 5°. (Only partial nitration occurs at temperatures just below 0°, and the diacetyl compound may be recovered unchanged from its solution in a mixture of equal volumes of acids of *d* 1.5 and *d* 1.42, kept at 0° to -5°.) The solution is poured on ice, and the precipitate obtained is crystallised from alcohol.

*4-Bromo-3-nitrophenol.*—*ON*-Diacetyl-3-nitro-4-aminophenol was slowly added to 10 times its weight of boiling hydrobromic acid (*d* 1.49). Boiling was continued for  $\frac{1}{2}$  hour and the suspension of 3-nitro-4-aminophenol hydrobromide was then diluted and diazotised: diazotisation was slow. The excess of nitrous acid was removed by addition of urea and the solution obtained was poured into a suspension of copper powder in 25% hydrobromic acid. The copper slowly dissolved and needles separated. These crystallised from water in brown needles, *m. p.* 146.5—147.5°, and from dilute hydrochloric acid in yellow needles having the same *m. p.*

4-Chloro-3-nitrophenol was obtained in a precisely similar manner from diacetyl-3-nitro-4-aminophenol. The diazotisation proceeded more easily than with the bromo-compound. The product crystallised from dilute hydrochloric acid in yellow needles, *m. p.* 127—128°.

3-Bromo-2-nitrophenol was prepared by Hodgson and Moore's method (*J.*, 1926, 157). In the intermediate sulphonation we obtained good results with 20% oleum, but with acid of the composition (27% oleum) used by Hodgson and Moore, our sulphonation mixture set almost solid and would not dissolve even in a large quantity of concentrated sulphuric acid.

3-Bromo-2-nitrophenyl *p*-toluenesulphonate, readily obtained in the usual way, crystallised from alcohol, in which it was very sparingly soluble, in colourless rectangular plates, *m. p.* 136.5—137.5° (Found: Br, 21.4.  $C_{13}H_{10}O_5NBrS$  requires Br, 21.5%).

3-Bromo-2-aminophenyl *p*-Toluenesulphonate.—The preceding nitro-compound was reduced with a mixture of 2 parts of crystalline stannous chloride, 2 parts of concentrated hydrochloric acid, and 7 parts of glacial acetic acid at 100°. Much alkali was added and the suspension produced was extracted with ether. Evaporation of the dried ethereal extract, followed by crystallisation from alcohol,

gave colourless needles of the *amino*-compound, m. p. 120—121° (Found: Br, 23·6.  $C_{13}H_{12}O_3NBrS$  requires Br, 23·4%).

**2:3-Dibromophenol.**—The *amino*-compound was diazotised in concentrated sulphuric acid at 15—20°, with a solution of sodium nitrite in concentrated sulphuric acid prepared at -10°. The reaction mixture was poured on ice. A small portion was found to couple normally with alkaline  $\beta$ -naphthol, and the main portion was added to cuprous bromide-hydrobromic acid. The resulting solution was heated on a boiling water-bath under reflux for  $\frac{3}{4}$  hour and then distilled in steam. The white solid that passed over was dried over concentrated sulphuric acid (desiccator) and crystallised from light petroleum (b. p. 40—60°). The 2:3-dibromophenol obtained formed stout prisms, m. p. 68—69° (Found: Br, 63·6.  $C_6H_4OBr_2$  requires Br, 63·6%). It is much less soluble in light petroleum than 2:3-dichlorophenol and is very much less volatile.

**Monobromination of Wet m-Nitrophenol.**—(a) When a dilute solution of bromine (1 mol.) was added to a cold dilute solution of *m*-nitrophenol (1 mol.) and anhydrous sodium acetate (1 mol.) in glacial acetic acid, a mixture of substances was formed, the examination of which led to no positive results.

(b) A solution of 20 g. of *m*-nitrophenol and 8·8 c.c. of bromine in 30 c.c. of glacial acetic acid was gently boiled under reflux for 2 hours; it then became almost colourless. The solvent was evaporated on a boiling water-bath and the residue, which became crystalline on cooling, was dissolved in dilute aqueous alkali. Addition of acid precipitated an almost colourless solid which, after being crystallised from dilute hydrochloric acid, melted at 117—120°, and after a further crystallisation from light petroleum (b. p. 80—100°), at 118·5—121° (Found: Br, 36·4.  $C_6H_4O_3NBr$  requires Br, 36·7%). The following experiments show that this substance is 2-bromo-5-nitrophenol.

2-Bromo-5-nitrophenyl *p*-toluenesulphonate was formed in good yield by the usual process; it crystallised from alcohol in colourless plates, m. p. 131·5—132·5° (Found: Br, 21·6.  $C_{13}H_{10}O_5NBrS$  requires Br, 21·5%).

2-Bromo-5-aminophenyl *p*-toluenesulphonate, obtained by the reduction of the nitro-compound with stannous chloride, hydrochloric acid, and acetic acid, crystallised from alcohol in colourless bunches of prisms, m. p. 135—136° (Found: Br, 23·3.  $C_{13}H_{12}O_3NBrS$  requires Br, 23·4%).

**2:5-Dibromophenol.** (a) The last-named *amino*-compound was diazotised in concentrated sulphuric acid exactly as described under the preparation of 2:3-dibromophenol. The steam-distilled 2:5-dibromophenol was dried over concentrated sulphuric acid

(desiccator) and then crystallised from light petroleum (b. p. 40—60°); it formed prismatic needles, m. p. 73—74° (Found: Br, 63.4.  $C_6H_4OBr_2$  requires Br, 63.6%). It was readily converted into 2:5-dibromophenyl *p*-toluenesulphonate, which separated from alcohol in colourless prisms, m. p. 109—110° (Found: Br, 39.7.  $C_{13}H_{10}O_3Br_2S$  requires Br, 39.4%).

(b) 2:5-Dibromoaniline (44 g.), obtained in good yield by reducing 2:5-dibromonitrobenzene by West's method, was dissolved in 150 c.c. of warm concentrated sulphuric acid. The solution was cooled to room temperature and treated with a solution of 13 g. of sodium nitrite in 150 c.c. of concentrated sulphuric acid (prepared at -10°). After an hour, 150 c.c. of water were added and the resulting solution, after addition of purified sand, was heated under reflux over a small flame for 2 hours. (A small portion of the diluted diazo-solution coupled readily with alkaline  $\beta$ -naphthol.) The whole was then distilled in steam, 37 g. of 2:5-dibromophenol, containing a trace of 2:5-dibromoaniline, passing over. The phenol was freed from the base by solution in alkali and filtration and then recovered by acidification; it had m. p. 73—74°, b. p. 256—257° (corr.)/755 mm. The *p*-toluenesulphonyl derivative melted at 109—110°.

Mixtures of the phenols or of their *p*-toluenesulphonyl derivatives obtained by methods (a) and (b) had the same m. p. as those of the single substances.

*Monobromination of Dry m-Nitrophenol.*—(1) A current of dry carbon dioxide was passed through bromine and then through 10.5 g. of *m*-nitrophenol heated at 120—140°. When the calculated increase of weight had occurred, the product was freed from the excess of bromine by a rapid current of carbon dioxide and at once dissolved in excess of dilute sodium hydroxide solution. After addition of dilute hydrochloric acid, yellow needles of 4-bromo-3-nitrophenol separated for some time, and later, an oil made its appearance. At this stage the liquid was filtered and the solid was crystallised from dilute hydrochloric acid, 7 g. of the 4-bromo-compound, m. p. 146.5—147.5°, being obtained.

(2) *m*-Nitrophenol (28 g.) was brominated, the weight being allowed to increase to 43 g. When the product was worked up as before, 22 g. of pure 4-bromo-3-nitrophenol were obtained.

The products from both experiments did not depress the m. p. of 4-bromo-3-nitrophenol prepared from diacetyl-*p*-aminophenol.

*Attempted Monobromination of 4-Bromo-3-nitrophenol.*—When the monobromo-compound (1 mol.), dissolved together with 1 mol. of anhydrous sodium acetate in glacial acetic acid, was treated with 1 mol. of bromine dissolved in the same solvent, a mixture was obtained containing unchanged 4-bromo-3-nitrophenol.

*Attempted Monobromination of 2-Bromo-5-nitrophenol.*—This appeared to proceed readily. The acetic acid was evaporated, and the hard solid obtained (on cooling) crystallised from light petroleum (b. p. 80—100°). The product had the appearance of an individual substance, but melted at 68—108°.

*Monochlorination of m-Nitrophenol.*—Chlorine was passed into *m*-nitrophenol (42 g.) at 120—140° until the weight increased by 9.5 g. A rapid current of carbon dioxide was passed through the molten product until the excess of chlorine had disappeared and the whole was then dissolved in dilute alkali solution. Dilute hydrochloric acid was added until no further evident precipitation occurred and the yellow needles produced were washed and dried (14 g.). After crystallisation from dilute hydrochloric acid, 12 g. of pure 4-chloro-3-nitrophenol, m. p. 127—128°, were obtained. The mother-liquor from the first filtration was strongly acidified, and filtered after some time: the yellow precipitate obtained, having been washed and dried, weighed 16 g. and after crystallisation from dilute hydrochloric acid gave 10 g. of 2-chloro-3-nitrophenol, m. p. 120° (Found: Cl, 19.6. Calc.: Cl, 20.0%). The mother-liquor from the second precipitation was evaporated to a small bulk under reduced pressure and then extracted with ether. Evaporation of the extract gave 12.5 g. of an oily mixture of chloro-compounds. The total yield of crude chloro-compounds was 85% of the theoretical yield.

The 4-chloro-3-nitrophenol obtained produced no depression of the m. p. of the material prepared from *ON*-diacetyl-*m*-nitro-*p*-aminophenol.

The 2-chloro-3-nitrophenol was reduced with iron, hydrochloric acid, and alcohol, and the filtered solution evaporated to dryness. Diazotisation, followed by addition of copper powder and hydrochloric acid, gave 2:3-dichlorophenol, m. p. 56—57°: this depressed the m. p. of 2:5-dichlorophenol (m. p. 57°). 2:3-Dichlorophenol is extraordinarily volatile, and vacuum desiccation over sulphuric acid and phosphoric oxide was accompanied by considerable loss. This property and the intense odour of the compound appear to differentiate this dichlorophenol from its isomerides (compare Holleman, *Rec. trav. chim.*, 1917, 37, 96), and the volatility accounts for the poor analytical figure obtained (Found in air-dried specimen: Cl, 41.7. Calc.: Cl, 43.6%).

Some of the preliminary work on the dibromodinitrodiphenyl ether was carried out by Miss G. I. Sharp, B.Sc.

CXV.—*The Unsaturation and Tautomeric Mobility of Heterocyclic Compounds. Part II.  $\alpha$ - and  $\beta\beta$ -Naphthathiazoles.*

By ROBERT FERGUS HUNTER and JOHN WILLIAM THOMAS JONES.

RING closure, producing the heterocyclic nucleus in  $\alpha$ -naphthathiazoles (I) and in benzthiazoles (II), takes place much more readily in the former than in the latter case : for instance, (1) the ratio of

the yields of the 1-chloro-derivatives (I and II; R = Cl) obtained from the corresponding arylthiocarbimides and phosphorus pentachloride under similar conditions (Hofmann, *Ber.*, 1879, 12, 1126) is 62 : 15; (2) oxidation of  $\beta$ -naphthylthiourethane and of phenylthiourethane with alkaline ferricyanide at 80–90° gives 60% and 40% yields, respectively, of the corresponding ethoxythiazoles (I and II; R = OEt) (Jacobson, *Ber.*, 1886, 19, 1069); and (3) the action of bromine on *s*-phenyl- $\beta$ -naphthylthiocarbamide yields solely 1-anilino- $\alpha$ -naphthathiazole (I; R = NHPh), no trace of the isomeric 1- $\beta$ -naphthylaminobenzthiazole (II; R = NH·C<sub>10</sub>H<sub>7</sub>), which has been synthesised from 1-chlorobenzthiazole and  $\beta$ -naphthylamine, being isolable. These results are evidently conditioned by the high reactivity of the  $\alpha$ -hydrogen atom of the naphthalene nucleus.

The aromatic nature of the heterocyclic nucleus in  $\alpha$ -naphthathiazole is manifested in the alkylation of semi-cyclic amidines containing this complex (III  $\rightleftharpoons$  IV). For instance, the methyl-

ation of 1-amino- $\alpha$ -naphthathiazole (III; R = H) yields 1-imino-2-methyl-1 : 2-dihydro- $\alpha$ -naphthathiazole, unaccompanied by the isomeric 1-methylamino- $\alpha$ -naphthathiazole (compare Hunter, *J.*, 1926, 1385; Hunter and Styles, *J.*, 1928, 3019). 1- $\beta$ -Naphthylamino- $\alpha$ -naphthathiazole (III; R = C<sub>10</sub>H<sub>7</sub>) behaves similarly and yields only 1- $\beta$ -naphthylimino-2-methyl-1 : 2-dihydro- $\alpha$ -naphthathiazole on methylation, although it contains the  $\beta$ -naphthyl group which might exert a conjugating influence favouring the iminodihydro-phase (IV), similar to that of the phenyl group in the three-carbon system (Linstead and Williams, *J.*, 1926, 2735; Linstead, *J.*, 1929, 2501). The isomeric 1-methyl- $\beta$ -naphthylamino- $\alpha$ -naphthathiazole has been

obtained from 1-chloro- $\alpha$ -naphthathiazole and methyl- $\beta$ -naphthylamine and also by the action of bromine on methyl-*s*-di- $\beta$ -naphthylthiocarbamide,  $C_{10}H_7 \cdot NMe \cdot CS \cdot NH \cdot C_{10}H_7$ .

The methylation of 1-hydroxy- $\alpha$ -naphthathiazole is analogous to that of 1-hydroxybenzthiazole (Hunter, this vol., p. 128), the sole product being the ketomethyldihydro-derivative (V), whose constitution follows from its synthesis from 1-nitrosoimino-2-methyl-1:2-dihydro- $\alpha$ -naphthathiazole (VI).

3-Bromo-1-amino- $\beta\beta$ -naphthathiazole (VII) has been obtained from 1-bromo- $\beta$ -naphthylamine by way of the thiocarbimide and thiocarbamide in the usual way (compare Fries, *Annalen*, 1927, 454, 260).

#### EXPERIMENTAL.

Considerable difficulty was encountered in preparing  $\beta$ -naphthylthiocarbimide by the methods given in the literature. It was most readily obtained by boiling a mixture of *s*-di- $\beta$ -naphthylthiocarbamide (50 g.) and acetic anhydride (100 c.c.) for 3 minutes, diluting the solution with hot water, and isolating the thiocarbimide by prolonged distillation in steam superheated to  $140^\circ$ . The yield never exceeded 30%. The thiocarbimide to be used for the preparation of the chloronaphthathiazole was melted over calcium chloride and redistilled in a vacuum, the fraction, b. p.  $182\text{--}184^\circ/12$  mm., being separately collected.

1-Chloro- $\alpha$ -naphthathiazole.—A mixture of 14 g. of  $\beta$ -naphthylthiocarbimide and phosphorus pentachloride (16 g.) was heated in a sealed tube at  $160\text{--}180^\circ$  for 5–6 hours, and the product fractionated. After removal of phosphorus trichloride and a small quantity of unchanged thiocarbimide ( $183^\circ/15$  mm.), the chlorothiazole distilled at  $260\text{--}270^\circ/15$  mm. The yield after redistillation and crystallisation from alcohol was 62%; m. p.  $80^\circ$ , b. p.  $245\text{--}246^\circ/13$  mm. (Found: Cl, 16.0; S, 14.8.  $C_{11}H_6NCIS$  requires Cl, 16.1; S, 14.5%).

1-Hydroxy- $\alpha$ -naphthathiazole.—A solution of the chloronaphthathiazole (0.8 g.) in absolute alcohol (20 c.c.) was diluted with 4 c.c. of concentrated hydrochloric acid, heated for 20 hours under reflux, and evaporated on a steam-bath. On recrystallisation from alcohol, the hydroxy-base formed aggregates of shining prisms, m. p.  $230\text{--}$

231° (Found: S, 16.2.  $C_{11}H_7ONS$  requires S, 15.9%). This compound is less soluble in alkalis than the benzthiazole analogue.

*1-Amino- $\alpha$ -naphthathiazole*.—Although Hofmann states (*Ber.*, 1879, **12**, 1126) that 1-aminobenzthiazole is obtained by digesting 1-chlorobenzthiazole with alcoholic ammonia at 100°, the chloro-naphthathiazole was recovered unchanged under such conditions, and also after being heated in a sealed tube (0.5 g. of the chloro-base) with alcoholic ammonia (5 c.c. of alcohol and 2 c.c. of ammonia,  $d$  0.880) at 100–140° for  $\frac{1}{2}$  hour.

(i) A mixture of 0.5 g. of 1-chloro- $\alpha$ -naphthathiazole and 5 c.c. of ammonia ( $d$  0.880) was heated at 200° for 18 hours. On recrystallisation from alcohol, 1-amino- $\alpha$ -naphthathiazole was obtained, m. p. 258° alone and when mixed with the specimen prepared from  $\beta$ -naphthylthiocarbamide (previously given, *J.*, 1926, 1400, as m. p. 249–251°; the compound is there erroneously named “2-amino- $\alpha$ -naphthathiazole”). The identity was further confirmed by the formation of the same acetyl derivative. (ii) Treatment of a suspension of  $\beta$ -naphthylthiocarbamide (m. p. 194°; Cosiner, *Ber.*, 1881, **14**, 59, recorded m. p. 180°, and Hector, *Ber.*, 1890, **23**, 362, m. p. 186°) (1 g.) in chloroform (10 c.c.) with bromine (1 c.c. in 1 c.c. of chloroform) yielded a yellow *hydrotribromide*, which sintered at 160–161° after drying in a vacuum [Found: Br, 54.8.  $C_{11}H_8N_2S \cdot HBr(Br_2)$  requires Br, 54.4%]. On reduction with sulphurous acid, basification with ammonia, and recrystallisation from methyl alcohol, this gave the aminonaphthathiazole in plates, m. p. 257° (Found: S, 16.2. Calc.: S, 16.0%).

*1-Acetamido- $\alpha$ -naphthathiazole*.—(i) The product of acetylation of the amino-base with acetic anhydride separated from benzene-ethyl acetate in soft crystals, m. p. 265° (Found: S, 12.9.  $C_{13}H_{10}ON_2S$  requires S, 13.2%).

Hugershoff (*Ber.*, 1899, **32**, 3649) states that treatment of  $\beta$ -naphthylthiocarbamide with acetic anhydride at 80° yields *as*-acetyl- $\beta$ -naphthylthiocarbamide,  $C_{10}H_7 \cdot NAc \cdot CS \cdot NH_2$ , which isomerises to *s*-acetyl- $\beta$ -naphthylthiocarbamide,  $C_{10}H_7 \cdot NH \cdot CS \cdot NHAc$ , m. p. 158°, at its melting point. The product which we isolated from  $\beta$ -naphthylthiocarbamide and acetic anhydride at 80° had m. p. 145–147° and proved to be a mixture containing unchanged naphthylthiocarbamide. On the other hand, *s*-acetyl- $\beta$ -naphthylthiocarbamide was readily prepared by dissolving  $\beta$ -naphthylthiocarbamide in an excess of acetic anhydride at 80° (compare Hunter and Pride, *J.*, 1929, 944); it melted at 171–172° after recrystallisation.

(ii) The solution obtained from 0.3 g. of *s*-acetyl- $\beta$ -naphthylthiocarbamide, 6 c.c. of chloroform, and 0.5 c.c. of bromine was heated

under reflux for 2 minutes, and the orange bromo-addition compound (m. p. 154—156°) obtained was reduced with sulphurous acid. On recrystallisation from boiling alcohol, the acetamidonaphthathiazole formed plates, m. p. 264° alone and when mixed with the specimen obtained in (i).

*1-Ethoxy- $\alpha$ -naphthathiazole*.—10 G. of  $\beta$ -naphthylthiourethane (m. p. 96°; prepared in 95% yield by heating a solution of the thiocarbimide in absolute alcohol, containing a few drops of quinoline, under reflux for 4 hours) were rubbed with a small quantity of alcohol and dissolved in 75 c.c. of 30% aqueous sodium hydroxide. The solution was diluted with water to 200 c.c. and added in 20 c.c. portions at 5-minute intervals to 300 c.c. of a well-stirred 20% solution of potassium ferricyanide at 85°; the cooled mixture was extracted with ether, and the product recrystallised from alcohol (yield, 5.9 g.; 60%). The *ethoxy-base* formed needles, m. p. 80° (Found: S, 14.1.  $C_{13}H_{11}ONS$  requires S, 14.0%).

*Hydrolysis*. 1-Ethoxy- $\alpha$ -naphthathiazole (1 g.) was heated with 7 c.c. of hydrobromic acid (*d* 1.45) for 15 minutes; the mixture was diluted with water (10 vols.), and the product recrystallised from alcohol-ethyl acetate (animal charcoal), 0.4—0.5 g. of 1-hydroxy- $\alpha$ -naphthathiazole being obtained, m. p. 231° alone and when mixed with the specimen obtained from the chloronaphthathiazole.

*1-Ethoxybenzthiazole*.—A similar experiment with 10 g. of phenylthiourethane gave 4 g. of 1-ethoxybenzthiazole (yield, 40%), which was characterised by its hydrolysis to 1-hydroxybenzthiazole, m. p. 138° (Hunter, this vol., p. 135).

*1- $\beta$ -Naphthylaminobenzthiazole*.—When a mixture of 1-chlorobenzthiazole (1 g.) and  $\beta$ -naphthylamine (0.8 g.) was heated, a vigorous reaction took place. The product was extracted with alcohol, the extracts were decolorised with animal charcoal and evaporated on a steam-bath, and the residue was basified and recrystallised from methyl alcohol-ethyl acetate. The *naphthylaminobenzthiazole* (yield, 60%) formed small silky needles, m. p. 191—192° (Found: S, 11.8.  $C_{17}H_{12}N_2S$  requires S, 11.6%). The acetyl derivative could not be crystallised.

*1-Anilino- $\alpha$ -naphthathiazole*.—The tenacious gum obtained by condensing 1-chloro- $\alpha$ -naphthathiazole (1 g.) with aniline (0.5 c.c.) solidified on treatment with hot aqueous ammonia (*d* 0.880). On recrystallisation from methyl alcohol-ethyl acetate, 1-anilino- $\alpha$ -naphthathiazole was obtained in soft silky needles, m. p. 211—212° (Found: S, 11.7.  $C_{17}H_{12}N_2S$  requires S, 11.6%).

*Condensation of Phenylthiocarbimide with  $\beta$ -Naphthylamine*.—6.5 C.c. of phenylthiocarbimide were added to a boiling solution of 7 g. of  $\beta$ -naphthylamine in absolute alcohol (70 c.c.); the mixture

became semi-solid owing to the separation of the phenylnaphthylthiocarbamide (yield, 13 g.; m. p. 161—162°). On recrystallisation from ethyl acetate and thereafter from amyl acetate, *s*-phenyl- $\beta$ -naphthylthiocarbamide was obtained in silvery plates, m. p. 166—167° (Found: S, 11.8. Calc.: S, 11.6%). Mainzer (*Ber.*, 1882, 15, 1471), Freund and Wolf (*Ber.*, 1892, 25, 1468), and Wheeler (*J. Amer. Chem. Soc.*, 1901, 33, 226) give the m. p. as 157°, 165°, and 182—183°, respectively.

*Condensation of  $\beta$ -Naphthylthiocarbimide with Aniline.*—Owing to the readiness with which  $\beta$ -naphthylthiocarbimide combines with alcohol in the presence of amines, this condensation was carried out in benzene solution. After recrystallisation, the product had m. p. 166°, alone and when mixed with the phenylnaphthylthiocarbamide described above.

*Wheeler's "Phenylnaphthylthiocarbamide."*—A mixture of 1 g. of  $\beta$ -naphthylamine and 1.5 c.c. of phenylthiocarbimide was heated until it boiled; the product, which solidified on cooling, was recrystallised from amyl acetate. It formed ill-defined crystals, m. p. 182—184° (softening at 175°), and m. p. 188—189° after extraction with boiling alcohol, in which it was very sparingly soluble. From its properties and the m. p. of its mixture with a genuine specimen (m. p. 193—195°), Wheeler's product (*loc. cit.*) was evidently *s*-di- $\beta$ -naphthylthiocarbamide. Its mixture with a genuine specimen of *s*-phenyl- $\beta$ -naphthylthiocarbamide melted at 158—159°.

It appears probable that *s*-phenyl- $\beta$ -naphthylthiocarbamide is formed initially in Wheeler's experiment and then undergoes decomposition at the elevated temperature attained during the condensation. This supposition is borne out by the following experiment.

*Thermal Decomposition of s-Phenyl- $\beta$ -naphthylthiocarbamide.*—1 G. of the thiocarbamide was kept at 220—230° for 2 minutes, hydrogen sulphide being evolved. The product, which crystallised on cooling, was repeatedly extracted with boiling alcohol, finely ground, and re-extracted with boiling alcohol and thereafter with ethyl acetate. The residue melted at 191—193°, and at 192—194° when mixed with a genuine specimen of *s*-di- $\beta$ -naphthylthiocarbamide.

The alcoholic extracts yielded *s*-phenyl- $\beta$ -naphthylthiocarbamide and some phenylthiocarbimide on evaporation, but the presence of thiocarbimide could not be detected.

*The Action of Bromine on s-Phenyl- $\beta$ -naphthylthiocarbamide.*—A suspension of 3 g. of the thiocarbamide in 30 c.c. of chloroform was treated with bromine (1.2 c.c. in 3 c.c. of chloroform) (an excess of bromine, such as is normally used in the Hegershoff reaction, causes

the production of ill-defined bromo-substitution derivatives) and the mixture was heated under reflux for 3 minutes, cooled, and evaporated to dryness under reduced pressure at laboratory temperature. The product was dissolved in chloroform, the solution shaken with sulphurous acid, and the reduction completed by passage of sulphur dioxide. On basification and removal of the chloroform, a base, m. p. 202—205°, was obtained which on recrystallisation from ethyl acetate yielded 2.2 g. of 1-anilino- $\alpha$ -naphthathiazole, m. p. 206—211°. The mother-liquor furnished a further 0.7 g. of the same base (m. p. ca. 200°). On recrystallisation both fractions had m. p. 211°, alone and when mixed with the specimen of 1-anilino- $\alpha$ -naphthathiazole obtained from 1-chloro- $\alpha$ -naphthathiazole (p. 944). No trace of the isomeric naphthylaminobenzthiazole was found.

1-*p*-Bromoanilino- $\alpha$ -naphthathiazole, which could not be obtained by the bromination of 1-anilino- $\alpha$ -naphthathiazole in chloroform, was prepared by the condensation of 1-chloro- $\alpha$ -naphthathiazole and *p*-bromoaniline; it formed small prisms, m. p. 250° (Found: Br, 22.8.  $C_{17}H_{11}N_2BrS$  requires Br, 22.5%).

*Methylation of 1-Amino- $\alpha$ -naphthathiazole and the Synthesis of 1-Imino-2-methyl-1:2-dihydro- $\alpha$ -naphthathiazole and of 1-Methyl-amino- $\alpha$ -naphthathiazole from the Corresponding Naphthylmethylthiocarbamides.*—A mixture of 1-amino- $\alpha$ -naphthathiazole (2.6 g.) and methyl iodide (3 c.c.) was heated in a sealed tube at 100° for 15 hours. The product was basified with alcoholic potash and the mixture was diluted with water and extracted with ethyl acetate, 1.45 g. of 1-imino-2-methyl-1:2-dihydro- $\alpha$ -naphthathiazole, m. p. 178°, being obtained (Found: S, 15.0.  $C_{12}H_{10}N_2S$  requires S, 14.9%) unaccompanied by any trace of the 1-methylamino-isomeride.

Methyl- $\beta$ -naphthylamine was conveniently prepared as follows: Sodium (1 atom) was dissolved in a hot solution of aceto- $\beta$ -naphthalide (20 g.) in xylene (200 c.c.). After 15 minutes, crystallisation commenced, methyl sulphate (30 c.c.) was added to the semi-solid mass, and the mixture heated for 5 minutes. The xylene was then distilled in steam, and the product heated with alcoholic potash for 24 hours; the alcohol was evaporated on a steam-bath, and the mixture diluted with water and extracted with ether. Distillation of the residue obtained after removal of the ether yielded 8.5 g. of the methylnaphthylamine, b. p. 189°/30 mm. (yield, 50%).

*as- $\beta$ -Naphthylmethylthiocarbamide*, prepared from the methylnaphthylamine, hydrochloric acid, and potassium thiocyanate at 100° (compare Hunter and Styles, J., 1928, 3025), separated from ethyl acetate in small crystals, m. p. 170° (Found: S, 14.7.  $C_{12}H_{12}N_2S$  requires S, 14.8%).

*Reaction with bromine.* A solution of *as- $\beta$ -naphthylmethylthio-*

carbamide (0.5 g.) in chloroform (5 c.c.) was treated with bromine (0.2 c.c. in 2 c.c. of chloroform) and the mixture was heated under reflux for 10 minutes and then shaken with excess of sulphurous acid. The chloroform was evaporated on a steam-bath, and the product basified and recrystallised from alcohol-ethyl acetate, giving 1-imino-2-methyl-1 : 2-dihydro- $\alpha$ -naphthathiazole, identical with the specimen already described.

*s*- $\beta$ -Naphthylmethylthiocarbamide, prepared by condensing  $\beta$ -naphthylthiocarbimide with methylamine in hot alcoholic solution, crystallised in large prisms, m. p. 130° (Found : S, 15.6%).

1-Methylamino- $\alpha$ -naphthathiazole, prepared as in the case of the isomeric iminomethylidihydronaphthathiazole, crystallised in small needles, m. p. 189° (Found : S, 14.7%).

1- $\beta$ -Naphthylamino- $\alpha$ -naphthathiazole, prepared by condensing  $\beta$ -naphthylamine with 1-chloro- $\alpha$ -naphthathiazole, had m. p. 222° alone and when mixed with a specimen prepared from *s*-di- $\beta$ -naphthylthiocarbamide (Hunter, J., 1925, 127, 2270). It is most conveniently prepared from the dinaphthylthiocarbamide in the same way as 1-anilino- $\alpha$ -naphthathiazole is obtained from *s*-phenyl- $\beta$ -naphthylthiocarbamide (p. 945).

*Methylation of 1- $\beta$ -Naphthylamino- $\alpha$ -naphthathiazole.*—The paste obtained from 1 g. of 1- $\beta$ -naphthylamino- $\alpha$ -naphthathiazole and 3 c.c. of chloroform was suspended in 50 c.c. of water containing 10 g. of potassium hydroxide and well shaken with 5 c.c. of methyl sulphate, and again after addition of a further 5 g. of potassium hydroxide and 5 c.c. of methyl sulphate; after  $\frac{1}{2}$  hour the mixture was boiled to remove the chloroform. Recrystallisation of the product from alcohol yielded 1 g. of 1- $\beta$ -naphthylimino-2-methyl-1 : 2-dihydro- $\alpha$ -naphthathiazole (Found : S, 9.5.  $C_{22}H_{16}N_2S$  requires S, 9.4%), unaccompanied by 1-methyl- $\beta$ -naphthylamino- $\alpha$ -naphthathiazole.

*Synthesis of 1-Methyl- $\beta$ -naphthylamino- $\alpha$ -naphthathiazole from Methyl-*s*-di- $\beta$ -naphthylthiocarbamide and from 1-Chloro- $\alpha$ -naphthathiazole and Methyl- $\beta$ -naphthylamine.*—Methyl-*s*-di- $\beta$ -naphthylthiocarbamide, prepared by condensation of  $\beta$ -naphthylthiocarbimide and methyl- $\beta$ -naphthylamine in alcohol, crystallised in soft white plates, m. p. 178° (Found : S, 9.5.  $C_{22}H_{18}N_2S$  requires S, 9.4%).

A solution of this thiocarbamide (0.3 g.) in chloroform (4 c.c.) was treated with 1.6 c.c. of a 10% solution of bromine in the same solvent and the mixture was heated under reflux for 5 minutes, cooled, reduced with sulphurous acid, and basified. On recrystallisation from ethyl acetate, 1-methyl- $\beta$ -naphthylamino- $\alpha$ -naphthathiazole formed shining prisms, m. p. 235° (Found : S, 9.2.  $C_{22}H_{16}N_2S$  requires S, 9.4%). The picrate, prepared from acetone solutions of

the base and picric acid, formed yellow prisms, m. p. 278°, identical with the picrate described below (mixed m. p. 281°).

A mixture of 0.3 g. of 1-chloro- $\alpha$ -naphthathiazole and an equal quantity of methyl- $\beta$ -naphthylamine was heated; on basification an uncrystallisable gum was obtained, which was converted into the picrate, yellow prisms, m. p. 282°, in the usual way (Found: S, 5.6.  $C_{22}H_{16}N_2S, C_6H_3O_7N_3$  requires S, 5.6%).

*Methylation of 1-Hydroxy- $\alpha$ -naphthathiazole and the Synthesis of 1-Keto-2-methyl-1:2-dihydro- $\alpha$ -naphthathiazole from 1-Imino-2-methyl-1:2-dihydro- $\alpha$ -naphthathiazole.*—A solution of 0.5 g. of 1-hydroxy- $\alpha$ -naphthathiazole in 5 c.c. of chloroform was shaken with 6 c.c. of 30% potassium hydroxide solution and 4 c.c. of methyl sulphate, the mixture was heated under reflux for 5 minutes, a further 2 g. of potassium hydroxide and 2 c.c. of methyl sulphate were added, and the heating was continued for a short time. On removal of the chloroform, 1-keto-2-methyl-1:2-dihydro- $\alpha$ -naphthathiazole was obtained in long needles, m. p. 135–136° (Found: S, 15.2.  $C_{12}H_9ONS$  requires S, 14.9%).

1-Nitrosoimino-2-methyl-1:2-dihydro- $\alpha$ -naphthathiazole, prepared from the 1-imino-compound in glacial acetic acid and sodium nitrite (compare Hunter, this vol., p. 145), formed small orange-yellow crystals, which exploded at 165° (Found: S, 12.8.  $C_{12}H_9ON_3S$  requires S, 13.2%).

When the nitrosoimino-compound was heated in xylene until nitrogen ceased to be evolved, and the product crystallised from methyl alcohol, the keto-compound described above was obtained.

*Synthesis of 3-Bromo-1-amino- $\beta\beta$ -naphthathiazole.*—A solution of 3 g. of 1-bromo- $\beta$ -naphthylamine in 20 c.c. of chloroform was gradually added with continuous shaking to a suspension of thiocarbonyl chloride (1.5 c.c.) in water (10 c.c.). After  $\frac{1}{2}$  hour the chloroform and the excess of thiocarbonyl chloride were removed, on a steam-bath, through a fractionating column; the 1-bromo- $\beta$ -naphthylthiocarbimide, rapidly crystallised from alcohol, formed small crystals (1.2 g.), m. p. 90° (Found: Br, 29.5.  $C_{11}H_6NBrS$  requires Br, 30.3%).

1-Bromo- $\beta$ -naphthylthiocarbamide, prepared from the thiocarbimide and ammonia in alcoholic solution, formed white plates, m. p. 204° (Found: Br, 28.5.  $C_{11}H_9N_2BrS$  requires Br, 28.5%).

A suspension of 1 g. of the thiocarbamide in chloroform (10 c.c.) was heated under reflux with 1 c.c. of bromine for 10 minutes; the bromo-addition compound which separated was reduced with sulphurous acid. The 3-bromo-1-amino- $\beta\beta$ -naphthathiazole separated from ethyl acetate in small prisms, m. p. 250° (Found: Br, 28.8.  $C_{11}H_7N_2BrS$  requires Br, 28.7%). The acetyl derivative, obtained

from the base and acetic anhydride in the usual way, formed small needles, m. p.  $289^{\circ}$  (Found: S, 10.0.  $C_{13}H_9ON_2BrS$  requires S, 10.0%).

The authors wish to express their gratitude to Professor J. F. Thorpe, F.R.S., for his interest in this work, and to the Trustees of the Dixon Fund of the University of London for grants which have defrayed the cost of the materials.

### CXVI.—*The Calculation of Activity Coefficients from Solubility Measurements: Thallous Chloride.*

By HERBERT EDWARD BLAYDEN and CECIL WHITFIELD DAVIES

THE study of activities by the method of solubility measurements with a sparingly soluble salt in the presence of other electrolytes has led to the following generalisations: (1) in very dilute solutions the results furnish a striking verification (Brönsted, *Trans. Faraday Soc.*, 1927, 23, 416) of the Debye-Hückel theoretical equation  $-\log f_{\pm} = A\sqrt{\mu}$ , where  $f_{\pm}$  is the mean ion activity coefficient,  $\mu$  is the ionic strength of the solution, and the constant  $A$  has the value 0.505 for a uni-univalent salt in aqueous solution at  $25^{\circ}$ ; (2) at concentrations greater than  $0.01M$ ,  $\log f_{\pm}$  no longer gives a linear relation with  $\sqrt{\mu}$  and depends, moreover, on the nature of the added electrolyte. Thus, Harned (Taylor's "Treatise on Physical Chemistry," 1925, p. 774), speaking of the data on thallous chloride (shown by the series of broken curves in Fig. 2 of this paper), says ". . . the influence of one electrolyte on the activity coefficient of another is a problem of great complexity. Each mixture exhibits individual behavior even in solutions of ionic strength as low as 0.03."

These conclusions are widely accepted, but the figures on which they rest are all based on the assumption that the salts employed are completely dissociated, an assumption which in some instances is invalid. The present paper deals with thallous chloride, the dissociation constant of which is known, and it is shown (1) that in very dilute solutions the value of  $A$  for this salt is much lower than the Debye-Hückel value 0.505, and (2) that when allowance is made for incomplete dissociation, the apparent complexity of the curves disappears, and the activity coefficient is independent of the nature of the other ions present, up to concentrations of  $0.1N$ . Further, this new relationship is shown to be of value for estimating the degree of dissociation of other electrolytes of unknown strength.

*Dissociation Constant of Thallous Chloride.*—The dissociation constant of thallous chloride has been found from conductivity data at 18° to be  $K = 0.31$  (Onsager, *Physikal. Z.*, 1927, **28**, 277) or  $K = 0.30$  (Davies, *Trans. Faraday Soc.*, 1927, **23**, 354). This value has been confirmed by a rather different method (Davies, "Conductivity of Solutions," 1930, p. 141): by evaporating a saturated solution, the Earl of Berkeley (*Phil. Trans.*, 1904, *A*, **203**, 208) found the solubility of the salt to be 0.0132 g.-equiv. per litre (interpolated value at 18°), and by the conductivity method Kohlrausch (*Z. physikal. Chem.*, 1908, **64**, 129) found the value 0.01278 g.-equiv. per litre; the latter figure really represents the ionic concentration of the saturated solution, and the difference between the two values, *viz.*, 0.0004<sub>2</sub>, gives the concentration of undissociated molecules. This agrees very well with the value, 0.00044, calculated from the dissociation constant  $K = 0.30$ .

*Solubility Measurements.*—The solubility of thallous chloride has been measured at 25° in the presence of numerous salts (Noyes, *ibid.*, 1892, **9**, 609; *J. Amer. Chem. Soc.*, 1924, **46**, 1107; Bray and Winninghoff, *ibid.*, 1911, **33**, 1666; Butler and Hiscocks, *J.*, 1926, 2558; Randall and Chang, *J. Amer. Chem. Soc.*, 1928, **50**, 1535). The results in the presence of other univalent chlorides will first be considered, for here the added electrolyte is completely dissociated.

*Solubilities in the Presence of Chlorides of Univalent Metals.*—The degree of dissociation of the pure saturated solution of thallous chloride is first calculated. In the equation  $f_{\pm}^2 c_i^2 / f_u c_u = K$ , where  $c_i$  is the concentration of the ions,  $f_u$  the activity coefficient of the undissociated molecules, and  $c_u$  their concentration, we can put  $K = 0.30$ , and  $f_u$  can be assumed to be equal to unity at low concentrations (compare Randall and Failey, *Chem. Reviews*, 1927, **4**, 291);  $f_{\pm}$  can be calculated from the Debye-Hückel formula by giving  $A$  the value 0.505 as a first approximation, and  $c_i + c_u = 0.01612$ , the solubility of the salt. Solving by successive approximations, we find  $c_i = 0.01552$ ,  $c_u = 0.00060$ ; and for the solubility product,  $S = f_{\pm}^2 \cdot c_i^2 = 18.03 \times 10^{-5}$ .

In a 0.025*N*-potassium chloride solution the solubility of thallous chloride is 0.00872 (Noyes, *loc. cit.*), whence (with  $f_u = 1$ ),  $c_i = 0.00872 - 0.00060 = 0.00812$  and  $f_{\pm}^2 = S / [Cl][Tl] = 18.03 \times 10^{-5} / 0.03312 \times 0.00812 = 0.6708$ , or  $\log f_{\pm} = 1.9133$ . Fig. 1, Curve 1 shows the values calculated in this way for other concentrations of added chloride plotted against the square root of the ionic strength. The points up to 0.1*N* lie on a straight line, the slope of which should give the value of  $A$ , but the extrapolation of this cannot be reconciled with the limiting value  $\log f_{\pm} = 0$  when  $c = 0$ . This, of course, is because the value  $A = 0.505$  was arbitrarily taken in fixing the

position of the first point of the curve, whereas the experimental points lie on a straight line with the slope 0.40. It will be evident that only one value for the factor  $A$  can be consistent both with the corrected solubility values and with the limiting equation  $-\log f_{\pm} = A\sqrt{\mu}$ . This value lies very close to 0.40, and has been found by trial and error to be  $A = 0.38$ .

It is shown below that this same value holds good when the added salt is other than the chloride of a univalent element. In dilute solutions, therefore, the mean ion activity coefficient of thallous

FIG. 1.

chloride varies with the ionic strength of the solution according to the equation  $-\log f = 0.38\sqrt{\mu}$ . Application of this to the conductivity figures used in calculating  $K$  alters  $K$  from 0.30 to 0.284, and similarly the solubility figures give  $S = 19.18 \times 10^{-5}$ . The data recalculated on this basis are given in Table I and are shown in Fig. 1, Curve 2.

*The Value of the Factor A.*—It is of interest to compare the value  $A = 0.38$  with the results for other uni-univalent electrolytes. The Debye-Hückel theory requires the common value 0.505 and the measurements of Brönsted and La Mer (*J. Amer. Chem. Soc.*, 1924, 46, 555) on complex cobalt salts are in striking agreement with this. On the other hand, some of the most accurate experimental investig-

ations have failed to confirm this value. Nonhebel (*Phil. Mag.*, 1926, 2, 1085), from *E.M.F.* measurements, and Randall and Vanselow (*J. Amer. Chem. Soc.*, 1924, 46, 2418), from freezing-point measurements, both find  $A = 0.39$  for hydrochloric acid; further, the value 0.38 has previously been found for several organic acids (Davies, *Phil. Mag.*, 1927, 4, 244). This value might have been regarded as peculiar to the acids, but it now appears to hold also for thallic chloride. For other univalent electrolytes, the data available, although probably less accurate, have led Noyes (*J. Amer. Chem. Soc.*, 1924, 46, 1098) to suggest for them a common  $A$  value of about 0.41. In view of these results—reached by very diverse methods—there seems to be justification for believing that for the simple inorganic ions and some, at least, of the organic anions, the value of the activity factor  $A$  should, in the absence of experimental evidence, be assumed to be 0.39 and not 0.50. Further data alone can show whether  $A$  in reality varies from ion to ion.

*Solubilities in the Presence of Other Salts the Degrees of Dissociation of which are known.*—The data, calculated on the same basis as before, are given in Table I, where the concentrations and solubilities (Sol.) are in g.-equivs. per litre.

TABLE I.

$$S = 19.18 \times 10^{-5}.$$

0.200	0.00283	0.5497	0.1805				

The figures for the bivalent chlorides represent the data of Noyes for magnesium, calcium, barium, zinc, manganous, and cupric chlorides, and it has been assumed that these are completely dissociated.

For thallic nitrate the calculations are complicated by the fact

that the added salt is itself incompletely dissociated, so that the solution contains both undissociated thallous chloride and undissociated thallous nitrate. The concentration of undissociated thallous chloride is the same as that in any other solution saturated with respect to this salt, and the concentration of undissociated thallous nitrate is calculated from its dissociation constant,  $K = 0.56$  (Davies, *loc. cit.*), on the assumption that  $A$  has the value 0.38; an error in this assumption would have only a very small effect on the final results, because the concentration of the undissociated nitrate is itself small. Thus, in 0.025*N*-thallous nitrate the solubility of thallous chloride is 0.00883 g.-equiv. per litre (Noyes, *loc. cit.*). Of this quantity, 0.00068 is undissociated molecules, and  $[Cl'] = 0.00815$ . If  $x$  is the concentration of undissociated thallous nitrate,  $[NO'_3] = (0.025 - x)$  and  $[Tl'] = (0.00815 + 0.025 - x)$ ; hence  $f^2 (0.025 - x) (0.03315 - x)/x = 0.56$ , where  $f$ , the mean ion activity coefficient of thallous nitrate is given by  $-\log f = 0.38 \times \sqrt{0.03315 - x}$ , the term under the square-root sign being the ionic strength. By a series of approximations,  $x$  is found to be 0.00101, whence  $[Tl'] = 0.03214$ ,  $f_{\pm}^2 = S/[Cl'][Tl'] = 0.0001918/(0.00815 \times 0.03214)$ , and  $-\log f_{\pm} = 0.0677$ . Similar calculations are applied to the remaining data for thallous nitrate.

When potassium nitrate is the saturating salt, the solution contains three undissociated salts, *viz.*, thallous chloride and nitrate and potassium nitrate ( $K = 1.37$ , Davies, *loc. cit.*). In this case the true concentrations of the ions are calculated by a series of approximations, the method being similar to that just described.

Fig. 2 shows the data for twelve different added salts. The lower series of points, connected by broken lines, is calculated on the assumption that both the thallous chloride and the added salt are completely dissociated; they illustrate the individual differences in behaviour that were formerly believed to exist. The upper series of points, through which a continuous line has been drawn, shows the data as recalculated in this paper. The possible experimental error in the measurements is illustrated by the two bracketed values for the thallous nitrate solution,  $\sqrt{\mu} = 0.308$ ; the lower value was obtained from the figures of Noyes, and the upper from the measurements of Butler and Hiscocks.

The most important conclusion to be drawn is that up to a concentration of about 0.1*N*, the mean ion activity coefficient of thallous chloride depends only upon the ionic strength of the solution and not upon the nature of the other ions present. That the corrections here applied for incomplete dissociation should have so uniformly removed the specific deviations seems, apart from its intrinsic interest, to provide strong support for the dissociation constants derived from

conductivity measurements. It is also noteworthy that the linear relationship between  $\log f_{\pm}$  and  $\sqrt{\mu}$  is found to hold, for thallous chloride at least, up to a higher concentration than 0.01N, the usually accepted limit.

*Solubilities in the Presence of Other Salts.*—If it is accepted that the activity coefficient of thallous chloride, in the more dilute solutions, is dependent only on the ionic strength and not upon the nature of the added salt, then the calculations described may be reversed,

FIG. 2.

Activity coefficients of thallous chloride in the presence of: KCl, etc.  $\odot$ ; HCl  $\square$ ; BaCl<sub>2</sub>, etc.  $\oplus$ ; KNO<sub>3</sub>  $\diamond$ ; TlNO<sub>3</sub>  $\nabla$ ; Tl<sub>2</sub>SO<sub>4</sub>  $\triangle$ .

Broken curves are based on the assumption of complete dissociation. The full curve is based on an allowance for incomplete dissociation.

solubility measurements being made to provide a new method of determining the degree of dissociation of salts.

With the data already available the method can be applied to thallous sulphate, but here allowance must be made for the probable equilibria:

It seems reasonable to suppose, by analogy with sulphuric acid (Noyes and Sherrill, *J. Amer. Chem. Soc.*, 1926, 48, 1861), that in dilute solutions the amount of undissociated sulphate will be

negligibly small, and that step (2) may be disregarded as a first approximation. The dissociation constant of the first stage,  $K_1$ , can now be calculated from the solubility measurements in the following way. In 0.02*N*-thallous sulphate solution the solubility of thallous chloride is 0.01034 (Bray and Winninghoff, *loc. cit.*). If  $x$  is the concentration of  $\text{TlSO}_4'$ , the concentrations of the other species present are as follows:  $[\text{TlCl}] = 0.00068$ ;  $[\text{Cl}'] = 0.01034 - 0.00068 = 0.00966$ ;  $[\text{SO}_4''] = 0.01 - x$ ;  $[\text{Ti}'] = 0.00966 + 0.02 - x$ . The ionic strength of the solution is  $0.03966 - 2x$ , and we have  $f_{\pm}^2[\text{Ti}'][\text{Cl}'] = S$ , in which  $-\log f_{\pm} = 0.38\sqrt{\mu}$ . By successive approximations  $x$  can be found, and the left-hand side of the equation

$$\frac{[\text{Ti}'][\text{SO}_4'']}{[\text{TlSO}_4']} = \frac{K_1 \cdot f_{\text{TlSO}_4'}}{f_{\text{Ti}'} \cdot f_{\text{SO}_4''}} = K'_1$$

is thereby determined. The figures are shown in Table II, where the concentration of added salt and the solubility are in g.-equiv./l., and col. 4 gives  $K'_1$ , the "apparent dissociation constant" of the thallosulphate ion. Col. 5 shows the value of  $K_1$ , the true dissoci-

TABLE II.  
Added salt : Thallous sulphate.

Conc.	Solubility.	$\sqrt{\mu}$ .	$K'_1$ .	$K_1$ .
0	0.01612	0.1243	—	—
0.020	0.01034	0.1868	0.0876	0.0371
0.050	0.00626	0.2588	0.125	0.0380
0.100	0.00423	0.3463	0.169	0.0343

ation constant of this ion, calculated from  $K'_1$  on the assumptions that, at any ionic strength,  $f_{\text{TlSO}_4'} = f_{\text{Ti}'}$ , and  $f_{\text{SO}_4''}$  is given by the Debye-Hückel equation  $-\log f_{\text{SO}_4''} = 2.0\sqrt{\mu}$ : the values are as constant as could be expected in view of the probable errors of calculation and measurement; the mean value of  $K_1$  also agrees well with a second determination by a different method, which will be described in another paper. These figures are of interest as being the first obtained, on the basis of the interionic attraction theory, for the dissociation of a uni-bivalent salt, and they further emphasise the errors involved in a general application of the "complete dissociation of salts" hypothesis. Thus, the value  $K_1 = 0.036$  implies that in a 0.05*M*-solution of thallous sulphate about one-third of the total sulphate radical exists as  $\text{TlSO}_4'$ .

For thallous chlorate a single measurement is available; Noyes (*loc. cit.*) found the solubility of thallous chloride in 0.025*N*-thallous chlorate to be 0.00895 g.-equiv. per litre. Applying the same methods of calculation as before, we find the thallous chlorate to

be 6.4% undissociated, and give  $K = 0.34$  as a provisional value for the dissociation constant of this salt.

### *Summary.*

In determining activity coefficients by measuring the solubility of one salt in the presence of others, allowance must be made for the incomplete dissociation of the salts concerned. The necessary corrections are applied to the data for thalious chloride with the following results.

(1) The logarithm of the activity coefficient gives a straight line when plotted against the square root of the ionic strength up to a value of the latter considerably greater than 0.1.

(2) The slope of the curve is not 0.505, as the Debye-Hückel theory requires, but 0.38, a value previously found for several monobasic acids.

(3) The irregularities previously attributed to specific influences of the added ions disappear below a concentration of 0.1N, being due to neglect of incomplete dissociation of the salts.

(4) The dissociation constant of the  $\text{TiSO}_4^+$  ion is found to be 0.036, and that of thalious chlorate to be 0.34.

BATTERSEA POLYTECHNIC, S.W. 11.

[Received, March 12th, 1930.]

## CXVII.—*iso*- $\beta$ -Naphthol Sulphide.

By LEONARD ARTHUR WARREN and SAMUEL SMILES.

WHEN 2-naphthol 1-sulphide (I) is oxidised by alkaline ferricyanide, two hydrogen atoms are removed (J., 1914, 105, 1750) and the dehydro-sulphide is formed. Reduction of the latter substance yields the *iso*- $\beta$ -naphthol sulphide by absorption of two hydrogen atoms; these are removed by suitable oxidation, the dehydro-sulphide being regenerated (*loc. cit.*).

The *iso*-sulphide contains two active hydrogen atoms (J., 1913, 103, 346) and it yields lead and zinc derivatives which are insoluble in acetic acid (Hinsberg, *J. pr. Chem.*, 1914, 90, 345) in contrast with 2-naphthol 1-sulphide (I). Lesser and Gad (*Ber.*, 1923, 56, 970) found that a disulphide is formed from this *iso*-sulphide by oxidation with iodine and they obtained further evidence showing that the *iso*-sulphide is a hydroxy-mercaptan. These authors, assuming the structure (II) proposed by Hinsberg (*J. pr. Chem.*, 1915, 91, 307) for the dehydro-sulphide, considered that the *iso*- $\beta$ -naphthol sulphide should be represented by (III), which has the merit of providing a simple explanation of the conversion of the

substance into 2-naphthol 1-sulphide (I) by aqueous alkali hydroxide. On the other hand, this formula does not represent the substance

as a mercaptan, but assigns to it a dipolar structure derived from dinaphthylsulphonium hydroxide, to which the properties of a mercaptan can hardly be ascribed.

Apart from this criticism of a general nature, there are others which taken together make necessary a revision of the structure (III). For instance, the *iso*-sulphide is unattacked by aqueous acids and no indication of the formation of a sulphonium salt is obtained. If the dipolar structure and the explanation of the action of alkali which it affords were correct, acids as well as alkaline reagents should effect the conversion into 2-naphthol 1-sulphide (I). The zinc derivative of the *iso*-sulphide behaves as if the metal were associated with sulphur. With methyl iodide it gives a methyl ether (Hinsberg, *J. pr. Chem.*, 1916, **93**, 277) which is now shown to be the *S*-methyl derivative, since it is not oxidised by iodine and yields methyl mercaptan on reduction. This behaviour of the salt and its insolubility in acetic acid accord with the character of a zinc mercaptide. The *S*-methyl ether is not attacked by boiling aqueous alkali hydroxide or by boiling concentrated hydrochloric acid. According to the formula of Lesser and Gad (III with SMe in place of SH) 2-naphthol 1-sulphide should be obtained with these reagents, especially easily with the former, since Kehrman and Duttenhofer (*Ber.*, 1905, **38**, 4198) have shown that dinaphthyl-methylsulphonium decomposes rapidly under alkaline conditions, liberating the aromatic sulphide.

The *S*-methyl ether is converted by suitable oxidation into the sulphone: it is difficult to understand how a substance of that type could be formed from the structure in question (III; SH = SMe) without rupture of the molecule.

Finally,  $\alpha\beta\beta'\alpha'$ -dinaphthathioxin (IV) is obtained by dehydration of the *iso*-sulphide (J., 1913, **103**, 347, 909). Lesser and Gad, anticipating that this "*iso*"-dinaphthathioxin might have the structure later found to be correct (J., 1929, 210), assumed (*Ber.*, 1925, **58**, 2557) that migration of sulphur from the 1- to the 2-position takes place during dehydration and suggested a mechanism which involves the formation of a three-membered ring (V). This explan-

ation appears incomplete; moreover, there is difficulty in admitting that the dipolar structure would survive the attack of concentrated sulphuric acid while hydroxyl is being removed from the naphthalene nucleus. The experiments now described were undertaken as a result of these and other considerations.

Since it is evidently unsafe to attempt to derive any structure of the *iso*-sulphide from that hitherto ascribed to the dehydro-sulphide (II), the question has been approached independently. The chief characteristics of the *iso*-sulphide are those of a hydroxy-mercaptan (see, *e.g.*, Lesser and Gad, *loc. cit.*). When the substance is dehydrated,  $\alpha\beta\beta'\alpha'$ -dinaphthathioxin (IV) is formed: during the process, hydroxyl is removed and thiol survives as the thio-group. Interpreted in the simplest manner, this result leads to a structure such as (VI) for the *iso*-sulphide, which would thus appear as a derivative of 1:2'-dinaphthyl ether. Experiments have been made to isolate this group by removing sulphur from the substance.

Since the sulphonic group is easily removed from the naphthalene nucleus by alkaline reduction (Friedländer, *Ber.*, 1893, 26, 3208), the *S*-methyl ether was converted into the *sulphone*. This substance was easily attacked by sodium amalgam, the methanesulphonyl group being eliminated. The sulphur-free residue was identified as 2-hydroxy-1:2'-dinaphthyl ether (VII) by comparison of its *methyl* ether with the product synthesised from 1-bromo-2-methoxynaphthalene and potassium 2-naphthoxide in presence of copper.

Hydrogen iodide slowly attacked this sulphone, liberating methyl mercaptan, but with this reagent no pure substance was isolated from the sulphur-free products. On the other hand, the *S*-methyl ether, although slowly attacked by sodium amalgam under more

intense conditions, was easily attacked by hydrogen iodide, giving good yields of methyl mercaptan and the hydroxydinaphthyl ether

(VII) in question. Moreover, the *iso*-sulphide and the dehydro-sulphide were easily resolved by warm hydrogen iodide into hydrogen sulphide and this ether.

The *iso*-sulphide is therefore to be regarded as the thiol derivative of 2-hydroxy-1:2'-dinaphthyl ether, and, since  $\alpha\beta\beta'\alpha'$ -dinaphthathioxin (IV) is formed on dehydration, the thiol group must be in the 1'-position as indicated by (VI). This structure accords well with all the properties of the *iso*-sulphide hitherto observed and also with the formation of the sulphone and sulphonium derivatives now recorded.

With this information concerning the *iso*-sulphide, the constitution of the dehydro-sulphide may be profitably discussed. This substance is formed from 2-naphthol 1-sulphide (I) or the *iso*-sulphide (VI) by loss of two hydrogen atoms; evidently it contains the 1:1'-thio- and the 1:2'-oxido-group of the respective generators and should be represented as (VIII), reduction to the *iso*-sulphide taking place by rupture of the five-membered ring as indicated. The formation of the substance from 2-naphthol 1-sulphide may be represented as involving the oxidation of a tautomeric form of the latter (IX); some justification for this view (compare Willstätter and Schuler, *Ber.*, 1928, 61, 362) is found in the fact that this sulphide and others of its type yield only the monopotassium salts from solutions in more than two molecular proportions of the alkali hydroxide (Lesser and Gad, *Ber.*, 1925, 58, 2557). The structure (II) assigned by Hinsberg (*loc. cit.*) to this substance was founded on the formation of a monohydrazone and on experiments which indicated the formation of a very unstable perchlorate; but the existence of the latter substance cannot here be accepted as conclusively proving the presence of the sulphonium group, since it is well known that carbonyl in many ketones and quinones is capable of forming additive compounds with acids and salts (Pfeiffer, "Organisch Molekül-Verbindungen," 1927). The properties of the dehydro-sulphide are therefore adequately represented by the *spiro*-structure proposed. Moreover it should be noticed that this structure represents complete analogy with the dehydrophenols investigated by Pummerer (*Ber.*, 1914, 47, 1472, 2957; 1919, 52, 1392), who showed, for example, that dehydro-1-bromo-2-naphthol (X), which is obtained by oxid-

ation of 1-bromo-2-naphthol, yields on reduction the 1'-bromo-2-hydroxy-1:2'-dinaphthyl ether (XI), the quinolic bromine atom being eliminated. The greater stability of the dehydro-sulphide compared with that of other dehydrophenols is well explained by the presence of the five-membered thioxole system.

Finally it must be noticed that the conversion of the *iso*-sulphide into 2-naphthol 1-sulphide by heating or by the action of alkali hydroxide now appears to be an intramolecular change. Further experiments are being made concerning this process and the nature of dehydro-2-naphthol-1-sulphone.

#### EXPERIMENTAL.

The *iso*-2-naphthol sulphide (VI) used in these experiments was prepared as previously described (J., 1912, 101, 1423). The characteristic brown nickel derivative, formed by addition of nickel acetate to an alcoholic solution of the mercaptan, is very soluble in benzene.

*The S-Methyl Ether of the iso-Sulphide* (VI with SME in place of SH).—A concentrated solution of zinc acetate (10 g.) in hot water was added to a boiling solution of the *iso*-sulphide (20 g.) in alcohol (100 c.c.). The zinc salt (95%) separated in the crystalline state and was purer and more easily manipulated than the amorphous material prepared from cold solutions. A mixture of this zinc salt (10 g.), methyl iodide (5 c.c.), and ethyl alcohol (100 c.c.) was boiled until the zinc salt had dissolved (*ca.* 1 hour). The solvent was evaporated from the filtered solution and the residue was purified from acetic acid. The product (80–90%) had m. p. 134° (Found : C, 76.1; H, 4.8. Calc. : C, 75.9; H, 4.8%). The substance did not react with iodine in ethereal solution in presence of sodium bicarbonate, and it was recovered unchanged from a boiling ( $\frac{1}{4}$  hour) solution in aqueous sodium hydroxide (2*N*) and from a boiling (1½ hours) alcoholic solution containing hydrochloric acid. The formation of a yellow insoluble material when bromine vapour is added to an acetic acid solution may be conveniently used as a test for the presence of the substance.

The *benzoyl* derivative, prepared in cold pyridine, formed plates, m. p. 84–85° (Found : C, 77.2; H, 4.8.  $C_{23}H_{20}O_3S$  requires C, 77.1; H, 4.6%).

The *mercuri-iodide* of the *dimethylsulphonium iodide* (VI; SH =  $SMe_2I, HgI_2$ ) was rapidly formed when acetone containing equimolecular proportions of the *S*-methyl ether and mercuric iodide and a large excess of methyl iodide was boiled. After the mercuric iodide had dissolved, ether was added to the cooled liquid until it became turbid. The required substance separated in pale yellow

prisms, m. p.  $101^{\circ}$  (decomp.); these contained acetone which could not be quantitatively removed without further decomposition of the substance (Found: C, 32.1; H, 2.9; Hg, 20.0.  $C_{22}H_{19}O_2I_3SHg, 2C_3H_6O$  requires C, 32.1; H, 3.0; Hg, 19.2%).

The dimethyl ether of the *iso*-sulphide (VI; OH and SH = OMe and SMe respectively) was obtained as a clear viscous oil by the action of methyl sulphate on the sodium derivative of the *S*-methyl ether in methyl alcohol. It was characterised as the *methosulphate*, which was formed by heating a mixture of methyl sulphate ( $1\frac{1}{4}$  mols.) and the dimethyl ether (1 mol.) at  $100^{\circ}$  for 1 hour. The required substance was isolated from the product and further purified by addition of ether to a chloroform solution. It formed plates, m. p.  $178^{\circ}$  (decomp.), which were moderately easily soluble in water (Found: C, 61.4; H, 5.4; S, 13.3.  $C_{22}H_{18}O_2S, Me_2SO_4$  requires C, 61.0; H, 5.1; S, 13.6%).

The *S*-methylsulphone (VI; SH =  $SO_2Me$ ) was obtained by oxidation of the *S*-methyl ether. A product of this process has been described by Hinsberg (*J. pr. Chem.*, 1916, **93**, 277) as the sulphone derived from the monomethyl ether and as having m. p.  $218^{\circ}$ . The formation of a substance of this m. p. has been confirmed, but analytical data show that it is a mixture of sulphone and sulfoxide in approximately equal proportion (Found: C, 70.7; H, 4.7. Calc. for sulphone: C, 69.2; H, 4.4%. Calc. for sulfoxide: C, 72.4; H, 4.6%). Moreover, it was attacked by zinc and acetic acid, yielding a mixture of lower and indefinite m. p. ( $185$ – $190^{\circ}$ ) which was found by the bromine test to contain the *S*-methyl ether. The required sulphone was obtained by renewed oxidation. Acetic acid (20 c.c.) containing the *S*-methyl ether (4 g.) and hydrogen peroxide (8 c.c. of 30%) was heated at  $100^{\circ}$  for  $\frac{1}{2}$  hour and rapidly cooled. The product (4.1 g.), m. p.  $204$ – $209^{\circ}$ , was re-oxidised ( $\frac{1}{2}$  hour) with twice its weight of hydrogen peroxide (30%) in sufficient acetic acid for complete solution at  $100^{\circ}$ . The material (2.5 g.), which slowly separated from the cooled liquid, crystallised from acetic acid in plates, m. p.  $200^{\circ}$  (Found: C, 69.2; H, 4.5; *M*, 367.  $C_{21}H_{16}O_4S$  requires C, 69.2; H, 4.4%; *M*, 364). The substance was not attacked by zinc dust and acetic acid. The *benzoyl* derivative, prepared in cold pyridine, formed plates, m. p.  $149$ – $150^{\circ}$  (Found: C, 71.9; H, 4.7.  $C_{28}H_{20}O_5S$  requires C, 71.8; H, 4.3%). This substance was also obtained by oxidation of the *benzoyl* derivative of the *S*-methyl ether.

*2-Hydroxy-1:2'-dinaphthyl Ether* (VII).—This was obtained by the following methods: (a) A mixture of the *S*-methylsulphone (2 g.), aqueous sodium hydroxide (1 mol., 2*N*), ethyl alcohol (10 c.c.), and water (50 c.c.) was treated with sodium amalgam (150 g., 3%)

in the course of 12 hours, sufficient alcohol being added at intervals to redissolve insoluble material. Eventually the alcohol was evaporated and the sparingly soluble sodium salt was collected and decomposed with dilute sulphuric acid. The product (1 g.) crystallised from acetic acid in needles, m. p.  $197^{\circ}$ .

(b) The *S*-methyl ether (1 g.) was gently boiled with purified hydrogen iodide (25 c.c., *d* 1.7) in a long-necked flask. A slow stream of nitrogen passed through the apparatus, and the emergent vapours were washed by aqueous mercuric chloride. When the liberation of methyl mercaptan had ceased, the precipitated mercury derivative was collected (97%) (Found : Hg, 70.6. Calc. for  $\text{CH}_3\cdot\text{S}\cdot\text{HgCl}$  : Hg, 70.8%). The cooled contents of the reaction vessel were added to a large bulk of water; the solid was collected, washed (75%), and purified from acetic acid. It had m. p.  $197^{\circ}$ .

(c) A mixture of the zinc salt of the *iso*-sulphide (1 g.) and hydrogen iodide (10 c.c.) was treated as described in (b). Decomposition rapidly took place with liberation of hydrogen sulphide. The product, isolated and treated as described, was purified (36%) from acetic acid and had m. p.  $197^{\circ}$ .

(d) Similar treatment of the dehydro-sulphide (VIII) with hydrogen iodide gave hydrogen sulphide and a product which after purification (45%) had m. p.  $197^{\circ}$ .

The products from these four sources (*a*, *b*, *c*, and *d*) were identical with one another and with the product formed by reduction of dehydro-2-naphthol-1-sulphone (Hinsberg, *J. pr. Chem.*, 1915, 91, 307) under suitable conditions (Found : C, 84.0; H, 4.8. Calc. for  $\text{C}_{20}\text{H}_{14}\text{O}_2$  : C, 83.9; H, 4.9%). The structure suggested by Hinsberg (*Ber.*, 1915, 48, 2092) for this substance has been supported by Pummerer (*Ber.*, 1919, 52, 1414) and is now entirely confirmed by the synthesis of its methyl ether. It yielded a bromo-derivative, m. p.  $133$ – $134^{\circ}$ , apparently identical with that (XI) isolated by Pummerer and Cherbuliez (*loc. cit.*) from dehydro-1-bromo-2-naphthol; but no close comparison was made.

*2-Methoxy-1 : 2'-dinaphthyl Ether* (VII;  $\text{OH} = \text{OMe}$ ).—(a) Potassium 2-naphthoxide was prepared by heating (1 hour,  $110$ – $120^{\circ}$ ) the requisite quantities of 2-naphthol and potassium hydroxide in a current of nitrogen. A mixture of this material (2 mols.) and 1-bromo-2-methoxynaphthalene (1 mol.) containing a little copper acetate was heated (6 hours,  $230$ – $240^{\circ}$ ) in an atmosphere of nitrogen. During the process 2-naphthyl methyl ether sublimed; a further quantity of this substance was removed from the product by a current of steam in an alkaline medium. The dark-coloured insoluble material was set aside until it had solidified; then, when dry, it was heated in a vacuum (1–2 mm.). The desired *ether*

sublimed, and crystallised from acetone-alcohol in plates, m. p. 161°.

(b) The hydroxy-derivative (VII) obtained by the processes of reduction described above was methylated in aqueous alkaline solution with methyl sulphate. The product after purification had m. p. 161° and was identical with that obtained as described in (a) (Found : C, 83·7; H, 5·4.  $C_{21}H_{16}O_2$  requires C, 84·0; H, 5·3%).

In conclusion we wish to thank Dr. A. Cohen for the synthesis of 2-methoxy-1 : 2'-dinaphthyl ether and for his help in some of these experiments.

KING'S COLLEGE, LONDON.

[Received, February 6th, 1930.]

### CXVIII.—*The Nitrosation of Phenols. Part VIII.* *Resorcinol Monoethyl Ether.*

By HERBERT HENRY HODGSON and HUBERT CLAY.

KIETAIBL (*Monatsh.*, 1898, **19**, 536) described two *o*-nitrosoresorcinol monoethyl ethers, but was unable to settle their constitutions. It has now been shown that in his nitrosation process 6-nitroso-3-ethoxyphenol alone is produced, for the product on oxidation gives only 6-nitro-3-ethoxyphenol : this compound has also been prepared from 4-nitro-3-aminophenetole, and both specimens give 4-nitro-resorcinol diethyl ether on ethylation.

Only the 3-chlorine could be replaced by ethoxyl when an excess of ethyl-alcoholic sodium ethoxide reacted with 1 : 3-dichloro-4-nitrobenzene (see Hodgson and Handley, J., 1928, 163, for the replacement of both chlorine atoms by methoxy-groups) : the 4-nitro-group renders the 3-carbon more positive than the 1-carbon atom by the general effect (Allan, Oxford, Robinson, and Smith, J., 1926, 401) and consequently the anionoid reagent ( $NaOAlk^{\oplus}$ ) first replaces the 3-chlorine by the  $OAlk$  group; but since ethoxyl is much more strongly anionoid than methoxyl, its excess of "negativity" so diminishes the general (electron-attracting) effect of the nitro-group on the 1-carbon atom that the anionoid reagent is unable under ordinary conditions to displace the chlorine atom in position 1.

The explanation of the predominant ortho-nitrosation of resorcinol monoethyl ether is similar to that for the monomethyl ether (Hodgson and Clay, J., 1929, 2775, formula I with Et in place of Me). With the assumption there made regarding the partly ionised hydroxyl group, since ethoxyl has a greater repressive effect on ionisation than methoxyl, the activation of hydrogen in the 4-position should be

relatively increased; moreover, the kationoid reagent in its polarised phase,  $\text{HONO}^{\oplus}$ , will have less tendency for attachment to the less highly charged phenolic hydroxyl group. On both counts the monoethyl ether should undergo nitrosation in the 4-position: this actually takes place to the extent of 10–15%. The same argument holds for nitration and is confirmed by the experimental results.

Alternatively, should the ethoxy-group exert an inductive electron-attraction, the 4-carbon (*loc. cit.*, formula III, with Et in place of Me) would be deactivated to a less extent in the ethoxy- than in the methoxy-compound, and so be relatively more reactive.

The solubility (1.32%) of 6-nitroso-3-ethoxyphenol in benzene is appreciably less than that (2.26%) of 6-nitroso-3-methoxyphenol, showing that the co-ordination (*loc. cit.*, formula V) of the *o*-nitroso- and the hydroxyl group is relatively weakened in the former compound. It would appear, therefore, that the increased repression of ionisation (see above) exceeds the concurrent increased activation of the chelating electrons of the nitroso-group.

#### EXPERIMENTAL.

*The Nitrosation of Resorcinol Monoethyl Ether.*—The method described by Hodgson and Clay (*loc. cit.*, p. 2777) for the nitrosation of resorcinol monomethyl ether, when applied to the monoethyl ether, gave a larger yield (5.5 g.) of crude product than that (4.7 g.) obtained by Kietaihl's method (*loc. cit.*). The quantities used were: resorcinol monoethyl ether 5 g., water 250 c.c., sodium hydroxide 2.5 g., sodium nitrite 3 g., concentrated sulphuric acid 5 c.c., water 100 c.c.

*Separation of the isomerides.* Kietaihl's method of extraction with boiling benzene was used, the operation being continued until the solvent remained practically colourless. From the extract, only one product could be crystallised, and this had the characteristics of Kietaihl's  $\alpha$ -*o*-nitroso-3-ethoxyphenol as described by Henrich (*J. pr. Chem.*, 1904, **70**, 313) (Found: N, 8.5. Calc.: N, 8.4%).

The residue insoluble in benzene (0.79 g.) crystallised from alcohol (charcoal) in small yellow needles, which slowly decomposed above 170° (Found: N, 8.6%).

*Oxidation of the Benzene-soluble Fraction with Dilute Nitric Acid.*—The substance (1 g.) was suspended in water (10 c.c.) and vigorously stirred during the gradual addition of 10 c.c. of a mixture of nitric acid (*d* 1.4; 3 parts) and water (1 part). After 5 hours, the mixture was diluted with water and the product was collected and distilled with steam; the 6-nitro-3-ethoxyphenol (0.9 g.) that passed over crystallised from alcohol or light petroleum in yellow needles, m. p.

and mixed m. p. with an authentic specimen (see later) 79° (Found : N, 7.8. Calc. : N, 7.65%). Weselsky and Benedikt (*Sitzungsber. Akad. Wiss. Wien*, 1880, **82**, 1219) describe a steam-volatile mononitro-derivative of resorcinol monoethyl ether as sulphur-gold needles, m. p. 79°.

*Oxidation of the Benzene-insoluble Fraction with Alkaline Potassium Ferricyanide.*—The substance (0.5 g.), dissolved in 10% aqueous potassium hydroxide (30 c.c.), was mixed with a saturated aqueous solution of potassium ferricyanide (10 g.) and heated on the water-bath until the colour became yellow. The solution was then filtered hot, cooled, and acidified. After some time, long greenish-yellow needles of 4-nitro-3-ethoxyphenol separated. These, after recrystallisation from dilute alcohol, melted, alone or mixed with an authentic specimen, at 131° (Found : N, 7.9. Calc. : N, 7.65%). The respective dibrominated products, separately or mixed, melted at 69° (Found : Br, 46.7, 47.0. Calc. : Br, 46.9%). Weselsky and Benedikt (*loc. cit.*) give m. p. 69° for 2 : 6-dibromo-4-nitro-3-ethoxyphenol.

*Oxidation of the Crude Nitrosation Mixture.*—(a) *With alkaline potassium ferricyanide.* The crude product (5 g.) was dissolved in 10% aqueous potassium hydroxide (300 c.c.) and oxidised with a saturated aqueous solution of potassium ferricyanide (100 g.) as described above. The solution was filtered hot, cooled, acidified with dilute sulphuric acid, and extracted with ether. The extracted product was steam-distilled : 6-nitro-3-ethoxyphenol (3.0 g.) passed over ; the liquor in the flask, on cooling, deposited a substance (1.5 g.) from which 4-nitro-3-ethoxyphenol (0.9 g.) was obtained by crystallisation from alcohol (charcoal). From the results of the oxidation of the benzene-soluble fraction (above), these combined amounts would account for almost the whole of the original crude mixture, to the exclusion of any other *o*-nitrosophenol such as Kietaihl's so-called  $\beta$ -*o*-nitroso-3-ethoxyphenol.

Under the above conditions the crude nitrosation product (3.0 g.) from resorcinol monomethyl ether yielded no 4-nitro-3-methoxyphenol, but gave 2.5 g. of the steam-volatile 6-nitro-isomeride.

(b) *With dilute nitric acid.* The crude nitrosation product (5 g.), suspended in water (60 c.c.), was oxidised as described above with 54 c.c. of dilute nitric acid. The yield of steam-volatile 6-nitro-3-ethoxyphenol was 3.6 g. The non-volatile residue consisted of tarry matter, from which a small amount of the 4-nitro-isomeride was obtained by extraction with ether.

*Nitration of Resorcinol Monoethyl Ether.*—The following method gives a better yield of the mononitro-derivatives than the method of Weselsky and Benedikt (*loc. cit.*). The ether (5 g.), dissolved in

acetic anhydride (20 c.c.), was nitrated below  $0^{\circ}$  by the gradual addition of nitric acid ( $d$  1.5; 2 c.c.) in acetic anhydride (8 c.c.). The mixture was kept over-night and then poured on ice. The precipitate was collected, washed, and steam-distilled; the volatile 6-nitro-3-ethoxyphenol (2.0 g.) crystallised from light petroleum in greenish-yellow needles, m. p.  $79^{\circ}$  (Weselsky and Benedikt, *loc. cit.*, give m. p.  $79^{\circ}$ ) (Found: N, 7.7. Calc.: N, 7.65%). The hot filtrate from the non-volatile tarry residue was cooled and extracted with ether, 0.5 g. of 4-nitro-3-ethoxyphenol being obtained which crystallised from alcohol in pale yellow needles, m. p.  $131^{\circ}$  (Weselsky and Benedikt, *loc. cit.*, give m. p.  $131^{\circ}$ ) (Found: N, 7.75. Calc.: N, 7.65%).

*Proof of the Constitution of 6-Nitro-3-ethoxyphenol.*—(a) *Conversion into 4-nitroresorcinol diethyl ether.* The potassium salt (1.3 g.), suspended in absolute alcohol, was heated under reflux with excess of ethyl iodide for 6 hours. The mixture was then made alkaline and steam-distilled; the volatile 4-nitroresorcinol diethyl ether (0.4 g.) crystallised from alcohol in almost colourless leaflets which, alone or mixed with an authentic specimen (Kauffmann and de Pay, *Ber.*, 1906, **39**, 2725), melted at  $85^{\circ}$  (Found: N, 6.9. Calc.: N, 6.6%). The liquor in the distillation flask, on acidification and steam-distillation, yielded 0.4 g. of unchanged 6-nitro-3-ethoxyphenol.

An attempt was made to obtain 4-nitroresorcinol diethyl ether by the action of excess of ethyl-alcoholic sodium ethoxide on 1:3-dichloro-4-nitrobenzene (compare Hodgson and Handley, *loc. cit.*). The product, however, was 3-chloro-6-nitrophenetole, which crystallised from alcohol in colourless leaflets, m. p.  $63^{\circ}$  (Blanksma, *Rec. trav. chim.*, 1904, **23**, 322, gives m. p.  $63^{\circ}$ ) (Found: Cl, 17.5. Calc.: Cl, 17.6%), identical with the product obtained from 3-chloro-6-nitrophenol by ethylation (compare Haworth and Lapworth, *J.*, 1923, **123**, 2986).

The same method, applied to 3-chloro-2-nitrophenol (13 g.), gave 3-chloro-2-nitrophenetole (12 g.), which crystallised from alcohol in colourless leaflets, m. p.  $52^{\circ}$  (Found: Cl, 17.5.  $C_8H_8O_3NCl$  requires Cl, 17.6%).

(b) *Synthesis from 3-chloro-4-nitrophenetole.* The ethylation of 3-chloro-4-nitrophenol as above gave 3-chloro-4-nitrophenetole, which crystallised from alcohol in colourless micro-prisms, m. p.  $39-40^{\circ}$  (Found: Cl, 17.4%). This was converted into 4-nitro-3-aminophenetole by heating it (2 g.) with concentrated aqueous ammonia (6 c.c.) and alcohol (5 c.c.) in a sealed tube at  $170-180^{\circ}$  for 8 hours. The product (1 g.), isolated from the reaction mixture after dilution with water, crystallised from alcohol in yellow needles,

m. p. 105–106° (Found : N, 15.5. Calc. : N, 15.4%), and was identical with a specimen prepared by the method of Reverdin and Lokietek (*Bull. Soc. chim.*, 1916, **19**, 252; *Arch. Sci. phys. nat.*, 1916, **42**, 47). The 4-nitro-3-aminophenetole (1 g.) was diazotised in dilute sulphuric acid and then converted by the standard procedure (Hodgson, E. P. 200714) into 6-nitro-3-ethoxyphenol (0.3 g.).

### CXIX.—*The Nitrosation of Phenols. Part IX. Further Study of the Nitrosation of m-Bromophenol.*

By HERBERT HENRY HODGSON and ARNOLD KERSHAW.

THE alleged geometrical isomerides of 3-bromobenzoquinone-4-oxime (Hodgson and Moore, J., 1925, **127**, 2260) prove to have been impure specimens of one individual (compare 3-chlorobenzoquinone-4-oxime, J., 1929, 1553).

The chelation between the halogen and the oximino-hydrogen atom previously assumed (*loc. cit.*) in order to account for the stability of 3-chlorobenzoquinone-4-oxime appears to be even stronger in 3-bromoquinone-4-oxime, since this is much more stable to boiling dilute mineral acids than its 3-chloro-analogue : Auwers' cryoscopic data (*Z. physikal. Chem.*, 1903, **42**, 542) indicate that the co-ordination tendency of bromine is greater than that of chlorine.

3-Bromo-4-nitrosoanisole has an emerald-green colour, whereas 3-bromo-4-nitrosophenol is bright yellow, both in the solid state and in solution. 3-Bromobenzoquinone-4-oxime, however, gives pale green solutions, whereas its *methyl* ether is yellow and gives yellow solutions.

Similarly to the chloro-analogue, 3-bromo-4-nitrosophenol is converted immediately by concentrated sulphuric acid into the oxime; yet both substances give Liebermann nitrosoamine reactions, which differ in that the oxime produces a bluer colour.

The melting points of 3-bromo-4-nitrosoanisole (69°) and 3-bromobenzoquinone-4-oxime methyl ether (130°) are in accordance with the view expressed by Hodgson and Moore (*loc. cit.*), that nitroso-compounds melt at a lower temperature than the corresponding oximes.

## EXPERIMENTAL.

3-Bromobenzoquinone-4-oxime, prepared both by the alkali and by the acid method (*loc. cit.*), crystallises from benzene, in which it is sparingly soluble, in pale greenish-yellow, elongated parallelepipeds, m. p.  $196^{\circ}$  (compare Hodgson and Moore, *loc. cit.*) (Found : Br, 39.5; N, 7.0. Calc. : Br, 39.6; N, 6.9%).

The molecular weight of 3-bromo-4-nitrosophenol, determined cryoscopically, is 207 in naphthalene and 187 in phenol (calc., 202); the oxime is very sparingly soluble in naphthalene, but has  $M = 188$  in phenol. The benzoate, prepared and crystallised in the same way as the chloro-analogue, forms pale yellowish-brown, flat rhombs, m. p.  $181^{\circ}$  (Found : Br, 26.0.  $C_{13}H_8O_3NBr$  requires Br, 26.1%).

3-Bromo-4-nitrosoanisole (2.4 g.), prepared in the same way as the chloro-analogue (*loc. cit.*) by the oxidation of 3-bromo-4-aminoanisole hydrochloride (4.3 g.) with Caro's acid but with only 2 hours' stirring, crystallises from alcohol in emerald-green needles or prisms, m. p.  $69^{\circ}$  (Found : Br, 37.0.  $C_7H_6O_2NBr$  requires Br, 37.0%).

3-Bromobenzoquinone-4-oxime methyl ether is obtained by the addition of methyl sulphate to a solution of 3-bromobenzoquinone-4-oxime or 3-bromo-4-nitrosophenol in saturated aqueous sodium carbonate, followed by a few drops of aqueous sodium hydroxide. It is readily isolated by steam distillation and crystallises from 50% aqueous alcohol in yellow needles, m. p.  $130^{\circ}$  (Found : Br, 37.1.  $C_7H_6O_2NBr$  requires Br, 37.0%).

The authors desire to thank the British Dyestuffs Corporation for gifts of chemicals.

CXX.—Symmetrical Triad Prototropic Systems.  
Part VI. The Effect of Substitution on Tautomeric Mobility and Equilibrium in the  $\alpha$ -Diphenylpropene System.

By CHARLES WILLIAM SHOPPEE.

IN Part IV of this series (J., 1929, 447) tautomeric interchange between the isomerides (I  $\rightleftharpoons$  II) and (III  $\rightleftharpoons$  IV) was shown to occur in the presence of a catalyst, and methods were described whereby the mobility and equilibrium of such systems could be determined. The present paper gives an account of the systems

corresponding to (III  $\rightleftharpoons$  IV) for a series of *p*-substituents : Me, Cl, Br, I, NMe<sub>2</sub>, and  $\overset{\oplus}{\text{N}}\text{Me}_2\text{Et}$ .

Before the theoretical significance of the results is discussed, consideration must be given to certain fundamental principles underlying the relation of mobility and equilibrium to the structural features of a tautomeric system.

*Substitution and Mobility.*—In certain recent papers on prototropy and allied topics there has been a notable tendency to short-circuit the actual theory of the subject by referring to orientation in aromatic substitution as a practical criterion of the polar effects of groups and as, therefore, a direct analogy for their theoretically anticipated behaviour in relation to prototropic and other systems. Aromatic hydrogen-substitutions (even meta-) depend on the negativity of the field at the point of reaction, and the requisite electron availability may result either from the permanent *polarisation* of the molecule due to the electron repulsion (+ *I*) of a substituent, or from the molecular *polarisability* which is enhanced by the presence of a substituent containing unshared electrons, provided that a path exists for the propagation of electron displacements with covalency changes to the point of reaction (+ *T*) (compare Ingold and Shaw, J., 1927, 2923); these will be activating influences. Molecular polarisation resulting from a substituent possessing high electron-affinity (− *I*) will decrease electron-availability at the seat of reaction, and will be a deactivating influence, but polarisability arising from the presence of a substituent capable of sharing additional aromatic electrons and the existence of a free path for the electron transfer (− *T*) will not cause deactivation, because the displacements would lead to a recession of electrons from the seat of reaction, and for this there is no demand. On the other hand, prototropy depends on the positivity of the field at the seat of ionisation; the necessary electron-recession may arise from molecular polarisation due to the electron affinity (− *I*) of a substituent, or from molecular polarisability resulting from the presence of a substituent capable of sharing unshared electrons possessed by the system, provided that a path exists for the electron-transfer (− *T*); these will be facilitating influences. Molecular polarisation due to a substituent-repelling electron (+ *I*) will oppose the production of a positive field at the seat of ionisation, and hence will constitute

a retarding influence; molecular polarisability, resulting from the presence of a substituent possessing unshared electrons and capable of sharing these with the system if a path for the electron transfer exists (+  $T$ ), will not lead to electron displacements because such displacements would involve electron-accession to the seat of ionisation and for this there is no demand. In short, whereas

benzene hydrogen-	{	is facilitated by effects + $I$ and + $T$
substitution		is retarded by effect - $I$ only;
prototropy	{	is facilitated by effects - $I$ and - $T$
		is retarded by effect + $I$ only;

so that retardation of benzene hydrogen-substitution does not run parallel with facilitation of prototropy, and *vice versa*, unless *tautomeric effects of either sign* ( $\pm T$ ) are structurally impossible. Burton and Ingold exemplified this (J., 1928, 904) by stating that  $\text{NR}_3^+$  and COR activate prototropy by different mechanisms (-  $I$ , and -  $I - T$  respectively), but deactivate the benzene nucleus by the same mechanism (-  $I$  only; -  $T$  here being inoperative).

The +  $T$  effect can enter into the consideration of prototropy only when an activating group of the -  $I - T$  type is considered "piece-meal," and the +  $T$  effect of one portion is treated as subtractable from the (greater) -  $T$  effect of the other, as may be

possible, for instance, for COR in (three-carbon)  Since the order of +  $T$  effects of R is  $\text{O}^\ominus > \text{NR}_2 > \text{OR} > \text{Hals.} > \text{Me}$  (zero for the last member), that of the -  $T$  effect for COR is  $\text{COMe} > \text{COHal.} > \text{CO}_2\text{R} > \text{CO}\cdot\text{NR}_2 > \text{CO}\cdot\text{O}^\ominus$ , and this is the order of facilitation of prototropy (Ingold, Shoppee, and Thorpe, J., 1926, 1477). The -  $I$  effects of the same variants of the group COR are in the different order  $\text{COHal.} > \text{CO}_2\text{R} > \text{CO}\cdot\text{NR}_2 > \text{COMe} > \text{CO}\cdot\text{O}^\ominus$  (Cooper and Ingold, J., 1927, 838), and this is all that enters into the theory of aromatic substitution (-  $T$  is inoperative), and is the order of *m*-orientation. This point has been treated at some length because of Linstead's recent comments (J., 1929, 2498) on the apparent lack of agreement between the two series.

In continuation of previous investigations (J., 1929, 447, 1199), in which it was shown that systems of the forms

became mobile in the presence of sodium ethoxide, it has now been proved for the system (VII  $\rightleftharpoons$  VIII)—system (IX  $\rightleftharpoons$  X) is still being investigated—that the effect of R on the velocity of inter-conversion under constant conditions of temperature and catalysis is as follows (time units, hours)\* :

Group R	NMe <sub>2</sub> .	OMe.	I.	Br.	Cl.
$k_1 + k_2$ .....	<<0.050	0.058	0.39	0.64	1.02
Moment .....	+1.39	-0.80	-1.25	-1.51	-1.56

The bottom row of the table contains the recorded values of the molecular electric moments of the compounds C<sub>6</sub>H<sub>5</sub>R in E.S.U.  $\times 10^{-18}$ , the attached sign indicating the polarity of R; the numbers are direct measures of the state of polarisation ( $\pm I$ ) induced by R directly attached to the aromatic nucleus in a series of compounds such as those investigated. The parallelism between this measure of  $-I$  and the mobility figures will be obvious.

None of the groups investigated is known to exert a  $-T$  effect; if it had been capable of so doing, the parallelism would, of course, have failed (*e.g.*, COR, CN, NO<sub>2</sub>). On the other hand, the groups tabulated are all structurally capable of  $+T$  effects, but this, as already explained, does not enter into prototropy (when the *whole* activating group is considered and not merely a part of it). The cases, therefore, differ from those studied by Kon and Linstead, which involve the  $-T$  effect, and an alternative statement of the difference is that the systems examined by these investigators are pentad keto-enols, involving the common enolide ion  $\text{C}=\text{C}-\text{C}=\text{C}-\overset{\text{O}}{\underset{\text{S}}{\text{O}}}$ .

Although the three-carbon systems here examined contain a group (carbethoxyl) normally capable of a  $-T$  effect, the position of this ( $\beta$ -) is such that this effect cannot be propagated by tautomeric electron displacements to the seat of ionisation. A feeble  $-I$  effect should, however, reach the ionising centre, and in addition to this, polar and steric disturbances due to the spatial proximity of the group are to be anticipated.

In this connexion, Linstead's argument (*loc. cit.*) that the preliminary ionic dissociation is unimolecular, whereas the final recombination of ions is bimolecular, and that this furnishes a basis for consideration of the mechanism of steric inhibition in prototropy,

\* The value for R = Me is of the same order as for R = OMe, but is not tabulated because the velocity coefficients were not good enough to give an accurate significance to their mean. Theoretically, Me should fit in between OMe and NMe<sub>2</sub>.

is unacceptable to the writer, who regards the catalyst as promoting ionic dissociation; from this point of view the dissociation must at least be bimolecular, for it is common knowledge that it depends on the catalyst (*e.g.*,  $\text{OEt}^\ominus$  ion) as well as on the compound ionised.

*Substitution and Equilibrium.*—The general theory of the effect of substitution on equilibrium in three-carbon systems containing activating groups of the  $-I-T$  type (pentad keto-enol and pentad cyano-imino systems) has already been given (Ingold, Shoppee, and Thorpe, *loc. cit.*; Ingold, *Ann. Reports*, 1927, 111; 1928, 118; Bennett, *ibid.*, 1929, 119), and is in excellent agreement with the available data, including the most recent results (Kon and Linstead, J., 1929, 1269; Kandiah and Linstead, *ibid.*, p. 2139); nevertheless, confusion has again arisen, through the application of the process previously described as short-circuiting. Ingold, Shoppee, and Thorpe discussed the effect of a  $\beta$ -carbethoxyl group and showed that it should lead ( $-T$  effect) to predominance of the  $\beta\gamma$ -unsaturated form (*e.g.*, in the system citraconic ester-itaconic ester, the latter is the favoured phase). Linstead has concluded from this (*loc. cit.*) that the theory implies that a  $\beta$ -methyl group ( $+I$  effect) should produce the opposite result, that is, a stable  $\alpha\beta$ -form, which is contrary to fact (Goldberg and Linstead, J., 1928, 2343). It cannot be too strongly insisted that the effect of  $+I$  cannot be deduced by mechanical inversion of that of  $-T$ , and that all such short cuts involve unsound procedure, with the sole exceptions of that for  $+I$  to  $-I$ , and its converse. In the case considered, the formulæ (XI) show the enolide ions in the critical

stage immediately preceding their combination with a proton. The  $-T$  effect of the  $\beta$ -carbethoxyl group ( $b, b_1$ ) acts on the displaceable double-bond electrons, inhibiting  $a_3$ ; the  $+I$  effect of the  $\beta$ -methyl group ( $c$ ) acts on the  $\beta$ -carbon atom, charging it negatively and directing the electrons away from  $a_2$  into the alternative route  $a_1$ ; since  $a_3$  depends on initiation from  $a_2$  (which in turn depends on  $a$ ), the  $+I$  effect ( $c$ ) will also, indirectly, inhibit  $a_3$ . The facts (that the influences of  $\beta$ -methyl and  $\beta$ -carbethoxyl groups are qualitatively similar) are thus in complete agreement with the theory.

Reference is also necessary to another point raised by Linstead, namely, the effect of  $\beta$ - and  $\gamma$ -phenyl substituents. The polar effect

of the phenyl group is represented by  $\pm T$ , that is, it is able to furnish either electron-accession to or electron-recession from an adjacent carbon atom, according to the sign of the field required at the seat of reaction. This duplex polar capacity of the phenyl group is manifested in its ability to activate both prototropy (these papers) and anionotropy (Burton and Ingold, *loc. cit.*), and to confer stability on free radicals (*idem*, *Proc. Leeds Phil. Soc.*, 1929, i, 421). Owing to its ambi-polar charge-distributing mechanism, phenyl

tends to absorb the charge on  $C_a$  in either polarisation  $\text{Ph}-\overset{\curvearrowright}{\text{C}}_a=\text{C}_\beta$ ,  $\text{Ph}-\text{C}_a=\overset{\curvearrowleft}{\text{C}}_\beta$ , with the result, *inter alia*, that  $\text{Aryl}\cdot\text{CH}\cdot\text{CH}\cdot\text{CH}_2[\text{H}]$  and  $\text{Aryl}\cdot\text{CH}\cdot\text{CH}\cdot\text{CH}_2[\text{Br}]$  are stable tautomerides; to attribute such phenomena to a special "non-polar element of stability associated with conjugated systems" is to conceal their essentially polar nature. Probably the simplest illustration of the duplex polar functions of phenyl is that additions of either polar sign to styrene are uniformly initiated at  $C_\beta$  (Ingold, *Ann. Reports*, 1928, 146); for instance, addition of thiophenol to styrene occurs through the strongly basic (prone to co-ordinate) potential anion  $\text{PhS}^\ominus$ , whereas in the addition of hydrogen bromide the relatively unstable potential kation (proton) commences the attack; addition is probably initiated by a partly polarised molecule, with subsequent liberation of the more stable ion of the additive complex :

Now in the case of a  $\gamma$ -phenyl substituent, consideration of formula (XII), which shows the enolide ion in the critical stage preceding co-ordination of the proton, indicates that charge absorption will deactivate  $C_\gamma$  (like  $C_a$  in styrene) and the proton will combine at  $C_a$ ;

the phenyl group could activate  $C_\beta$  towards a proton (like  $C_\beta$  in styrene), but the structure is such that  $C_\beta$  cannot take advantage of this tendency. In the case of a  $\beta$ -phenyl substituent (XIII), the phenyl group will activate  $C_\gamma$  towards a proton (like  $C_\beta$  in styrene) and this will favour combination at  $C_\gamma$ ; the other effect, namely, deactivation of  $C_\beta$  (like  $C_a$  in styrene), does not enter into the problem for obvious reasons. Once again it is seen that the theory is adequate when properly applied.

In the experimental work here described, special attention has been given to the establishment of a small, but apparently real, anomaly, for which several explanations, none of which can as yet be proved, are possible. The system examined is the simple three-carbon system formulated on p. 970 ( $\text{VII} \rightleftharpoons \text{VIII}$ ), and the substituents R are of the forms normally characterised by the effects  $-I$ ,  $-I + T$ , and  $+I$ . In the simple three-carbon system the anionic charge is necessarily borne by carbon and the essential consideration determining equilibrium pertains to the relative ionisability of the isomerides. Obviously the predominance of form (VII) (see equation) should diminish as the electron-affinity of R decreases (from  $-I$  to  $+I$ ). The table shows that, although the three kinds of groups are arranged in the right way, the members of the central group are inverted amongst themselves.

Type	$-I$		$-I + T$		$+I$
R	NMe <sub>2</sub> Et	OMe	Br	Cl	Me
VII (%)	>90	56.5	54.0	50.0	48.0

It is thought that this anomaly is probably related to the similar anomalies revealed in Tasman's results on the alkaline hydrolysis of phthalides (*Rec. trav. chim.*, 1927, **46**, 653) and in Kindler's on the alkaline saponification of benzoic esters (*Annalen*, 1926, **450**, 1), though in the latter two examples of aromatic side-chain reactivity the anomaly relates to the halogens only and does not include methoxyl. It is possible (but the point must await proof) that these apparent inversions are dependent on changes shown to be possible by Sidgwick's limiting-valency rule, and in a classification of groups relating to an aspect of aromatic substitution more closely analogous to prototropy than ordinary hydrogen substitution, a  $-T$  effect has tentatively been ascribed to halogens (other than fluorine) in the presence of basic reagents.

## EXPERIMENTAL.

### Methyl Compounds.

$\alpha$ -*p*-Methylbenzylcinnamic Acid (formula as VIII).—*p*-Methylcinnamic acid was obtained in 70% yield by condensing *p*-tolu-aldehyde with malonic acid in pyridine solution in the presence of piperidine on the steam-bath.  $\beta$ -*p*-Tolylpropionic acid can be obtained from it by reduction with phosphorus and hydriodic acid (von Miller and Rohde, *Ber.*, 1890, **23**, 1898), but is contaminated with a considerable quantity of *p*-toluic acid: the use of 3% sodium amalgam (Krober, *ibid.*, p. 1053) gives a pure product.

Sodium  $\beta$ -*p*-tolylpropionate (45 g.), benzaldehyde (26 g.), and acetic anhydride (30 g.) were heated together at 160° for 10 hours,

the melt was poured into a solution of crystallised sodium carbonate (150 g.) and extracted with ether, and the extract washed twice with 2*N*-sodium hydroxide. The ethereal extract contained a hydrocarbon, and the alkaline washings on acidification yielded 2 g. of  $\alpha$ -*p*-methylbenzylcinnamic acid, which separated from dilute alcohol in long prisms, m. p. 181°, and instantly decolorised alkaline permanganate (as did also all the substituted cinnamic acids described later in this paper) (Found: C, 81.0; H, 6.4.  $C_{17}H_{16}O_2$  requires C, 80.9; H, 6.3%). A further quantity was obtained from the sodium carbonate solution by acidification and fractional crystallisation of the product from dilute alcohol.

$\alpha$ -Benzyl-*p*-methylcinnamic Acid (formula as VII).—*p*-Tolualdehyde (48 g.), sodium  $\beta$ -phenylpropionate (69 g.), and acetic anhydride (49 g.) were heated at 150° for 8 hours and the procedure described above (sodium carbonate, 300 g.) was then followed. The sodium hydroxide washings on acidification yielded  $\alpha$ -benzyl-*p*-methylcinnamic acid (2 g.), which separated from alcohol in needles, m. p. 200° (Found: C, 80.8; H, 6.3%). A further quantity (5 g.) was isolated from the sodium carbonate solution. The ethereal extract yielded 25.5 g. of *p*-tolualdehyde, b. p. 92–94°/13 mm., and a hydrocarbon.

The following m. p.'s are uncorrected, but were determined under identical conditions. The m. p.'s of artificial mixtures of the two preceding acids lie on a two-branch curve, the eutectic point of which corresponds to a mixture, m. p. 163°, containing 64.0% of  $\alpha$ -*p*-methylbenzylcinnamic acid (A).

A, %	0.0	20.8	35.2	47.9	56.8	68.2	85.1	100.0

*Interconversion of the Ethyl Esters.*—*Preparation of the esters.* These two esters, and those described subsequently, were obtained by the action of ethyl iodide upon the silver salts. Ethyl  $\alpha$ -*p*-methylbenzylcinnamate (VIII; R = Me) is a colourless oil, b. p. 178–180°/1 mm., 197–198°/6 mm. (Found: C, 81.2; H, 7.2.  $C_{19}H_{20}O_2$  requires C, 81.4; H, 7.2%). Ethyl  $\alpha$ -benzyl-*p*-methylcinnamate (VII; R = Me) also is a colourless oil, b. p. 205–207°/7 mm.,  $n_D^{20}$  1.58415 (Found: C, 81.0; H, 7.4%).

*Alkaline hydrolysis of the esters.* The standard conditions and the method of isolation described for the methoxy-compounds (J., 1929, 447) were employed. As only a small quantity (0.01 g.) was used for a m. p. determination, the whole of the hydrolysis product was first melted, to ensure homogeneity. The ester (VII) gave 96% of unpurified acid, m. p. 200.0°, and the ester (VIII) gave 95%, m. p. 180.5° (the m. p.'s of the pure acids are 200.0° and 181.0°, respectively).

These results establish (a) that no interconversion of the isomerides takes place in the presence of hydroxide ions at 100° under the conditions given, and (b) that, since the yields are practically quantitative in both cases, and no impurities affecting the m. p.'s of the acids are introduced, hydrolysis and subsequent thermal analysis of the acids can be used to follow the interconversion of the esters.

*Stability of the esters to heat.* Redistillation of the esters and subsequent hydrolysis gave the same results. The esters were interconverted under the standard conditions (1.45*N*-alcoholic sodium ethoxide at 85°), the approach towards equilibrium being followed by hydrolysis under the standard conditions, and thermal analysis.

Equilibrium : VIII (52.0%)  $\rightleftharpoons$  (48.0%) VII;  $k_1 + k_2$  (mean) = 0.088 hr.<sup>-1</sup>;  $k_1/k_2 = 1.083$ ;  $k_1 = 0.0046$ ;  $k_2 = 0.0042$ .

#### *Chloro-compounds.*

*$\alpha$ -p-Chlorobenzylcinnamic Acid* (formula as VIII).—*p*-Chlorocinnamic acid was obtained by condensing *p*-chlorobenzaldehyde (50 g.) and malonic acid (37 g.) with piperidine (5 c.c.) in pyridine (125 c.c.); it separated from alcohol in fine colourless needles (yield, 85%), m. p. 244–245°. Gabriel and Herzberg (*Ber.*, 1883, 16, 2037) described it as yellow and indistinctly crystalline, m. p. 240–242°. The acid was rapidly reduced by 3% sodium amalgam at about 45° and gave a 75% yield of  $\beta$ -*p*-chlorophenylpropionic acid, m. p. 122° after crystallisation from dilute acetic acid.

Sodium  $\beta$ -*p*-chlorophenylpropionate (62 g.), benzaldehyde (32 g.), and acetic anhydride (34 g.) were heated at 160° for 8 hours and the melt was poured into a solution of 100 g. of crystallised sodium carbonate. After 12 hours, the white solid was filtered off, washed with ether, suspended in warm water, and agitated with hydrochloric

acid. The precipitate was filtered off and twice crystallised from alcohol,  $\alpha$ -*p*-chlorobenzylcinnamic acid being obtained in clusters of prisms (10 g.), m. p. 194.5° (Found: C, 70.0; H, 4.9.  $C_{16}H_{13}O_2Cl$  requires C, 70.4; H, 4.8%).

Extraction of the aqueous liquor with ether gave a solution containing a chlorohydrocarbon and the above acid (4 g., removed by sodium hydroxide); on acidification, the sodium carbonate solution gave a further quantity of the acid (57 g., crude).

*p*-Chloro- $\alpha$ -benzylcinnamic Acid (formula as VII).—Sodium  $\beta$ -phenylpropionate (49 g.), *p*-chlorobenzaldehyde (40 g.), and acetic anhydride (35 g.) were heated together for 8 hours at 160°, and the melt was poured into a solution of 100 g. of crystallised sodium carbonate. The solution was extracted with ether and then acidified. The acid product separated from boiling alcohol in colourless needles, m. p. 163°, unchanged by further crystallisation (Found: C, 68.5, 68.6; H, 4.5%). These figures indicate that the product consisted of a mixture of the required acid (82%) and *p*-chlorocinnamic acid (18%); these could not be separated by fractional crystallisation. The mixed acids (10 g.) were treated with two successive quantities of sodium carbonate (50 c.c.; 2.2 g.  $Na_2CO_3$  in 150 c.c. water), from which, by acidification of the two filtrates, three fractions, A, B, and C, were obtained.

Fraction A, recrystallised from alcohol, melted at 223–225° and consisted largely of *p*-chlorocinnamic acid.

Fractions B and C, recrystallised from alcohol, gave *p*-chloro- $\alpha$ -benzylcinnamic acid in colourless needles, m. p. 171.5° (Found: C, 70.3; H, 4.7%).

Mixtures of  $\alpha$ -*p*-chlorobenzylcinnamic and *p*-chloro- $\alpha$ -benzylcinnamic acids melted as follows: A denotes the former acid.

A, %	0	20.6	31.6	36.2	42.0	45.9	50.3	53.6	69.7	100.0
M. p.	171.5°	162.5°	156.5°	153.5°	155.0°	161.0°	165.0°	168.0°	178.0°	194.5°

*Interconversion of the Ethyl Esters.*—Ethyl  $\alpha$ -*p*-chlorobenzylcinnamate (VIII; R = Cl) has b. p. 197°/3 mm. and separates from ligroin (b. p. 40–60°) in prisms, m. p. 55° (Found: C, 71.8; H, 5.8.  $C_{18}H_{17}O_2Cl$  requires C, 71.9; H, 5.7%). Ethyl *p*-chloro- $\alpha$ -benzylcinnamate (VII; R = Cl) has b. p. 208°/6 mm. (Found: C, 71.8; H, 5.7%).

Under standard conditions, hydrolysis of (VIII) afforded a quantitative yield of the corresponding acid, m. p. (crude) 194°, and (VII) gave a 99% yield of its acid, m. p. 170.5°.

The interconversion of the esters in 1.45*N*-alcoholic sodium ethoxide was observed in the manner described for the methoxy- and methyl compounds.

### Bromo-compounds.

*α-p-Bromobenzylcinnamic Acid* (formula as VIII).—Sodium *β-p*-bromophenylpropionate (Gabriel and Zimmermann, *Ber.*, 1880, **13**, 1683) (67 g.), benzaldehyde (28 g.), and acetic anhydride (33 g.) were heated together for 10 hours at 160° and the melt was submitted to the usual treatment. The sodium hydroxide washings of the ethereal extract yielded on acidification *α-p-bromobenzylcinnamic acid*, which crystallised from alcohol in prisms, m. p. 200° (Found : C, 60.8; H, 4.1. C<sub>16</sub>H<sub>13</sub>O<sub>2</sub>Br requires C, 60.5; H, 4.1%). The sodium carbonate liquor gave a large quantity of an acid, which was not investigated, and the ethereal extract contained a bromohydrocarbon.

*p-Bromo-α-benzylcinnamic Acid* (formula as VII).—*p*-Bromobenzaldehyde (Jackson and White, *Ber.*, 1878, **11**, 1023) (24 g.), sodium *β*-phenylpropionate (23 g.), and acetic anhydride (17 g.) were similarly treated. The sodium hydroxide washings gave *p-bromo-α-benzylcinnamic acid*, which was obtained in fine long needles, m. p. 193°, after several crystallisations from ethyl acetate-ligroin (Found : C, 60.5; H, 4.0%). The sodium carbonate solution yielded a large quantity of *p-bromocinnamic acid*, m. p. 257° after two crystallisations from boiling absolute alcohol (Found : C, 47.8; H, 3.0. Calc. for C<sub>9</sub>H<sub>7</sub>O<sub>2</sub>Br : C, 47.6; H, 3.1%). The ethereal extract contained a bromohydrocarbon.

Mixtures of the two acids melted as follows : A denotes *α-p*-bromobenzylcinnamic acid :

*Interconversion of the Ethyl Esters*.—Ethyl *α-p*-bromobenzylcinnamate (VIII; R = Br) is a colourless oil, b. p. 200°/1 mm.

(Found : C, 62.6; H, 4.9.  $C_{18}H_{17}O_2Br$  requires C, 62.6; H, 4.9%). Hydrolysis under the standard conditions affords the corresponding acid, m. p.  $200^\circ$  without purification, in 98% yield. *Ethyl p-bromo- $\alpha$ -benzylcinnamate* (VII; R = Br) is a colourless oil, b. p.  $200^\circ/3$  mm. (Found : C, 62.6; H, 5.0%); on hydrolysis under the standard conditions it gives the corresponding acid, m. p.  $193^\circ$  without purification, in 98.5% yield.

The esters were interconverted under the standard conditions and the process was followed by hydrolysis (standard conditions) and thermal analysis. In the case marked with an asterisk 0.45 g. of ester was used.

Equilibrium : VIII (46.0%)  $\rightleftharpoons$  VII (54.0%);  $k_1 + k_2$  (mean) = 0.64 hr. $^{-1}$ ;  $k_1/k_2 = 0.852$ ;  $k_1 = 0.30$ ;  $k_2 = 0.34$ .

#### *Iodo-compounds.*

*$\alpha$ -p-Iodobenzylcinnamic Acid* (formula as VIII).—*p*-Iodobenzaldehyde was prepared by oxidation of *p*-iodobenzyl bromide with copper nitrate solution and had m. p.  $76^\circ$ . The aldehyde (20 g.) and malonic acid (9 g.) were condensed in pyridine solution with piperidine (2 c.c.); the *p*-iodocinnamic acid obtained separated from boiling alcohol in colourless prismatic needles, m. p.  $264^\circ$  (decomp.) (Gabriel and Herzberg, *Ber.*, 1883, 16, 2039, describe the acid as yellow and incompletely crystalline, decomposing at  $255^\circ$  without melting) (Found : C, 39.4; H, 2.6. Calc. for  $C_9H_7O_2I$ : C, 39.4; H, 2.6%).

Gabriel and Herzberg obtained the dihydro-acid by reduction with phosphorus and hydriodic acid for a short period (undefined). Little reduction takes place under these conditions, and the use of sodium amalgam in alkaline solution at  $45^\circ$  yields only  $\beta$ -phenylpropionic acid.  $\beta$ -*p*-Iodophenylpropionic acid is best obtained by iodination of  $\beta$ -phenylpropionic acid in 50% acetic acid with a 10% excess of iodine monochloride. The mixture, which becomes hot, is kept on the steam-bath for  $\frac{1}{2}$  hour. After 12 hours, the product is dissolved in ether and the solution is washed with aqueous sodium

thiosulphate and with water, dried, and evaporated. A large part of the residual oil solidifies after 48 hours; the acid is drained and then crystallised from 40% acetic acid; m. p. 139°. Yield, 14 g. from 50 g. of  $\beta$ -phenylpropionic acid.

Sodium  $\beta$ -*p*-iodophenylpropionate (34.5 g.), benzaldehyde (12.5 g.), and acetic anhydride (13 g.) were heated at 150–155° for 6 hours and the melt was poured into a solution of sodium carbonate (50 g.). After 12 hours, the solid (sodium salt of the required acid) was removed and washed with ether; the filtrate was extracted with ether. The extract, after being washed with *N*-sodium hydroxide, contained an iodohydrocarbon. The sodium carbonate solution, acidified with 2*N*-hydrochloric acid at 0°, gave  $\alpha$ -*p*-iodobenzylcinnamic acid (5 g.), m. p. 219.5° after crystallisation from glacial acetic acid (Found: C, 52.5; H, 3.5.  $C_{16}H_{13}O_2I$  requires C, 52.7; H, 3.6%). The sodium hydroxide washings also gave a small quantity of this acid.

*p*-Iodo- $\alpha$ -benzylcinnamic Acid (formula as VII).—*p*-Iodobenzaldehyde (46 g.), sodium  $\beta$ -phenylpropionate (34 g.), and acetic anhydride (25 g.) were heated together at 170–180° for 7 hours; the melt was poured into excess of sodium carbonate solution and treated as in the preceding case. The ethereal extract and the sodium hydroxide washings contained an iodohydrocarbon and  $\beta$ -phenylpropionic acid respectively.

The solid initially precipitated by the sodium carbonate was suspended in 2*N*-hydrochloric acid at 40–45° and stirred for  $\frac{1}{2}$  hour; the product was a mixture of *p*-iodocinnamic acid (2 parts) and *p*-iodo- $\alpha$ -benzylcinnamic acid (1 part), which could not be separated by fractional crystallisation (Found: C, 44.7, 44.8; H, 3.0, 3.1%). The mixture (10 g.) was converted through the acid chlorides (by thionyl chloride) into the ethyl esters, which were distilled. The lower fraction obtained (5 g.), b. p. 175–180°/5 mm., mainly at 177°/5 mm., crystallised readily, and separated from ice-cold ligroin (b. p. 40–60°) in long needles, m. p. 37–37.5°, consisting of ethyl *p*-iodocinnamate, identical with a specimen prepared from synthetic *p*-iodocinnamic acid. The second fraction (3.5 g.), b. p. 180–230°/5 mm., partly solidified; after being drained, the solid was crystallised from ligroin (b. p. 40–60°), giving ethyl *p*-iodo- $\alpha$ -benzylcinnamate, m. p. 53.5° (Found: C, 54.9; H, 4.4.  $C_{18}H_{17}O_2I$  requires C, 55.1; H, 4.4%). On hydrolysis under the standard conditions, this ester gave pure *p*-iodo- $\alpha$ -benzylcinnamic acid, m. p. 232° after crystallisation from alcohol (Found: C, 52.3; H, 3.7%).

On account of the decomposition which occurred in the later stages of the foregoing distillation, the following separation is to be preferred. The mixed acids (25 g.) were treated with a solution of

2.2 g. of sodium carbonate at 100° and the hot liquid was filtered. The filtrate gave a granular precipitate (A) on acidification. Repetition of the process afforded a flocculent precipitate (B). Recrystallisation of (A) and (B) from alcohol gave *p*-iodocinnamic acid (13 g.) and *p*-iodo- $\alpha$ -benzylcinnamic acid (7 g.), m. p. 229–230°, respectively. The sodium hydroxide washings (above) also gave a very small quantity of the latter acid.

Mixtures of  $\alpha$ -*p*-iodobenzylcinnamic acid (C) and *p*-iodo- $\alpha$ -benzylcinnamic acid melted as follows :

C, %	0	19.0	39.0	47.2	57.0	61.0	66.4	79.1	100.0
M. p.	232.0°	222.0°	210.5°	206.5°	201.5°	199.0°	204.0°	210.0°	219.5°

*Interconversion of the Ethyl Esters.*—Ethyl  $\alpha$ -*p*-iodobenzylcinnamate (VIII; R = I) has b. p. 212–214°/2 mm., and melts at 46.5° after crystallisation from ligroin (b. p. 40–60°) (Found : C, 55.0; H, 4.4. C<sub>18</sub>H<sub>17</sub>O<sub>2</sub>I requires C, 55.1; H, 4.4%). Ethyl *p*-iodo- $\alpha$ -benzylcinnamate (VII; R = I), m. p. 53.5°, prepared from the silver salt was identical with the ester described above.

*Hydrolysis.* The esters (VII) and (VIII) gave quantitative yields of the respective acids, m. p.'s 232° and 219°, on hydrolysis with aqueous-alcoholic alkali (standard conditions). They are hydrolysed with extraordinary ease by acids, even by cold 2*N*-acetic acid.

*Action of sodium ethoxide.* Treatment of either ester with 1.45*N*-sodium ethoxide at 85° caused conversion into the other, since, by hydrolysis under the standard conditions and fractional crystallisation of the product from acetic acid, both acids were obtained. Owing to the presence of impurities produced by a secondary reaction, probably involving the iodine atom, the composition of the equilibrium mixture of the acids could not be determined from the melting-point diagram. The esters could not be distilled owing to hydrolysis taking place, and the following procedure was therefore adopted.

Preliminary experiments indicated that the ester (VII) was more prone to decomposition than the isomeride (VIII); and that the quantity of the new isomeride produced during very short periods of interconversion ( $\frac{1}{4}$ — $\frac{1}{2}$  hour) was insufficient to give, after hydrolysis, a saturated solution of the corresponding acid in ethyl acetate at 0°. To minimise errors due to the secondary reaction, the ester (VIII) was employed : it was treated with 1.45*N*-sodium ethoxide at 85°, the product hydrolysed under the standard conditions, and the acids isolated in the usual manner. A known weight (0.20 g.) of the cooled fused acids was dissolved in ethyl acetate, and the solution concentrated by evaporation in a graduated test-tube as far as was

possible without separation of solid. The solution, its volume having been noted, was kept for 16 hours in the ice-chest and the crystalline product was then collected and weighed. Its composition was determined by thermal analysis (the mixtures showing binary character), and a correction made for the solubility of each isomeride in a saturated ethyl acetate solution of the other at 0°.

Time at 85° with NaOEt (hrs.).	Wt. crude acids (g.).	Wt. cryst. acids (g.).	Vol. EtAc (c.c.).

\* Depressed by trace of acid (VII).

† Elevated by trace of acid (VII).

Owing to the secondary reaction, the equilibrium point could not be ascertained. The velocity coefficients are calculated on the basis of the assumed equilibrium  $\text{VIII (45\%)} \rightleftharpoons \text{(55\% VII)}$ , which is approximately that found for the bromo-esters.

The solubility of  $\alpha$ -*p*-iodobenzylcinnamic acid (0.00592 g./c.c.) and of *p*-iodo- $\alpha$ -benzylcinnamic acid (0.00157 g./c.c.) in a saturated ethyl acetate solution of the other was determined by saturating ethyl acetate with both acids, keeping the solution at 0° for 16 hours, and evaporating a known volume of the solvent; the composition of the residue was found by thermal analysis.

#### *Dimethylamino-compounds.*

$\alpha$ -*p*-Dimethylaminobenzylcinnamic Acid (formula as VIII).—*p*-Dimethylaminobenzaldehyde (300 g.) and malonic acid (213 g.) were heated in pyridine (500 c.c.) in the presence of piperidine (20 c.c.) for some hours on the steam-bath. When the mixture ceased to evolve carbon dioxide, it was poured into a large volume of ice-water containing 500 c.c. of glacial acetic acid. The precipitate crystallised from boiling alcohol in yellow plates (335 g.), m. p. 225° (vig. decomp.). Weil (*Monatsh.*, 1908, 29, 899) gives m. p. 216° (decomp.).

The foregoing acid (250 g.) was reduced with 3% sodium amalgam at 45–50°, and the product isolated by acidification with hydrochloric acid (Congo) and treatment with saturated sodium acetate solution. The  $\beta$ -*p*-dimethylaminophenylpropionic acid formed colourless prisms, m. p. 106°, from dilute alcohol: a further quantity was obtained by extraction of the mother-liquor with ether (total yield, 140 g.). The sodium salt (120 g.), benzaldehyde (60 g.), and

acetic anhydride (66 g.) were heated together for 9 hours while the temperature rose from 160° to 180°, the melt was then poured into an excess of sodium carbonate solution, and the mixture was extracted with ether after standing. The aqueous liquid, by acidification and treatment with sodium acetate solution with mechanical stirring, afforded  $\alpha$ -*p*-dimethylaminobenzylcinnamic acid (24 g.), m. p. 146° after repeated crystallisation from methyl alcohol (Found: C, 76.7; H, 6.7.  $C_{18}H_{19}O_2N$  requires C, 76.9; H, 6.8%). A little more was obtained by acidification of the sodium hydroxide washings of the ethereal extract; the latter contained a small quantity of the *p*-dimethylamino-base.

*p*-Dimethylamino- $\alpha$ -benzylcinnamic Acid (as VII).—Condensation of potassium  $\beta$ -phenylpropionate (63 g.), *p*-dimethylaminobenzaldehyde (50 g.), and acetic anhydride (38 g.) at 160–170° for 9 hours, and isolation of that portion of the product soluble in hydrochloric acid but precipitated by sodium acetate, furnished an acid, m. p. 232° (decomp.) after crystallisation from methyl alcohol. The quantity was insufficient for analysis, but the following observations indicate that the acid was *p*-dimethylamino- $\alpha$ -benzylcinnamic acid.

$\alpha$ -*p*-Dimethylaminobenzylcinnamic acid was heated with sodium ethoxide solution under the standard conditions for 48 hours; the product was isolated by acidification and addition of sodium acetate. Crystallisation from methyl alcohol yielded  $\alpha$ -*p*-dimethylamino-benzylcinnamic acid, m. p. 144°, and a less soluble acid, m. p. 230° (decomp.) after repeated crystallisation (m. p. of a mixture with the above acid, 229° decomp.). Ozonolysis in glacial acetic acid solution yielded an acid, m. p. above 200° (*p*-dimethylaminobenzoic acid?), in quantity insufficient for complete purification; benzoic acid was not obtained.

$\alpha$ -*p*-Dimethylaminobenzyl- and *p*-dimethylamino- $\alpha$ -benzylcinnamic acids do not yield a m. p.—composition diagram of the usual form, probably owing to decomposition of the latter acid. Since thermal analysis could not be employed to estimate the composition of mixtures of the acids, the ethyl esters were investigated. Ethyl  $\alpha$ -*p*-dimethylaminobenzylcinnamate (VIII;  $R = NMe_2$ ) was obtained from the silver salt of the corresponding acid by treatment with 1 mol. of ethyl iodide in an equal volume of chloroform; it separated from ligroin (b. p. 40–60°) in rectangular prisms, m. p. 62.5° (Found: C, 77.6; H, 7.4.  $C_{20}H_{23}O_2N$  requires C, 77.6; H, 7.5%). On hydrolysis under the standard conditions it gave the corresponding acid, m. p. 146° without purification. As partial hydrolysis during isolation of the mixed esters obtained by equilibration of this ester with 1.45*N*-sodium ethoxide could not be prevented, the

preparation of the isomeric ester (VII) and the plotting of a m. p.-composition diagram for the esters were not proceeded with.

The conversion of the ester (VIII) into its isomeride in the presence of 1.45*N*-sodium ethoxide could be proved qualitatively only after 65 hours' treatment: from 0.50 g. of the ester (VIII), 0.02 g. of *p*-dimethylamino- $\alpha$ -benzylcinnamic acid, m. p. 229—230°, was isolated after hydrolysis under the standard conditions; the remainder (0.38 g.) consisted of the more soluble isomeric acid. These experiments indicate a minimum conversion of about 4% in 65 hours; in the absence of knowledge relating to the position of equilibrium, and assuming this to be of the same order as that found for the methoxy-compounds (J., 1928, 447), it appears that the mobility of the dimethylamino-compounds is much smaller than that of the methoxy-compounds.

#### *Dimethylethylammonium Compounds.*

*Internal Salt of p- $\beta$ -Carboxy- $\gamma$ -phenylallylphenyldimethylethylammonium Hydroxide.*—Silver  $\alpha$ -*p*-dimethylaminobenzylcinnamate was treated with an excess of ethyl iodide on the steam-bath for  $\frac{1}{2}$  hour. The mixture of crystalline solid and silver iodide produced was extracted with much boiling acetone. The extract, on addition of ligroin, cooling, and stirring, gave the *molecular compound* of *p*- $\beta$ -carbethoxy- $\gamma$ -phenylallylphenyldimethylethylammonium iodide and silver iodide (1 mol.) in colourless pearly plates, m. p. 155—156° (Found: C, 38.4; H, 4.0; ionic I, 18.5, 18.6; AgI, 34.3.  $C_{22}H_{28}O_2NI \cdot AgI$  requires C, 37.8; H, 4.0; ionic I, 18.1; AgI, 33.6%). By treatment with silver hydroxide in warm aqueous acetone solution, filtration, evaporation, and addition of alcoholic picric acid, *p*- $\beta$ -carbethoxy- $\gamma$ -phenylallylphenyldimethylethylammonium *picrate*, m. p. 130° after crystallisation from methyl alcohol, was obtained (Found: C, 58.6; H, 5.2.  $C_{28}H_{30}O_9N_4$  requires C, 59.3; H, 5.3%).

The molecular compound was boiled in aqueous-acetone solution with silver chloride, and the filtered solution evaporated; prolonged desiccation yielded a resinous solid, which could not be purified. This was probably the betaine, since it contained no ionisable halogen and gave with sodium picrate a sodium salt-picrate, m. p. 270° (decomp.). A satisfactory analysis could not be obtained, but ozonolysis in glacial acetic acid solution gave an almost quantitative yield of benzoic acid:

The resinous solid (0.50 g.) was treated with a solution of 0.54 g. of sodium in 15 c.c. of ethyl alcohol (giving an active ethoxide-ion concentration equal to that of 1.45*N*-sodium ethoxide) for 24 hours at 85°. The cooled product was poured into water, neutralised with hydrochloric acid, and evaporated to dryness. The residue was extracted with successive small quantities of hot glacial acetic acid and the combined extracts were treated with ozonised oxygen. From the ether-soluble portion of the decomposition products, only a trace of benzoic acid (a few mg.) could be isolated. The water-soluble portion yielded no identifiable substance.

Attempts were made to synthesise the pairs of isomerides in which the *p*-substituents were NHAc or CN. *p*-Cyanobenzaldehyde, m. p. 100°, prepared from *p*-cyanobenzyl bromide, condensed with sodium β-phenylpropionate and acetic anhydride at 160° to yield almost entirely *p*-cyanocinnamic acid, m. p. 254° after crystallisation from nitrobenzene (Found: C, 68.5; H, 3.6. Calc. for C<sub>10</sub>H<sub>7</sub>O<sub>2</sub>N: C, 69.4; H, 4.0%). *p*-Acetamidobenzaldehyde, sodium β-phenylpropionate, and acetic anhydride at 180–200° gave an *acid*, m. p. 267° after repeated crystallisation from nitrobenzene, to which no formula has been assigned (Found: C, 71.2, 71.3; H, 5.5, 5.8; N, 5.7, 5.7%). *p*-Acetamidocinnamic acid, yellow prismatic needles, m. p. 261° (decomp.), was readily obtained in 78% yield from *p*-acetamidobenzaldehyde and malonic acid in the presence of piperidine. Reduction of this with sodium amalgam at 40–45° in the presence of carbon dioxide afforded β-*p*-acetamidophenylpropionic acid, which crystallised from 2*N*-acetic acid as the *monohydrate*, m. p. 124° after softening at 87–88° (Found: C, 59.3; H, 6.6. C<sub>11</sub>H<sub>13</sub>O<sub>3</sub>N.H<sub>2</sub>O requires C, 58.8; H, 6.7%). Desiccation gave the anhydrous acid, m. p. 143°. Sodium β-*p*-acetylphenylpropionate, benzaldehyde, and acetic anhydride condensed at 160–170° to furnish an *acid*, m. p. 233–234°, of unknown constitution (Found: C, 71.0; H, 5.8; N, 4.9, 4.9%).

The author desires gratefully to acknowledge the kindly interest and advice of Professor C. K. Ingold, F.R.S., and grants from the Chemical Society and the Royal Society which have partly defrayed the cost of the work.

# CXXI.—Cannabis Indica Resin. Part I. The Constitution of Nitrocannabinolactone (Oxycannabin).

By ROBERT SIDNEY CAHN.

THE general problem presented by *Cannabis Indica* resin, the essential portion of the drug known as hashish, bhang, etc., will be considered in a later communication. The present paper is confined to oxycannabin, which is a product of oxidation by concentrated nitric acid of the higher-boiling portions of the resin.

Oxycannabin has been assigned various formulæ, viz.,  $C_{20}H_{20}O_7N_2$  (Bolas and Francis, J., 1869, **22**, 417; *Chem. News*, 1871, **24**, 77),  $C_{10}H_{11}O_4N$  (Dunstan and Henry, P., 1898, 44), and  $C_{11}H_{11}O_4N$  (Wood, Spivey, and Easterfield, J., 1899, **75**, 20), the last of which has been confirmed in the present investigation. Wood, Spivey, and Easterfield removed the nitro-group, *via* the amino- and iodo-groups, to obtain the substance  $C_{11}H_{12}O_2$ ; this they termed cannabinolactone, renaming oxycannabin as nitrocannabinolactone. Among other results they showed that cannabinolactone on fusion with potassium hydroxide yielded *m*-toluic acid, and as, further, it contains an excessively stable lactone group, they concluded that it must be represented by one of the  $\gamma$ -lactonic formulæ (I)—(III).

They did not, however, consider the possibility of its being a phthalide derivative, although these are known readily to yield derivatives of benzoic acid on fusion with alkali.

*Hydroxycannabinolactone* was chosen as the starting point of the present investigation, as it was hoped by means of this substance to determine also the position of the substituent group (compare Bauer, *Ber.*, 1908, **41**, 503, who obtained *m*-hydroxybenzoic acid from methoxy- $\alpha\alpha'$ -diethylphthalide). Hydroxycannabinolactone (prepared by boiling a diazotised solution of the amino-compound) on fusion with potassium hydroxide at 290–300° yielded 6-hydroxy-*m*-toluic acid and acetone, which are the products to be expected from a substance having either formula (IV) or (V) (Gucci, *R. Accad. Lincei*, 1897, **6**, i, 295). The production of acetone renders untenable formulæ (II) and (III) for cannabinolactone (also those representing it as an ethylphthalide), but is not incompatible with

formula (I). In this last case oxidation, starting at the carbon atom carrying the hydroxyl group formed by opening of the lactone

ring, would yield potassium malonate, from which acetone would be formed. Wood, Spivey, and Easterfield, however, showed that only the methyl group of cannabinolactone was oxidised by excess of alkaline potassium permanganate solution, and the present author found that under similar conditions nitrocannabinolactone absorbs only the three atoms of oxygen necessary for oxidation of the methyl group. On account of the stability of the alcoholic hydroxyl group, which must be present in alkaline solutions of cannabinolactone and its nitro-compound, it is impossible to regard these substances as primary or secondary alcohols.\* The only constitution which gives rise to a tertiary alcoholic group on ring opening is that of a dimethylphthalide, for which the two possibilities (IV) and (V) remain.

A by-product in the nitric acid oxidation of nitrocannabinolactone was a tribasic acid,  $C_9H_5O_8N$ , m. p. 228—230°, the formation of which Wood, Easterfield, and Spivey were unable satisfactorily to explain on the basis of their formulæ (I)—(III). However, the dimethylphthalide formulation being assumed, this acid clearly has the structure represented by (VI) or (VII). The former has not

(VI.)

(VII.)

(VIII.)

been synthesised. The latter melts at 175° (Schultz, *Ber.*, 1909, 42, 3607) and thus cannot be identical with the acid from nitrocannabinolactone, which must, therefore, be (VI). Nitrocannabinolactone itself must then be represented by formula (VIII).

During the preliminary experiments on the alkali fusion of hydroxycannabinolactone it was found that there was considerable danger of loss of carbon dioxide from the hydroxy-acid formed. In order to determine the conditions of the reaction, 4-hydroxy-dimethylphthalide (IX) was prepared from the corresponding amino-

\* *E.g.*, mandelic acid was found to be readily oxidised under the conditions used for nitrocannabinolactone.

compound\* (Teppema, *Rec. trav. chim.*, 1923, **42**, 30; Tasman, *ibid.*, 1927, **46**, 653). The cannabinolactone derivatives behave very similarly to those encountered in this preparation, the methylation of the hydroxy-derivative being particularly noteworthy, and the relative stability of the nitro-, amino-, and methoxy-compounds agrees qualitatively with that established by Tasman (*loc. cit.*) for phthalide derivatives. In an attempt to effect fission by a

method in which the possibility of oxidation was excluded, 4-hydroxydimethylphthalide was heated with aniline to 300°. A nearly quantitative yield of 4-hydroxy-N-phenyl- $\alpha$ -dimethylphthalimidine (X) resulted: the same compound was also obtained by heating with aniline and aniline hydrochloride to 210° (compare Emmert and Meyer, *Ber.*, 1921, **54**, 210).

#### EXPERIMENTAL.

Nitrocannabinolactone (oxycannabin), prepared according to the directions of Wood, Spivey, and Easterfield (*loc. cit.*), had the properties described by these authors (Found †: C, 59.8, 59.6; H, 5.1, 5.0; N, 6.6, 6.55; *M*, in camphor, 206, 196, 203, 212. Calc. for  $C_{11}H_{11}O_4N$ : C, 60.0; H, 5.0; N, 6.35%; *M*, 221). The working up of the hashish used for this preparation will be described in a later communication.

*Aminocannabinolactone*.—The following modification of Wood, Spivey, and Easterfield's method of preparation is more convenient and gives an improved yield. Red phosphorus (5 g.) was added to a solution of nitrocannabinolactone (9 g.) in glacial acetic acid (36 c.c.) and hydriodic acid (27 c.c., *d* 1.7), and the whole heated under reflux for 2–3 hours. The solution was diluted with water (300 c.c.) and filtered hot into a hot solution of sodium hydroxide (34 g.) in water (500 c.c.). The weakly acid solution was again filtered hot from a small amount of gummy impurity, which was washed with boiling water. On cooling, aminocannabinolactone (5.3 g.) separated as an oil which at once crystallised when seeded and was quite pure, m. p. 120° (Wood, Spivey, and Easterfield give m. p. 119°). By concentration of the mother-liquor (charcoal) a further quantity (0.5 g.) was obtained, m. p. 117–118° (total yield, 74.5% of the theoretical).

\* Named 5-aminodimethylphthalide by these authors, who start numbering from the carbonyl group.

† All analyses marked thus are microanalyses by Dr. Ing. A. Schoeller of Berlin.

*Hydroxycannabinolactone* (IV).—When potassium nitrite (2.54 g. in a little water) was added to a cold solution of aminocannabinolactone (5.7 g.) in 20% sulphuric acid (110 c.c.), and the mixture subsequently warmed on the water-bath until evolution of gas ceased, *hydroxycannabinolactone* separated in quantitative yield as an apricot-coloured powder. Recrystallised from aqueous alcohol or, better, from benzene, it formed pale yellow needles, m. p. 198—199° (Found †: C, 68.5; H, 6.3.  $C_{11}H_{12}O_3$  requires C, 68.7; H, 6.3%). The colour cannot be removed by ordinary methods, but the substance was recovered quite colourless from low-temperature potash fusions. *Hydroxycannabinolactone* dissolves immediately in cold sodium hydroxide and slowly in sodium bicarbonate solutions (to give bright yellow solutions, if the coloured substance is used), and is precipitated unchanged on acidification. An alcoholic solution does not, however, evolve carbon dioxide on treatment with sodium bicarbonate solution. Acetylation by acetic anhydride was not satisfactory, but *acetoxycannabinolactone* was readily obtained by addition of acetyl chloride to an ice-cold solution of the substance in pyridine and subsequent treatment with water. It crystallised from a little alcohol in colourless needles, m. p. 93° (Found †: C, 66.3; H, 6.1.  $C_{13}H_{14}O_4$  requires C, 66.6; H, 6.0%).

*Methoxycannabinolactone*.—On shaking a solution of hydroxycannabinolactone (0.9 g.) in 8% sodium hydroxide solution with methyl sulphate (20 c.c., added in portions), a homogeneous solution was obtained, from which *methoxycannabinolactone* was precipitated on acidification. It crystallised from methyl alcohol in colourless prisms, m. p. 182° [Found †: C, 69.6; H, 6.9; MeO, 14.1.  $C_{11}H_{11}O_2(OMe)$  requires C, 69.9; H, 6.8; MeO, 15.05%].

Once precipitated, the methoxy-compound is insoluble in sodium hydroxide solution, and the phthalide ring is only slowly opened; e.g., after the methoxy-compound (0.3 g.) had been refluxed with 10% aqueous-alcoholic potassium hydroxide solution (1:1) for 1 hour, addition of water precipitated 0.1 g. which had not undergone ring fission, the remainder being precipitated on acidification (compare Tasman, *loc. cit.*). As the methoxy-compound, when first formed, remained dissolved in the alkaline solution, it must have been formed as  $OH \cdot CMe_2 \cdot C_6H_2Me(OMe) \cdot CO \cdot O-$ . Whence it follows that the dimethylphthalide ring of the hydroxy-compound is opened on solution in cold alkali, and that the doubts of Tasman, who did not investigate hydroxy-compounds, as to the quinonoid structure of phenolphthalein compounds are unfounded.

*Methoxycannabinolactone* was also obtained by heating the hydroxy-compound in benzene solution with methyl iodide and

freshly prepared silver oxide, and by heating the silver salt with methyl iodide in benzene.

*Fusion of Hydroxycannabinolactone.*—The lactone (1 g.) was added during 8 minutes to molten potassium hydroxide at 290—300°, this temperature being maintained for a further 10 minutes. The cooled melt was dissolved in water, acidified, and then made alkaline with sodium bicarbonate. Extraction with ether removed a small amount of cresol and unchanged phthalide. Re-acidification of the alkaline liquid and extraction with ether yielded impure 6-hydroxy-*m*-toluic acid, which after recrystallisation from water formed needles containing  $\frac{1}{2}\text{H}_2\text{O}$  of crystallisation (Found:  $\text{H}_2\text{O}$ , 5.95, 6.4. Calc. for  $\text{C}_8\text{H}_8\text{O}_3 \cdot \frac{1}{2}\text{H}_2\text{O}$ :  $\text{H}_2\text{O}$ , 5.6%). When dried, it melted at 172—173° (Found: C, 63.45; H, 5.25. Calc. for  $\text{C}_8\text{H}_8\text{O}_3$ : C, 63.15; H, 5.3%). Yield after one crystallisation, 0.3 g. The acid gave no colour with ferric chloride solution.

The distillate from a similar fusion was collected under water and gave positive results with the following tests for acetone: iodoform, sodium nitroprusside-alkali-acetic acid, Denigès's test.

*Oxidation of Nitrocannabinolactone.*—4% Potassium permanganate solution was added in portions of 1 c.c. to a solution of nitrocannabinolactone (0.47 g.) and sodium hydroxide (1 g.) in water (15 c.c.) heated on the water-bath. Decolorisation, at first complete in 15 seconds, grew progressively slower until, when 16.4 c.c. (3 atoms of oxygen) had been added, 20 minutes were required. Thereafter, decolorisation was exceedingly slow, and on addition of a further 5.5 c.c. (1 atom of oxygen) and continued heating for 1 hour, very little reduction took place. After cooling, excess of sodium bisulphite and hydrochloric acid were added, which precipitated a rapidly crystallising gum. Recrystallised from water, it formed plates (0.2 g.), m. p. 227—229° (Wood, Spivey, and Easterfield give the melting point of cannabinolactonic acid as 229—230°).

4-*Hydroxy- $\alpha\alpha$ -dimethylphthalide* (IX).—4-Aminodimethylphthalide (Teppema, *loc. cit.*; Tasman, *loc. cit.*) was prepared (*a*) by the method described above for aminocannabinolactone, the pure compound crystallising (m. p. 117°) in 78% yield, or (*b*) by suitable modification of West's method (J., 1925, 127, 494), in 70% yield. For transformation into the hydroxy-compound the following conditions should be adhered to, deviations leading to much reduced yields. 4-Aminodimethylphthalide (8.85 g.) in water (100 c.c.) and concentrated sulphuric acid (10 c.c.) was diazotised at 10° by potassium nitrite (4.25 g. in a little water), and the cooled solution dropped slowly into boiling, mechanically stirred 1% sulphuric acid (500 c.c.). Boiling and stirring were continued for a further 2 hours and the solution was then filtered hot from a little tar. On standing

in the ice-chest, 4-hydroxy- $\alpha$ -dimethylphthalide (6.9 g.; 78% of the theoretical yield) was deposited in pale yellow crystals. It separated from benzene in very pale yellow crystals, m. p. 149–150° (Found: C, 67.5; H, 5.8.  $C_{10}H_{10}O_3$  requires C, 67.4; H, 5.7%). The substance was purified beyond this point only with difficulty, but was recovered from low-temperature potash fusions quite colourless and melting at 152°.

The acetyl derivative was prepared by the pyridine and acetyl chloride method, and crystallised from dilute acetic acid; it melted at 84°.

When the hydroxy-compound (0.5 g.), dissolved in 10% sodium hydroxide solution (20 c.c.), was shaken with methyl sulphate (3 c.c.), added in portions, a homogeneous solution was obtained, from which on acidification 4-methoxydimethylphthalide was precipitated; after being washed with dilute alkali (in which it was now insoluble) and recrystallised from aqueous methyl alcohol, it melted at 100° (Found: C, 68.5; H, 6.4.  $C_{11}H_{12}O_3$  requires C, 68.7; H, 6.3%).

4-Hydroxydimethylphthalide can be distilled in a vacuum and is unaffected by prolonged boiling with concentrated hydrochloric acid, 50% (by weight) sulphuric acid, or by fusion with potassium hydroxide below *ca.* 250°. On fusion with potassium hydroxide for 10 minutes at 280–300°, acetone, *m*-hydroxybenzoic acid, and some phenol were obtained.

4-Hydroxy-N-phenyl- $\alpha$ -dimethylphthalimidine (X).—4-Hydroxydimethylphthalide (2 g.) and aniline (10 c.c.) were heated for 2 hours at 300°. The violet liquid obtained was diluted with ether, and the aniline removed by dilute acid. The 4-hydroxy-N-phenyl- $\alpha$ -dimethylphthalimidine, which was only partly dissolved in the ether, was shaken into dilute sodium hydroxide solution and obtained on acidification as a pale blue powder. It crystallised from a little ethyl alcohol with one molecule of water of crystallisation (Found: C, lost; H, 6.3;  $H_2O$ , 6.5.  $C_{16}H_{15}O_2N \cdot H_2O$  requires H, 6.3;  $H_2O$ , 6.6%); or, better, from methyl alcohol, from which it formed colourless pseudo-rhombic crystals (showing well-developed domal faces), containing one molecule of methyl alcohol of crystallisation (Found: MeOH, 11.7; C, 71.4; H, 6.8. Found in dried material: C, 76.05; H, 6.1.  $C_{16}H_{15}O_2N \cdot MeOH$  requires C, 71.6; H, 6.7; MeOH, 11.2%.  $C_{16}H_{15}O_2N$  requires C, 75.85; H, 6.0%). Both crystalline forms and the anhydrous material melt at 214–215°.

The same substance was formed on heating 4-hydroxydimethylphthalide (1 g.) with aniline (5 c.c.) and aniline hydrochloride (5 g.) for 2 hours at 210° (but not on refluxing with aniline alone). In this case, however, considerably more of the coloured impurity

(possibly the phenylimide of X) was formed. On distillation with soda-lime, aniline was evolved in quantity.

The *acetoxy*-derivative was prepared (a) from the crystallised material by warming on the water-bath for 1 hour with ten times the quantity of acetic anhydride, and (b) from the dried material by the pyridine and acetyl chloride method. After crystallisation from methyl alcohol, both specimens, alone or mixed, melted at 219° (Found: C, 73·3; H, 5·9.  $C_{18}H_{17}O_3N$  requires C, 73·2; H, 5·8%). Mixed with the hydroxy-compound, the substance melted from 174° to 198°.

3 : 5-Dibromo-4-hydroxy- $\alpha\alpha$ -dimethylphthalide.—When bromine (0·9 g.) in a little acetic acid was gradually added to 4-hydroxy-dimethylphthalide (0·5 g.) in 50% acetic acid (10 c.c.), and the mixture kept for 30 minutes, 3 : 5-dibromo-4-hydroxy- $\alpha\alpha$ -dimethylphthalide (0·72 g.; 76% yield) separated. Recrystallised from 50% acetic acid, it formed plates with one molecule of water of crystallisation, which did not melt sharply. When dried, it melted at 125° (Found:  $H_2O$ , 5·2. Found in dried material: Br, 47·6.  $C_{10}H_8O_3Br_2 \cdot H_2O$  requires  $H_2O$ , 5·1%.  $C_{10}H_8O_3Br_2$  requires Br, 47·6%).

The author is very greatly indebted to Professor Sidney Smith, late Director of the Medico-Legal Section, Ministry of Justice, Cairo, for a supply of hashish, which enabled this investigation to be undertaken.

## CXXII.—*The Preparation of Secondary Alkylaryl-amines and their Purification.*

By WILFRED JOHN HICKINBOTTOM.

THE isolation of the pure secondary amine from the products of interaction of an alkyl halide and a primary arylamine can be economically and conveniently accomplished by the following process. The alkyl bromide is heated with an excess (usually  $2\frac{1}{2}$ —4 mols.) of the primary aromatic amine. The tendency for the alkyl halide to yield tertiary amine is thus repressed and the product consists almost entirely of the secondary amine and the excess of the primary amine combined with the hydrogen bromide liberated in the reaction. The separation of the primary and secondary

amines is effected by Morgan's method (E.P. 102,834, 1916) depending on the formation of sparingly soluble additive compounds of zinc chloride and aniline or its homologues of the general formula  $B_n \cdot ZnCl_2$ . The alkylanilines do not form compounds with zinc chloride in the presence of water (compare Reilly and Hickinbottom, J., 1920, 117, 127).

It has now been found that the excess of aniline or *m*-xylydine can be completely precipitated by the addition of a 50% solution of zinc chloride to the mixture of amines liberated from the product of the reaction between the primary amine and the alkyl halide; the uncombined secondary amine is isolated by draining the precipitated zincchloride and extracting with light petroleum. The yield of secondary amines thus obtained from *n*-propyl, isopropyl, and *n*-butyl bromides was upwards of 70% of the theoretical, calculated on the weight of the alkyl halide; frequently it was of the order of 75—85%. Further purification to remove small quantities of tertiary amines consisted in converting the crude secondary amine into its hydrobromide and crystallising this from alcohol (for *n*-butylaniline hydrobromide, benzene is a better solvent). Another method, also employed for ethyl-, *n*-propyl-, and isopropyl-anilines, was to prepare the acetyl derivative, which after distillation and crystallisation yielded the pure secondary amine on hydrolysis.

The yield of isobutylaniline obtained by the method now described was always small (30—40%). This is due, in part at least, to the presence of *tert*.-butyl bromide in the isobutyl bromide. According to Michael, Scharf, and Voigt (*J. Amer. Chem. Soc.*, 1916, 38, 653) this is a normal impurity in isobutyl bromide, and one very difficult to remove. It does not, however, affect the purity of the isobutylaniline, as the tertiary bromide yields butylene when warmed with aniline (compare Nef, *Annalen*, 1899, 309, 164).

#### EXPERIMENTAL.

*n*-Propylaniline.—Aniline (230 g.;  $2\frac{1}{2}$  mols.) was heated with *n*-propyl bromide (1 mol.) under reflux in a boiling water-bath for 5 hours, the product was rendered alkaline, and the amines were separated and treated with a solution of 150 g. of zinc chloride in 150 g. of water. The mixture, when cooled and stirred, was rapidly converted into a thick paste which, after 12 hours, was drained on a large Buchner funnel, washed with cold water, pressed to remove as much as possible of the water, and extracted several times with boiling light petroleum. The extracts were combined, washed with water and with dilute aqueous ammonia, and dried over potassium carbonate. Removal of the solvent left *n*-propylaniline,

which was obtained almost pure after two distillations: yield, 94.5 g. (70%); b. p. 218—222°. A further quantity (10 g.), collected between 222° and 230°, contained an appreciable amount of the tertiary amine.

A very convenient method of preparing aceto-*n*-propylanilide consisted in distilling equal weights of the secondary amine and acetic anhydride: the distillate collected between 240° and 265° and once crystallised from light petroleum was pure aceto-*n*-propylanilide, m. p. 48—49°.

*iso*Propylaniline, b. p. 206—208° (yield, 73%), was prepared in the same way from aniline and *isopropyl* bromide and freed from traces of tertiary amine by conversion into its acetyl derivative, m. p. 42°, and subsequent hydrolysis.

*n*-Butylaniline.—Aniline (130 g.) and *n*-butyl bromide (70 g.), heated in a boiling water-bath for 3 hours, gave, after removal of the excess of aniline by Morgan's method, approximately pure *n*-butylaniline (57 g.; yield, 75%). After purification through the hydrobromide, the amine had b. p. 235—235.5°/744 mm. (yield, 38 g.; 50%). A further quantity was obtained by fractional crystallisation of the mother-liquor of the hydrobromide.

*iso*Butylaniline.—*iso*Butyl bromide (prepared by heating *iso*-butyl alcohol with concentrated hydrobromic acid: it contained some *tert*.-butyl bromide) (120 g.) was heated with aniline (2½ mols.) in a boiling water-bath for 2 hours, and the excess of aniline subsequently removed as described above. The crude *isobutylaniline* gave the following fractions on distillation: 225°, 9 g.; 225—227°, 26 g.; 227—231°, 20 g.

Pure *isobutylaniline* was obtained by converting the crude product into hydrobromide by the addition of concentrated hydrobromic acid, crystallising the salt from absolute alcohol, and decomposing it with aqueous sodium hydroxide. The amine was characterised by its *p*-toluenesulphonyl derivative, which crystallised from alcohol in slender prismatic needles, m. p. 122—123° (Found: N, 4.7.  $C_{17}H_{21}O_2NS$  requires N, 4.6%).

The author desires to thank Mr. R. G. Ault and Mr. S. E. A. Ryder for their assistance in the experimental work.

CXXIII.—*Attempts to prepare Cyanine Dyes from Quaternary Salts of 2-Methylacenaphthpyridine and of 5-Methylacridine.*

By FRANCES MARY HAMER.

WITH any class of dye, there is a tendency for increase in molecular weight to be accompanied by a shift of the absorption bands towards the red end of the spectrum. Where the dyes are photographic sensitisers, there is a corresponding shift of the maxima of extra-sensitisation. Dyes which sensitise further into the red should therefore be obtainable by replacing the nuclei of known sensitisers by heavier nuclei. An example of the shift which occurs with increase in molecular weight is afforded by comparison of pina-cyanol (I), for which the maximum of the chief sensitising band lies at  $\lambda$  6375 Å., with the carbocyanine (II), which has its sensitising

maximum at  $\lambda$  6900 Å. (Mees and Gutekunst, *J. Ind. Eng. Chem.*, 1922, 14, 1060). So also, the cyanine dyes recently prepared from quaternary salts of methyl- $\alpha$ - and - $\beta$ -naphthathiazoles show absorption further towards the red than the corresponding dyes prepared from salts of methylbenzthiazole, the shift being greater with the thiocarbocyanines, where two benzthiazole nuclei are replaced by two naphthathiazole nuclei, than with the thio- $\psi$ -cyanines, where there is only one such replacement (Hamer, J., 1929, 2598). In this connexion it seemed of interest to prepare quaternary salts of 2-methylacenaphthpyridine (III) and of 5-methylacridine (IV) in order to see whether such salts would give rise to cyanine dyes and, if so, to examine the photographic properties of the latter.

2-Methylacenaphthpyridine has been prepared from 3-aminoacenaphthene. Sachs and Mosebach's original method for reducing 3-nitroacenaphthene (*Ber.*, 1911, 44, 3855), used also by Stewart (*J.*, 1925, 427, 1331), has been said by Fleischer and Schranz to

give only a 20% yield, the chief product being the sodium salt of *N*-acenaphthyl-3-sulphaminic acid (*Ber.*, 1922, **55**, 3253); their observation that this salt remains in solution was not confirmed. Their method of preparation (see also Morgan and Stanley, *J. Soc. Chem. Ind.*, 1924, **43**, 343T) was adopted, with very slight modification. The preparation, from 3-aminoacenaphthene, by the action of paraldehyde and hydrochloric acid, of 2-methylacenaphthpyridine has been described by Nair and Simonsen (*J.*, 1926, 3140). But as they proceed, without removal of the tar which accompanies the condensation product, to treat the reaction mixture with alkali, modification was required. Comparative experiments showed the large excess of paraldehyde and of hydrochloric acid to be unnecessary, as also is the protracted time of heating.

The *methiodide* of 2-methylacenaphthpyridine was prepared, but similar conditions gave only a trace of the corresponding ethiodide. The methiodide condenses with *p*-dimethylaminobenzaldehyde and with *p*-nitrosodimethylaniline: as in analogous cases (Hamer, *J.*, 1924, **125**, 1348; 1929, 2598), the former product (V) is a sensitiser and the latter (VI) a desensitiser. 2-Methylacenaphthpyridine

methiodide reacts with quinoline methiodide or ethiodide to give an isocyanine (VII) and with 2-iodoquinoline methiodide or ethiodide to give a *ψ*-cyanine (VIII), the latter condensation proceeding better in aqueous solution than in the more generally applicable alcoholic

solution (compare Hamer, *J.*, 1928, 206). Comparison of the absorption bands of these new cyanines, in alcoholic solution, with those of the parent dyes reveals a shift of 150 Å. towards the red. Mr. O. F. Bloch found the compounds to be photographic sensitisers, but of no outstanding merit. It is remarkable, in view of its reactivity, that 2-methylacenaphthpyridine methiodide does not yield

a carbocyanine by the ethyl orthoformate and pyridine method (Hamer, J., 1927, 2796); the use of acetic anhydride as solvent is no more successful.

5-Methylacridine has previously been prepared from diphenylamine by the action of acetonitrile or acetic acid (Bernthsen, *Annalen*, 1878, **192**, 29; Fischer and Rudolph, *Ber.*, 1882, **15**, 1500; Besthorn and Fischer, *Ber.*, 1883, **16**, 68; Bernthsen and Bender, *ibid.*, p. 1802; Fischer, *ibid.*, p. 1820; Bernthsen, *Annalen*, 1884, **224**, 1). In the present work, however, it was prepared from acetyldiphenylamine, by heating it with zinc chloride in a sealed tube; it was conveniently isolated as its tartrate, by Koenigs' method (*Ber.*, 1899, **32**, 3599).

5-Methylacridine methiodide has been prepared by Bernthsen (*Annalen*, 1884, **224**, 1), by Decker (*Ber.*, 1905, **38**, 2493), by Freund and Bode (*Ber.*, 1909, **42**, 1746), and by Kaufmann and Albertini (*Ber.*, 1911, **44**, 2052). Except for the statement of the last-named authors, that the dust of the methiodide attacks the breathing organs, there is no reference to the strong sternutatory action which is the most striking characteristic of this salt.

Now the reactivity of the methyl group in 5-methylacridine itself is manifested by its condensation with (a) chloral (Bernthsen and Muhlert, *Ber.*, 1887, **20**, 1541), (b) benzaldehyde and its *m*- and *p*-nitro-derivatives (Friedländer, *Ber.*, 1905, **38**, 2840; Porai-Koschitz, *Z. Farb. Text.-ind.*, 1907, **6**, 291), (c) *p*-nitrosodimethylaniline (Kaufmann and Vallette, *Ber.*, 1912, **45**, 1736), and (d) formaldehyde (Koenigs, *loc. cit.*; Homberger and Jensen, *J. Amer. Chem. Soc.*, 1926, **48**, 800). Since the quaternary salts of a base containing a reactive methyl group are, in general, more reactive than is the base itself (Mills and Smith, J., 1922, **121**, 2724), it was both surprising and interesting to obtain a series of negative results in the case of 5-methylacridine methiodide. For instance, it did not react (a) with ethyl orthoformate in the presence of pyridine to give a carbocyanine, (b) with quinoline methiodide in aqueous-alcoholic solution, under the influence of sodium hydroxide, to give an isocyanine, (c) with *p*-dimethylaminobenzaldehyde, in absolute alcoholic solution and in the presence of piperidine, or (d) with *p*-nitrosodimethylaniline, under similar conditions. (e) An attempt to effect condensation between it and 2-iodoquinoline methiodide by the normal procedure, absolute alcohol being used as solvent and potassium hydroxide as condensing agent (Hamer, J., 1928, 206), also gave a negative result. But when water was employed as the solvent medium, condensation between 5-methylacridine methiodide and 2-iodoquinoline methiodide or ethiodide took place. Although these new dyes (IX) may be regarded as

derived from the simple *isocyanine* (X), their absorption spectra are of a different character, showing one broad band, with an ill-

defined maximum, whereas the latter has two well-marked, relatively narrow bands. The maximum of this broad band is in approximately the same position as that of the chief band of the parent *isocyanine*, instead of showing the expected shift towards the red. Both the new dyes are entirely devoid of sensitising properties.

#### EXPERIMENTAL.

**3-Aminoacenaphthene.**—A mixture of 3-nitroacenaphthene (40 g.) with spirit (400 c.c.) and water (200 c.c.) was boiled in a flask (3 l. capacity). It was removed from the water-bath for the addition of sodium hydrosulphite (100 g.) in three portions, reaction occurring at each addition. After 15 minutes' boiling, the spirit was distilled off and the residue treated with water (500 c.c.) and boiled. When cold, the solid was filtered off, ground to a paste with water, and hydrolysed by heating on the water-bath with concentrated hydrochloric acid (300 c.c.) and water (1200 c.c.). The violent bumping, which occurs on boiling, does not take place on the water-bath, and the isolation of the solid before hydrolysis has the advantage of avoiding the copious evolution of sulphur dioxide, caused by addition of the acid to the reaction mixture, both these being points whereby the earlier method has been modified. The liquid was filtered hot, to remove a little black matter, and the filtrate was made alkaline with ammonia. The yield of base, after washing with water and drying, was 63–64%, and, after recrystallisation from petrol, 49–53%. M. p. 107°.

**2-Methylacenaphthpyridine.**—3-Aminoacenaphthene (40 g.; 1 mol.) was treated with hydrochloric acid ( $d$  1.19; 40 c.c.) and paraldehyde (26 c.c.; 2.5 mols.). The flask was cooled with water in order to abate the violence of the reaction, which occurs without the application of external heat. Finally it was heated on the water-bath for  $\frac{1}{2}$ -hour and water (1 l.) was added. When cold, the mixture was filtered from tar, and the filtrate and washings were treated with excess of ammonia. The aqueous liquid was poured off from the semi-solid base and the latter was twice extracted with hot 10% sulphuric acid (80 + 40 c.c.), the extract being filtered hot. The yellow sulphate, which slowly crystallised from the filtrate, was

collected, washed with acetone (31.9 g. obtained), dissolved in hot water, and treated with ammonia. The crude base (20.3 g.) was obtained in 39% yield and after recrystallisation from spirit the yield (15.2 g.) was 29%. M. p.  $131^{\circ}$ , as recorded by Nair and Simonsen (*loc. cit.*).

*2-Methylacenaphthpyridine Methiodide.*—2-Methylacenaphthpyridine (10 g.) and methyl iodide (10 c.c.) were heated in a sealed tube at  $100^{\circ}$  for 2 days. The product was extracted with ether; the undissolved residue (12.8 g.; 78% yield) separated from spirit in orange crystals (62% yield), m. p. about  $212^{\circ}$ . A specimen was dried in a vacuum desiccator before analysis, the method of Carius being used in this, and in all subsequent halogen determinations, except where otherwise stated (Found: I, 35.0.  $C_{17}H_{16}NI$  requires I, 35.2%).

*2-p-Dimethylaminostyrylacenaphthpyridine Methiodide (V).*—2-Methylacenaphthpyridine methiodide (3 g.; 1 mol.) and *p*-dimethylaminobenzaldehyde (1.24 g.; 1 mol.), dissolved in hot 99% spirit (300 c.c.), were treated with piperidine (0.5 c.c.) and the mixture was boiled for 5 hours. The solid was filtered off when cold, and the filtrate concentrated to  $\frac{1}{3}$  volume in order to obtain a second crop (total yield, 2.9 g.). The product was twice boiled out with methyl alcohol ( $2 \times 50$  c.c.), and the undissolved residue recrystallised from spirit (750 c.c.). The *methiodide* (V) (24% yield) was again recrystallised and was dried for analysis in a vacuum at  $100$ – $120^{\circ}$  (Found: I, 25.5.  $C_{26}H_{25}N_2I$  requires I, 25.8%). The green crystals melt at  $224^{\circ}$  (decomp.). The spirit solution has a wide absorption band with its maximum at about  $\lambda$  5200 Å. A plate bathed in this solution acquires a feeble extra sensitivity, extending to  $\lambda$  7100 Å., but the dye is less effective when added to the emulsion.

*p-Dimethylaminoanil of Acenaphthpyridine-2-aldehyde Methiodide (VI).*—2-Methylacenaphthpyridine methiodide (3 g.; 1 mol.) and *p*-nitrosodimethylaniline (1.25 g.; 1 mol.) were boiled in absolute alcoholic solution (50 c.c.), with addition of piperidine (2 drops), for 6 hours. The product (3.2 g.; 78% yield) was recrystallised from methyl alcohol (1500 c.c.; 2.05 g. obtained; 50% yield). After a second recrystallisation the olive-green crystals, m. p.  $195^{\circ}$  (decomp.), were dried for analysis in a vacuum at  $60$ – $80^{\circ}$  (Found: I, 25.4.  $C_{25}H_{24}N_3I$  requires I, 25.7%). The compound desensitises photographic plates more powerfully than does safranin, but is of no practical use because its desensitising action is destroyed by the sulphite and carbonate of the developer.

*isoCyanine (VII) from 2-Methylacenaphthpyridine Methiodide and Quinoline Methiodide.*—2-Methylacenaphthpyridine methiodide

(6 g.; 1 mol.) and quinoline methiodide (9.0 g.; 2 mols.) were boiled with absolute alcohol (300 c.c.) and the mixture was treated with sodium (0.46 g.; 1.2 mols.), dissolved in absolute alcohol (30 c.c.), and then boiled for 15 minutes. The solid (5.5 g.), which separated on cooling, was twice boiled out with methyl alcohol (50 + 100 c.c.), and the undissolved residue was recrystallised from methyl alcohol. The small green crystals (1.17 g.; 14% yield) obtained from this third fraction were again recrystallised from methyl alcohol (200 c.c.; 0.83 g. obtained; 10% yield). The *isocyanine* was dried in a vacuum at 60–80° (Found: C, 64.2; H, 5.0; I, 25.1.  $C_{27}H_{23}N_2I$  requires C, 64.5; H, 4.6; I, 25.3%). When it is heated, a change occurs between 160° and 170° and, if heating is rapid, the dye even melts; if slowly heated, melting with decomposition occurs between 220° and 240°, the exact point depending upon the rate of rise of temperature. The chief absorption band of the spirit solution has its maximum at  $\lambda$  5750 Å., and there is another maximum at  $\lambda$  5400 Å. A plate bathed in the solution shows a very uniform band of extra sensitisation, extending to  $\lambda$  6800 Å. for moderate exposures and with maxima at  $\lambda$  6100 Å. and  $\lambda$  5400 Å.

*isoCyanine from 2-Methylacenaphthpyridine Methiodide and Quinoline Ethiodide.*—Similarly, 2-methylacenaphthpyridine methiodide (6 g.) was condensed with quinoline ethiodide (9.47 g.) and the resultant dye (4.85 g.) was extracted with ether. The undissolved residue (4.5 g.) was boiled with insufficient methyl alcohol (50 c.c.) to dissolve it; the residue was recrystallised from methyl alcohol (200 c.c.), giving green crystals, m. p. about 217° (decomp.), in 16% yield (1.39 g.). They were dried for analysis in a vacuum at 100–110° (Found: I, 24.7.  $C_{28}H_{25}N_2I$  requires I, 24.6%). The chief absorption band of the spirit solution lies at  $\lambda$  5850 Å. and the secondary one at  $\lambda$  5400 Å. The sensitising action conferred on a plate bathed in a solution of the dye extends to  $\lambda$  6600 Å., and is not quite so uniform as that of the preceding compound, showing a distinct gap at  $\lambda$  5000 Å. One maximum, at  $\lambda$  6050 Å., is more strongly marked than the other, which is at  $\lambda$  5500 Å.

*$\psi$ -Cyanine (VIII) from 2-Methylacenaphthpyridine Methiodide and 2-Iodoquinoline Methiodide.*—Crude 2-iodoquinoline methiodide (8 g.; 1 mol.) was added to boiling water (500 c.c.), and a little undissolved periodide filtered off. 2-Methylacenaphthpyridine methiodide (7.27 g.; 1 mol.) was added, followed by an aqueous solution (40 c.c.) of potassium hydroxide (3.0 g.; 2.4 mols.), and boiling was continued for 5 minutes. The resultant solid was purified by boiling out with water and the residue (3.8 g.) was extracted with ether in a Soxhlet apparatus. The undissolved

residue (3.6 g.) was recrystallised from methyl alcohol (750 c.c.; 2.1 g. obtained; 21% yield). After a second recrystallisation from methyl alcohol (400 c.c. for 1.9 g., giving 1.2 g.; 13% yield), the  $\psi$ -cyanine was dried in a vacuum at 60–80° (Found: I, 24.9.  $C_{27}H_{23}N_2I$  requires I, 25.3%). The compact bronze crystals melt at 236° (decomp.). With a spirit solution, the chief absorption band has its crest at  $\lambda$  5400 Å.: the second band, which is almost as strong, has its crest at  $\lambda$  5100 Å. On bathing plates, a band of extra sensitisation is conferred, extending to  $\lambda$  6400 Å. for moderate exposures, and with its maximum at  $\lambda$  5700 Å.

*$\psi$ -Cyanine from 2-Methylacenaphthpyridine Methiodide and 2-Iodoquinoline Ethiodide.*—From 2-iodoquinoline ethiodide (4 g.) and 2-methylacenaphthpyridine methiodide (3.51 g.), the  $\psi$ -cyanine, similarly precipitated by the action of potassium hydroxide, was at first obtained in the form of a tar, which improved during boiling and hardened when cold. It was extracted with hot water and the residue (2.44 g.) was extracted with ether in a Soxhlet apparatus. That residue (2.33 g.) was recrystallised from methyl alcohol (200 c.c.; 1.32 g. obtained; 26% yield). It was dried for analysis in a vacuum at 100–110° (Found: I, 24.4.  $C_{28}H_{25}N_2I$  requires I, 24.6%). The dye forms small brownish-red crystals, m. p. 201° (decomp.). The principal absorption band is at  $\lambda$  5450 Å. and there is another at 5100 Å. It exerts a powerful sensitising action on plates bathed in its solution; the action extends to  $\lambda$  6400 Å. for moderate exposures and shows maxima at  $\lambda$  5700 Å. and 5100 Å.

*Acetyldiphenylamine.*—Diphenylamine has been acetylated by means of acetyl chloride (Meister, *Ber.*, 1872, 5, 283; Merz and Weith, *Ber.*, 1873, 6, 1511) and by acetic anhydride (Claus, *Ber.*, 1881, 14, 2365). In a modification of the latter method, diphenylamine (30 g.), acetic anhydride (60 c.c.), and fused sodium acetate (30 g.) were heated together on the water-bath for 1½ hours and the product was treated with water and ammonia. After recrystallisation from very dilute spirit, the base was obtained in 80% yield. It melted at 84–85° with previous softening, but lost solvent of crystallisation on drying on the water-bath and in a vacuum desiccator; the anhydrous substance melted at 101–102°. Meister, and Merz and Weith, give m. p. 99.5°, Claus gives m. p. 103°, and Wallach (*Annalen*, 1882, 214, 234) gives m. p. 101–102°.

*5-Methylacridine.*—A mixture of acetyldiphenylamine (5 g.) with five times its weight of powdered zinc chloride was heated in a sealed tube at 220–240° for 6½ hours. The dark mass was extracted with hot 50% sulphuric acid and the extract was treated with water and excess of ammonia to precipitate the base. This was extracted with benzene and, after removal of the solvent, the

residue was dissolved in hot spirit and treated, as by Koenigs (*loc. cit.*), with a hot solution of tartaric acid (5 g.) in spirit (50 c.c.). The tartrate (6.9 g.) was suspended in cold water and treated with excess of sodium carbonate solution and the base was extracted with ether, the extract being dried with potassium hydroxide. The residue (74% yield) after removal of the solvent was recrystallised from dilute spirit and dried on the water-bath and in a vacuum desiccator (46% yield). M. p. 117—118° as found by Koenigs (*loc. cit.*); Decker's observation (*loc. cit.*) as to the low m. p. before removal of solvent of crystallisation was confirmed.

**5-Methylacridine Methiodide.**—5-Methylacridine (3.7 g.) and methyl iodide (3.7 c.c.) were heated for 2 days in a sealed tube at 100°. The product was extracted with ether, and the undissolved residue (5.9 g.; 92% yield) recrystallised from water (about 300 c.c.; 4.1 g. obtained; 64% yield). It was dried in the steam-oven before analysis; a solution in dilute sulphuric acid was treated with silver nitrate (Found: I, 37.8. Calc. for  $C_{15}H_{14}NI$ : I, 37.9%). Melting with decomposition occurred at about 263°. Bernthsen (*Annalen*, 1884, 224, 1) gives m. p. 185° (decomp.), Freund and Bode (*loc. cit.*) give m. p. 273—275°, and Kaufmann and Albertini (*loc. cit.*) give m. p. 235—245°, with decomposition from 200°.

**1:1'-Dimethyl-2:3(or 2':3')-benzisocyanine Iodide (IX; R = Me).**—5-Methylacridine methiodide (1 g.; 1 mol.) and 2-iodoquinoline methiodide (1.2 g.; 1 mol.) were added to boiling water (60 c.c.), potassium hydroxide (0.4 g.; more than 2 mols.) dissolved in water (10 c.c.) was added, and the mixture was boiled for 5 minutes. The blue tar produced, which solidified on cooling, was filtered off and extracted with ether. The undissolved residue (0.84 g.; 59% yield) was recrystallised from methyl alcohol (40 c.c.), the *iodide* (IX) being thus obtained in 25% yield (0.36 g.). It was dried in a vacuum at 100—110° before analysis (Found: I, 26.8.  $C_{25}H_{21}N_2I$  requires I, 26.65%). It forms long crystals with a bronze lustre. M. p. about 250—265°, but the exact point is quite indefinite, since decomposition begins at about 230°. Its spirit solution has a broad absorption band extending from  $\lambda$  4700 Å. to 6200 Å., and with a maximum at about 5500 Å.

**1(or 1')-Methyl-1'(or 1)-ethyl-2:3(or 2':3')-benzisocyanine iodide** was similarly prepared from 5-methylacridine methiodide (3 g.) and 2-iodoquinoline ethiodide (3.68 g.). After ether extraction, the undissolved residue (3.05 g.) was dissolved in hot chloroform (800 c.c.). The solution was concentrated and from it, on cooling, the dye was obtained in crystalline form (2.0 g.). It was recrystallised from methyl alcohol (40 c.c.) and was thus obtained in 29% yield (1.25 g.). It was again recrystallised from methyl alcohol

and was dried for analysis in a vacuum at 100—110° (Found : I, 25.8.  $C_{26}H_{23}N_2I$  requires I, 25.9%). It forms lustrous dark green crystals, which soften at 150—160° but do not melt until about 232°; if they are put into a bath at 160°, however, melting occurs at once. The absorption of the spirit solution is very like that of the preceding dye.

BRITISH PHOTOGRAPHIC PLATES AND PAPERS, LTD.,

ILFORD, E.

[Received, March 10th, 1930.]

### CXXIV.—*Tetrachloroiodides of the Alkaloids.*

By FREDERICK DANIEL CHATTAWAY and GEORGE DAVID PARKES.

MANY of the commoner alkaloids yield well-characterised tetrachloroiodides when a solution of the alkaloid in concentrated hydrochloric acid is added to excess of a solution of tetrachloroiodic acid made by saturating with chlorine a suspension of finely powdered iodine in concentrated hydrochloric acid.

These alkaloidal tetrachloroiodides are all decomposed by a solution of sodium sulphite, the base being liberated. When they are treated with a solution of potassium iodide acidified with acetic acid, iodine is quantitatively liberated. This reaction has been used for the analysis of these compounds.

Hexamethylenetetramine also forms a stable tetrachloroiodide.

The tetrachloroiodides of many quaternary bases are easily made by saturating a solution of the iodide in concentrated hydrochloric acid with chlorine.

#### EXPERIMENTAL.

The solution of tetrachloroiodic acid used was obtained by suspending finely powdered iodine (15 g.) in concentrated hydrochloric acid (80 c.c.) and saturating it with chlorine.

*Quinine Tetrachloroiodide*,  $C_{20}H_{24}O_2N_2 \cdot 2HICl_4$ .—When a solution of 10 g. of quinine hydrochloride in 50 c.c. of concentrated hydrochloric acid was added to 60 c.c. of tetrachloroiodic acid solution, *quinine tetrachloroiodide* separated immediately as a bright yellow, microcrystalline powder. This was filtered off and dissolved in 150 c.c. of boiling glacial acetic acid, the solution was cooled, and 300 c.c. of concentrated hydrochloric acid were added; the tetrachloroiodide thus obtained, after being dried in a desiccator over phosphoric oxide and a few lumps of lime, melted at 114° (decomp.) (Found : Cl, 32.3.  $C_{20}H_{26}O_2N_2Cl_8I_2$  requires Cl, 32.9%).

*Cinchonine tetrachloroiodide*,  $C_{19}H_{22}ON_2 \cdot 2HICl_4$ , was similarly pre-

pared and purified. It separated as a bright yellow, microcrystalline powder, m. p.  $85^{\circ}$  (decomp.) (Found: Cl, 33.4.  $C_{19}H_{24}ON_2Cl_3I_2$  requires Cl, 34.0%).

*Strychnine Tetrachloroiodide*,  $C_{21}H_{22}O_2N_2.HCl_4$ .—A solution of 5 g. of strychnine in 20 c.c. of chloroform was saturated with hydrogen chloride and added to the solution formed by dissolving 3 g. of iodine in 20 c.c. of chloroform and saturating it with chlorine. *Strychnine tetrachloroiodide* separated at once as a pale yellow, microcrystalline powder, m. p.  $91^{\circ}$  (decomp.) (Found: Cl, 23.3.  $C_{21}H_{23}O_2N_2Cl_4I$  requires Cl, 23.5%).

*Morphine tetrachloroiodide*,  $C_{17}H_{19}O_3N.HCl_4$ , was prepared from 5 g. of morphine hydrochloride, dissolved in 40 c.c. of concentrated hydrochloric acid, and 10.5 c.c. of tetrachloroiodic acid solution. It crystallised from glacial acetic acid, in which it was very easily soluble, in small, pale orange needles, which melt at  $78^{\circ}$  (decomp.), and rapidly decompose when kept, even in a sealed tube (Found: Cl, 25.4.  $C_{17}H_{20}O_3NCl_4I$  requires Cl, 25.6%).

*Codeine tetrachloroiodide*,  $C_{18}H_{21}O_3N.HCl_4$ , was prepared similarly from 2 g. of codeine, dissolved in 20 c.c. of concentrated hydrochloric acid, and 4.5 c.c. of tetrachloroiodic acid solution. It crystallised from glacial acetic acid, containing a little iodine trichloride, in which it was easily soluble, in pale orange needles, but it was not found possible to dry the compound without slight decomposition occurring.

*Cocaine Tetrachloroiodide*,  $C_{17}H_{21}O_4N.HCl_4$ .—When a solution of 1 g. of cocaine hydrochloride in 5 c.c. of concentrated hydrochloric acid was added to 5 c.c. of tetrachloroiodic acid solution prepared as above, *cocaine tetrachloroiodide* separated as a bright yellow solid. It crystallised from glacial acetic acid, containing a little iodine trichloride, in which it was moderately easily soluble, in small, pale yellow, irregular, flat plates, m. p.  $141^{\circ}$  (decomp.) (Found: Cl, 25.3.  $C_{17}H_{22}O_4NCl_4I$  requires Cl, 24.75%).

*Hexamethylenetetramine tetrachloroiodide*,  $(CH_2)_6N_4.HCl_4$ , separated in bright yellow prisms, m. p.  $147^{\circ}$  (decomp.), when a solution of 5 g. of hexamethylenetetramine in 25 c.c. of concentrated hydrochloric acid was added to 30 c.c. of tetrachloroiodic acid solution (Found: Cl, 34.2.  $C_6H_{13}N_4Cl_4I$  requires Cl, 34.6%). It cannot be recrystallised, as when heated with glacial acetic acid it decomposes into formaldehyde and ammonium tetrachloroiodide.

*1-Methylpyridine Tetrachloroiodide*,  $C_5H_5NMeI_4$ .—5 G. of pyridine methiodide were dissolved in 25 c.c. of concentrated hydrochloric acid and a stream of chlorine was passed through the cooled solution. Iodine at first separated, but gradually disappeared and the bright yellow *1-methylpyridine tetrachloroiodide* separated.

It crystallised from boiling glacial acetic acid containing a little iodine trichloride, in which it was sparingly soluble, in clusters of small yellow needles, m. p.  $180^{\circ}$  (decomp.) (Found: Cl, 39.0.  $C_6H_8NCl_4I$  requires Cl, 39.1%).

1:2-*Dimethylpyridine tetrachloroiodide* separates from boiling glacial acetic acid, in which it is rather sparingly soluble, in bright yellow, irregular, twinned plates, m. p.  $185^{\circ}$  (decomp.) (Found: Cl, 37.5.  $C_7H_{10}NCl_4I$  requires Cl, 37.7%).

1:2:4:6-*Tetramethylpyridine tetrachloroiodide* separates from boiling glacial acetic acid, in which it is fairly easily soluble, in bright yellow, irregular, flat plates, m. p.  $130^{\circ}$  (decomp.) (Found: Cl, 35.2.  $C_9H_{14}NCl_4I$  requires Cl, 35.1%).

1-*Methylquinoline tetrachloroiodide* separates from glacial acetic acid, in which it is somewhat sparingly soluble, in pale yellow prisms, m. p.  $191^{\circ}$  (Found: Cl, 34.15.  $C_{10}H_{10}NCl_4I$  requires Cl, 34.4%).

6-*Chloro-1-methylquinoline tetrachloroiodide* separates from boiling glacial acetic acid, in which it is sparingly soluble, in long yellow needles, m. p.  $167^{\circ}$  [Found: Cl (added), 31.7.  $C_{10}H_9NCl_5I$  requires Cl (added), 31.7%].

6-*Bromo-1-methylquinoline tetrachloroiodide* crystallises from glacial acetic acid in bright yellow needles, m. p.  $176^{\circ}$  (Found: Cl, 29.1.  $C_{10}H_9NCl_4BrI$  requires Cl, 28.9%).

N-*Methylstrychnine tetrachloroiodide* separates from glacial acetic acid, in which it is moderately easily soluble, in minute, pale yellow needles which, when heated, decompose without melting (Found: Cl, 22.9.  $C_{22}H_{25}O_2N_2Cl_4I$  requires Cl, 23.0%).

NN-*Dimethylnicotine bistetrachloroiodide* separates from boiling glacial acetic acid, in which it is somewhat sparingly soluble, in fine yellow needles, m. p.  $145^{\circ}$  (Found: Cl, 38.6.  $C_{12}H_{20}N_2Cl_8I_2$  requires Cl, 38.9%).

## CXXV.—*The Properties of the Chlorides of Sulphur. Part IV. Density and Surface Tension, with an Appendix on the Parachors of Mixtures.*

By THOMAS MARTIN LOWRY and GILBERT JESSOP.

THE experiments described below were undertaken with the idea that measurements of density and surface tension, followed by calculations of values of the parachor, might afford a sensitive method for the detection of sulphur tetrachloride, in view of the

regular way in which "pervalent" compounds, such as  $\text{PCl}_5$ ,  $\text{POCl}_3$ ,  $\text{SOCl}_2$ , etc., exhibit a deficiency of about 26 units as compared with the values deduced from compounds of normal valency. From this point of view, the results were once more negative, since the densities, surface tensions, and parachors all provided evidence of the presence of the dichloride, without giving any indication of the presence of the tetrachloride. Interesting results were obtained, however, by comparing the parachor values of mixtures of sulphur monochloride and chlorine before and after chemical combination had taken place.

#### EXPERIMENTAL.

*Density.—Methods.* Since the sulphur chlorides are decomposed by moisture, and may have a vapour pressure as high as 6 atm. at room temperature, the densities were determined by flotation in sealed tubes. Silica floats were used, partly because the densities of glass floats were altered when the liquid in which they were suspended was heated to bring it to equilibrium, and partly because their small coefficient of expansion was an additional advantage. The floats were hollow, about 15 mm. long and of 3 mm. diameter. A series, ranging from 1.42 to 1.76 at intervals of 0.02, was made, the desired density being attained first by adjusting approximately the amount of silica in the solid tip of the float, and then by grinding the tip and rounding it off in the oxyhydrogen flame. They were calibrated in mixtures of bromoform and toluene, the densities of which were measured with a pycnometer with vertical arms, specially designed to avoid loss by creeping after adjustment.

The samples of sulphur chloride were sealed up in thick-walled tubes, about 12 mm. in bore and 15 cm. long, together with two or three floats of suitable densities and the capillaries for measurements of surface tension, and were heated to  $100^\circ$  to bring about a condition of equilibrium. The tube was then clamped upright in a large water-bath, the temperature of which was maintained for 10 minutes within  $0.02^\circ$  of the temperature of flotation of each float, since a difference of  $0.01^\circ$  was sufficient to make a float rise or sink slowly.

*Results.* The densities of 35 samples, of chlorine contents ranging from 36.9 to 100 atoms %, were measured at two or three temperatures by the method just described. The coefficients of expansion were then calculated and the densities at  $15^\circ$  and  $0^\circ$  were deduced. Measurements were also made of four mixtures of sulphur monochloride and chlorine, which had not yet interacted to form the red dichloride and were therefore still pale yellow. The results are given in Table I.

*Surface Tension.—Methods.* Since the measurements of surface tension had to be made in a sealed tube, the only method which could be used was that of capillary rise. On account of the difficulty of measuring accurately the position of the lower meniscus when using a single capillary tube, the double capillary method described by Sugden (J., 1921, 119, 1483) was finally adopted. Two capillaries, about 6 cm. long, with internal diameters of approx. 0.6 and 0.9 mm., were held together by glass bridges at the top and bottom. Glass projections were used in order to keep the capillaries upright and close to one side of the outer tube holding the liquid, so as to leave room for the silica floats which were also enclosed in the tube. Since the measurements were required primarily in order to calculate the parachor, which involves only the fourth root of the surface tension, no attempt was made to secure the

highest order of accuracy, nor was it considered necessary to procure capillaries which were accurately circular in cross section.

Calibration of the apparatus was carried out with benzene and checked with water, Sugden's values for the surface tension of these two liquids being used. The benzene was purified by fractional crystallisation and then distilled in an all-glass apparatus. The water was distilled from dilute permanganate in an all-glass apparatus, which had been thoroughly freed from grease, directly into the tube containing the capillary apparatus. The two calibrations agreed closely.

\* For definition of [ $P_{\Delta}$ ], see p. 1014.

If  $h$  is the difference in the heights of the liquid in the two tubes, measured from the base of one meniscus to the base of the other, and  $h_1$  and  $h_2$  are the respective heights of each meniscus, the corrected difference in rise,  $H$ , is given by  $H = h + \frac{1}{3}h_1 - \frac{1}{3}h_2$ , since Richards and Carver (*J. Amer. Chem. Soc.*, 1921, **43**, 827) found that  $\frac{1}{3}h$  is a sufficiently accurate meniscus correction for most purposes. If  $D$  is the density of the liquid, and  $d$  that of the

gas above the liquid, the surface tension is given by the equation  $\gamma = H(D - d)/k$ , where  $k$  is found from the calibrations. Values of  $d$  were estimated from the density of air together with Aten's values for the vapour pressure of sulphur chlorides of different compositions.

In making measurements of surface tension, the outer tube, with the apparatus enclosed, was clamped upright inside a small tank with a plate-glass front and back. It was illuminated from behind, through a water tank, to absorb heat rays, and a ground-

FIG. 1.

glass screen. The heights were read with a travelling microscope, reading to 0.001 mm. Comparative measurements on the same sample of liquid show a probable error of about 0.2 dyne per cm.

**Results.** The surface tensions, at room temperature or at 0° or both, of 23 equilibrium mixtures containing 50–100 atoms % of chlorine are set out in Table II, together with values for three mixtures of uncombined sulphur monochloride and chlorine.

Marchand (*J. Chim. physique*, 1913, 11, 574) gives for the surface tension of liquid chlorine the values 21.90 at 0° and 19.47 at 12.7°, as compared with our values, 21.22 at 0° and 18.87 at 12.9°.

### Discussion of Results.

(a) The densities at 15° and at 0° of mixtures of sulphur monochloride and chlorine at equilibrium are plotted in Fig. 1, I and III. The curves are nearly linear from  $S_2Cl_2$  to  $SCl_2$ , after which the densities decrease more rapidly towards that of pure chlorine, but without giving any indication of a change of direction at the composition of the tetrachloride. The densities at 0° of uncombined mixtures of sulphur monochloride and chlorine, which are plotted in Curve II, are lower throughout, since chemical combination (which is revealed by a red coloration) is accompanied by a contraction, which reaches a maximum at or near the composition of the dichloride. Mixtures containing less than 50 atoms % of

FIG. 2.

(a) Mean atomic volumes. (b) Partial atomic volumes of chlorine.

chlorine also become more dense after being heated, as may be seen by comparing curves IV and VI (unheated) with V and VII (heated). This contraction is attributed to the formation of polysulphides:

(compare Angeli and Magnani, *Gazzetta*, 1893, **23**, ii, 415; 1894, **24**, i, 349; Henrique, *Ber.*, 1894, **27**, 2993; Beckmann and Geib, *Z. anorg. Chem.*, 1906, **51**, 96; Bruni and Amadori, *Atti R. Accad. Lincei*, 1919, **28**, i, 217; Hammick and Zvegintzov, *J.*, 1928, 1785; Trautz, *Z. Elektrochem.*, 1929, **35**, 110).

An alternative way of displaying the densities is to plot the mean atomic volume,  $V = (A_1 n_1 + A_2 n_2)/d$ ; where  $A_1$  and  $A_2$  are the atomic weights, and  $n_1$  and  $n_2$  the atom fractions. The resulting curve for equilibrium mixtures at 15° (Fig. 2a) is at first nearly

linear, but rises more steeply as the composition of the dichloride is approached. A more sensitive method is to plot the partial atomic volume of the chlorine (Lewis and Randall, "Thermodynamics," New York, 1923), *i.e.*, the increase of volume when 1 g.-atom of chlorine is added to an infinite volume of the mixture and brought to equilibrium. The resulting curve (Fig. 2*b*) is at first horizontal, since monochloride is converted quantitatively into dichloride with a constant increment of volume, the mixture behaving in this respect as an "ideal solution." The curve then rises steeply through the composition of the dichloride; this rise corresponds with the range of dissociation of the dichloride, at the

FIG. 3.  
*Surface tensions.*

beginning of which the chlorine is all used to form dichloride whilst at the end it all remains free. Finally, the curve rises gently to the atomic volume of free chlorine, without any sign of discontinuity at the composition of the tetrachloride, although the slope of the line shows that the dichloride and chlorine do not form an ideal solution.

(*b*) The surface tensions, which are plotted in Fig. 3, increase progressively from 21.2 for chlorine to 45.7 for sulphur dichloride. The values for uncombined mixtures lie on a smooth curve; but those for equilibrium mixtures, which are higher throughout, cannot be represented by a simple curve. An attempt to represent the data by two curves unexpectedly revealed a discontinuity at

67 atoms % of chlorine, which is so close to the composition of the dichloride that the coincidence can scarcely be accidental. An even more striking discontinuity is seen in the "parachor deficiencies" (see below), but in neither case has any similar feature been observed at the composition of the tetrachloride.

### Summary.

1. The densities and surface tensions of equilibrium mixtures of the chlorides of sulphur have been measured from 37 to 100 atoms

% of chlorine, between  $-4^{\circ}$  and  $30^{\circ}$  and at  $0^{\circ}$  and room temperature respectively. The following constants have been determined:

	Densities.		Mol. volumes.		Surface tensions.	
	$0^{\circ}$ .	$15^{\circ}$ .	$0^{\circ}$ .	$15^{\circ}$ .	$0^{\circ}$ .	$15^{\circ}$ .
$S_2Cl_2$ .....	1.7106	1.6892	78.86	80.04	45.7	43.6
$SCl_2$ (equilm.) .....	1.6567	1.6285	62.10	63.2	36.6	34.4
$Cl_2$ .....	1.4671	1.4247	48.33	49.78	21.2	—

Well-marked discontinuities occur at the composition of the dichloride, but not of the tetrachloride. The densities and surface tensions of uncombined mixtures are lower than after combination has taken place.

2. The values found for the molecular parachors, *viz.*,  $\text{Cl}_2 = 104.6$ ,  $\text{S}_2\text{Cl}_2 = 205.5$ , lead to atomic parachors  $\text{S} = 50.48$ ,  $\text{Cl} = 52.28$ . The mean atomic parachors of intermediate mixtures are lower than those required by a linear law of mixing, but the deficiencies are smaller after combination (see Fig. 4 and Appendix). The single loop from  $\text{S}_2\text{Cl}_2$  to  $\text{Cl}_2$  is then replaced by a double loop from  $\text{S}_2\text{Cl}_2$  to  $\text{SCl}_2$  and from  $\text{SCl}_2$  to  $\text{Cl}_2$ , but with no indications of a break at  $\text{SCl}_4$ .

## APPENDIX.

*The Parachor of Mixtures.*—Hammick and Andrew (J., 1929, 754) recorded the existence of deviations from a linear relation in the parachors of mixtures, and suggested "that the deviation is connected with the Gibbs surface-adsorption effect," since it appeared to be associated with a *difference* in surface tension between the two components. Our experiments (which were completed nearly two years before, but had been circulated only in the form of a thesis) had already established the existence of similar deviations from the linear law, not only in mixtures of sulphur monochloride and chlorine, but also in mixtures of partly dissociated sulphur dichloride with sulphur monochloride and with chlorine; but, since the parachor is fundamentally a volume relationship, we do not regard the difference in surface tensions, nor the Gibbs surface-adsorption effect, as the only factor in producing these deviations. Thus, apart from the relative inaccuracy of all measurements of surface tension, there is no obvious reason why small changes of volume, produced by mixing a pair of optically isomeric compounds, should be exactly balanced by changes in the fourth root of the surface tension.

The methods and formulæ of Hammick and Andrew imply a knowledge of molecular constitution which we did not possess in this case. Our analysis of the problem was therefore carried out with the help of the mean atomic parachor, which we define by the equation  $[P_A] = (A_1n_1 + A_2n_2)\gamma^{1/4}/(D - d)$ , where  $A_1, A_2, n_1$  and  $n_2$  have the same significance as before (p. 1011). If there were no change in the parachors of the components, either on admixture or on chemical combination, the value of this function would be  $[P_A] = P_1n_1 + P_2n_2$ , where  $P_1$  and  $P_2$  are the atomic parachors of the two elements *as deduced from the molecular parachors of the limiting components of the system*. Our measurements give for the molecular parachors,  $\text{S}_2\text{Cl}_2 = 205.5$ ,  $\text{Cl}_2 = 104.6$ , whence  $\text{S} = 50.5$ ,  $\text{Cl} = 52.3$ ; whereas Sugden (J., 1925, 127, 1533) gives  $\text{S}_2\text{Cl}_2 = 205.1$ , and deduces (J., 1924, 125, 1188)  $\text{Cl}_2 = 111.5$  from the data of Marchand (*loc. cit.*), finally adopting for the atomic parachors the values  $\text{S} = 48.2$ ,  $\text{Cl} = 54.2$ .

The *atomic parachor deficiencies* plotted in Fig. 4, I and II, represent the differences ( $\times 100$ ) between the values of  $[P_A]$  derived from the two preceding equations (i) for equilibrium mixtures and (ii) for uncombined mixtures of sulphur monochloride and chlorine. It is therefore possible for the first time to make a direct comparison of the deviations from the linear law which are produced by chemical and by physical interaction between the components, in liquids of identical composition. The uncombined mixtures show the largest deviations, rising to a maximum of about 3% at about 75 atoms % of chlorine. When chemical combination takes place, this deviation is reduced, *e.g.*, to about 1% at the composition of the dichloride; but secondary maxima are then developed in mixtures of this compound with the two components from which it was formed. The curve III, which shows the change in the mean atomic parachor on chemical combination, rises to a maximum at or near the composition of the dichloride, but shows no analogous singularity at the composition of the tetrachloride.

## CXXVI.—2-Arylcoumaranones.

By WILSON BAKER.

AMONGST the methods available for the preparation of coumaranones are those in which a cyanohydrin or  $\alpha$ -monohalogeno-nitrile is condensed with polyhydric phenols under the conditions of the Hoesch synthesis (Sonn, *Ber.*, 1917, 50, 1262; Slater and Stephen, *J.*, 1920, 117, 309; Sonn and Falkenheim, *Ber.*, 1922, 55, 2975; Klarmann, *J. Amer. Chem. Soc.*, 1926, 48, 2366). Some years ago it was desired to synthesise 4 : 6-dihydroxy-2-p-methoxyphenylcoumaranone (I), since it appeared probable at one time that such a compound occurred naturally, and it was suggested to the author by Professor R. Robinson that such arylcoumaranones might be synthesised from the readily accessible *O*-benzoyl derivatives of aromatic aldehydes (Francis and Davis, *J.*, 1909, 95, 1404) by means of the Hoesch reaction. This expectation has been realised, but the yields are very poor and the products difficult to isolate except as acetyl derivatives. Further, the acetylation often takes an abnormal course. The use of aromatic aldehyde cyanohydrins themselves is prohibited owing to the ease with which they undergo condensation to derivatives of 1 : 4-diazines when treated with hydrogen chloride in ethereal solution (Minovici, *Ber.*, 1899, 32, 2206; Japp and Knox,

J., 1905, 87, 701; for mechanism of the reaction see Ingham, J., 1927, 694).

The interaction of *O*-benzoylanisaldehydecyanohydrin and phloroglucinol in ethereal solution with hydrogen chloride in presence of zinc chloride gave a solid ketimine, which after complete hydrolysis with concentrated hydrochloric acid yielded finally the coumaranone (I). Acetylation of the crude coumaranone with acetic anhydride and a trace of pyridine yielded 3 : 4 : 6-triacetoxy-2-*p*-methoxyphenylcoumarone (II) and *anhydro*-5-hydroxy-7-acetoxy-4- $\alpha$ -hydroxy-*p*-methoxybenzylcoumarin (III), which were separated by physical means. The constitution assigned to (III) is based on the facts that, unlike (I) and (II), it does not reduce Fehling's solution, and that its alcoholic solution has a violet fluorescence.

The analogous condensation of *O*-benzoylanisaldehydecyanohydrin and resorcinol gave, after complete hydrolysis, a product which could be obtained crystalline only after acetylation with acetic anhydride. This again proved to be a mixture, which was separated into 6-acetoxy-2-*p*-methoxyphenylcoumaranone (IV), and a compound of high molecular weight which did not reduce Fehling's solution and is tentatively regarded as 3-keto-6 : 3' : 6'-triacetoxy-2 : 2'-di-*p*-methoxyphenyl-2 : 3'-dicoumaranyl.

The condensation of *O*-benzoylbenzaldehydecyanohydrin with resorcinol yielded finally after acetylation 2 : 4-diacetoxy-*O*-acetylbenzoin (V), the ring in this case not having closed.

2-Arylcoumaranones of the type (I) could doubtless be prepared most readily by the condensation of  $\alpha$ -bromophenylacetonitriles with polyhydric phenols, and with this in mind  $\alpha$ -bromo- $\beta$ -phenylpropionitrile was condensed with resorcinol under the conditions of

the Hoesch reaction. Acid hydrolysis of the product gave a good yield of 6-hydroxy-2-benzylcoumaranone (VI), which on acetylation yielded 3:6-diacetoxy-2-benzylcoumarone. It is obvious that the condensation might proceed in a number of ways to give a compound  $C_{15}H_{12}O_3$ , which might be either (VI), 2:4-dihydroxyphenyl styryl ketone, 7-hydroxyflavanone, 7-hydroxy-4-phenyl-3:4-dihydrocoumarin (compare Fischer and Nouri, *Ber.*, 1917, 50, 611), or 7-hydroxy-3-benzylisocoumaranone. The physical properties of the reaction product are not in agreement with those of 2:4-dihydroxyphenyl styryl ketone (Ellison, J., 1927, 1720), and of the other possibilities only (VI) could give a diacetyl derivative.

Klarmann (*loc. cit.*) has condensed  $\alpha$ -bromo-*n*-butyronitrile with phloroglucinol by the Hoesch reaction and obtained a product which he describes as 4:6-dihydroxy-2-ethylcoumaranone. Although this reaction is exactly analogous to the case described above, and might lead to any of five isomeric products, no proof of the constitution of the substance was given; yet by analogy with the present case there can be little doubt that the compound isolated was actually the coumaranone.

The condensation of glycollonitrile with resorcinol has been described by Slater and Stephen (*loc. cit.*), who state that the reaction yields 6-hydroxycoumaranone. Karrer and Biedermann, however (*Helv. Chim. Acta*, 1927, 10, 441), find that the only product is  $\omega$ -hydroxyresacetophenone (fisetol). Full experimental details are not given by Slater and Stephen, but as the result of a number of experiments the author confirms the result of Karrer and Biedermann, and has further been unable to convert  $\omega$ -hydroxyresacetophenone into 6-hydroxycoumaranone by heating with various strengths of hydrochloric or sulphuric acid with or without the addition of zinc chloride—conditions which were probably used by Slater and Stephen in hydrolysing the ketimine.

#### EXPERIMENTAL.

*Condensation of O-Benzoylanisaldehydecyanohydrin with Phloroglucinol.*—(a) A solution of the cyanohydrin (30 g.; Francis and Davis, *loc. cit.*) and phloroglucinol (14.2 g.) in anhydrous ether (300 c.c.) was saturated with hydrogen chloride at room temperature. After 48 hours the solid ketimine was collected, washed with ether, and hydrolysed by heating with concentrated hydrochloric acid for 4 hours. The product was freed from benzoic acid by washing with sodium bicarbonate solution and was finally dissolved in alcohol (charcoal), and the solution concentrated to a small bulk. After several weeks the crystals which had separated from the viscous fluid were isolated by pressing the product between plates

of porous earthenware, and were then recrystallised from a very small volume of alcohol, being obtained in microscopic, almost colourless plates, m. p. 216—217° (Found: C, 66.2; H, 4.6.  $C_{15}H_{12}O_5$  requires C, 66.1; H, 4.4%). 4:6-Dihydroxy-2-p-methoxyphenylcoumaranone (I) gives a brownish-violet coloration with ferric chloride in alcoholic solution, and its solution in concentrated sulphuric acid is purplish-pink. It readily reduces Fehling's solution.

(b) A solution of the cyanohydrin (20 g.) and phloroglucinol (10 g.) in ether (200 c.c.) was saturated with hydrogen chloride, first at room temperature and then, after the addition of powdered anhydrous zinc chloride, at 0°. After 48 hours at 0°, water was added, and the ketimine hydrolysed by heating on the water-bath for 2 hours. The solid product was collected, heated for 1 hour in dilute sodium hydroxide solution, and reprecipitated by carbon dioxide. It was again collected, dried on porous earthenware, and acetylated by boiling with acetic anhydride and a trace of pyridine for 3 hours. The acetylated material was isolated by the addition of water and was obtained as light-brown crystals by recrystallisation from acetic acid (charcoal), in which it was sparingly soluble (yield, 7 g.). Three further crystallisations from acetic acid yielded a colourless product, which consisted of a mixture of compact prisms (A) and slender needles (B). An almost complete separation of the two substances was effected by stirring the mixture with alcohol, allowing the compact prisms to settle, and pouring off the alcohol while most of the thin needles were still suspended. The process was repeated several times, and finally both substances were separately crystallised from large volumes of alcohol.

Substance (A) separates from its hot alcoholic solution, which has a violet fluorescence, in thin, almost rectangular plates, m. p. 181—182° (Found: C, 67.4; H, 4.1.  $C_{19}H_{14}O_6$  requires C, 67.4; H, 4.1%). Anhydro-5-hydroxy-7-acetoxy-4- $\alpha$ -hydroxy-p-methoxybenzylcoumarin (III) gives a colourless solution in concentrated sulphuric acid, and does not reduce Fehling's solution.

Substance (B) separates from warm alcohol in very thin, prismatic needles, m. p. 174—175° (Found: C, 63.3; H, 4.6.  $C_{21}H_{18}O_8$  requires C, 63.3; H, 4.5%). 3:4:6-Triacetoxy-2-p-methoxyphenylcoumarone (II) gives a non-fluorescent solution in alcohol; the solution in concentrated sulphuric acid is a strawberry-red, which turns deep reddish-violet on standing. It readily reduces Fehling's solution.

*Condensation of O-Benzoylanisaldehydecyanohydrin with Resorcinol.*

—The condensation, and complete hydrolysis of the product, were carried out as in the case of the corresponding reaction with phloro-

glucinol (method b). The non-crystalline phenolic substance was acetylated by boiling with acetic anhydride for 6 hours, and the solid isolated by the addition of water was crystallised from acetic acid (charcoal) and then from alcohol, in the latter case the crystals being collected from the still warm solution. A further crystallisation from ethyl acetate gave small colourless needles, m. p.  $217^{\circ}$  (Found : C, 67.3; H, 5.2; *M*, by Rast's method, 646.  $C_{36}H_{30}O_{11}$  requires C, 67.7; H, 4.7%; *M*, 638). This substance gives a colourless non-fluorescent solution in alcohol; in concentrated sulphuric acid an orange solution is obtained, which slowly turns more pink. Prolonged hydrolysis with aqueous-alcoholic potassium hydroxide yields no benzoic acid, and the substance does not reduce Fehling's solution. It is most probably 3-keto-6:3':6'-triacetoxy-2:2'-di-*p*-methoxyphenyl-2:3'-dicoumaranyl.

The alcoholic mother-liquor from the crystallisation of the foregoing compound deposited minute slender needles, m. p. about  $135^{\circ}$ . This second substance was obtained, after two recrystallisations from alcohol, in colourless prismatic needles, m. p.  $139^{\circ}$  (Found : C, 68.4; H, 4.8.  $C_{17}H_{14}O_5$  requires C, 68.4; H, 4.7%). 6-Acetoxy-2-*p*-methoxyphenylcoumaranone (IV) readily reduces Fehling's solution and gives a colourless solution in concentrated sulphuric acid.

*Condensation of O-Benzoylbenzaldehydecyanohydrin and Resorcinol.*—A solution of the cyanohydrin (20 g.) and resorcinol (20 g.) in ether (150 c.c.) was saturated with hydrogen chloride at  $0^{\circ}$ , and powdered anhydrous zinc chloride added. After 24 hours water was added and the whole heated on the water-bath for 2 hours. The semi-solid product was dissolved in sodium hydroxide solution, reprecipitated with carbon dioxide, collected, and acetylated by boiling with acetic anhydride. The acetyl derivative isolated by the addition of water crystallised from alcohol in colourless prismatic needles, m. p.  $158^{\circ}$  (Found : C, 65.1; H, 4.5.  $C_{20}H_{18}O_7$  requires C, 64.9; H, 4.8%). 2:4-Diacetoxy-O-acetylbenzoïn (V) readily reduces Fehling's solution and gives a pale yellow colour in concentrated sulphuric acid.

*Condensation of  $\alpha$ -Bromo- $\beta$ -phenylpropionitrile and Resorcinol.*—A solution of  $\alpha$ -bromo- $\beta$ -phenylpropionitrile (10 g.; Baker and Lapworth, J., 1924, 125, 2333) and resorcinol (10 g.) in ether (100 c.c.) was saturated with hydrogen chloride at  $0^{\circ}$ , after the addition of a little powdered zinc chloride. After 48 hours water was added and the ketimine hydrolysed by heating on the water-bath for 1 hour. The solid ketone was collected and dissolved in dilute aqueous sodium hydroxide, and the solution shaken with chloroform. The alkaline layer was acidified; the solid obtained crystallised from chloroform (charcoal) in colourless, thick, diamond-shaped plates, m. p.  $161^{\circ}$

(Found in material dried at  $140^{\circ}$ : C, 74.7; H, 5.3.  $C_{15}H_{12}O_3$  requires C, 75.0; H, 5.0%). 6-Hydroxy-2-benzylcoumaranone (VI) gives no coloration with ferric chloride in alcohol, and does not reduce Fehling's solution. Its solution in concentrated sulphuric acid is pale-yellow.

The diacetyl derivative was prepared by boiling the parent substance (2 g.) with acetic anhydride (20 c.c.) and anhydrous sodium acetate (2 g.) for 3 hours. 3:6-Diacetoxy-2-benzylcoumarone, isolated by the addition of water, crystallised from methyl alcohol (charcoal) in colourless prismatic needles, m. p.  $76^{\circ}$  (Found: C, 70.5; H, 4.9.  $C_{19}H_{16}O_5$  requires C, 70.4; H, 5.0%). A monoacetyl derivative,  $C_{17}H_{14}O_4$ , requires C, 72.3; H, 5.0%).

## CXXVII.—Organic Derivatives of Silicon. Part XLII. cycloHexyl Derivatives of Silicane and Silicoethane.

By KEITH WILLIAM PALMER and FREDERIC STANLEY KIPPING.

As the only known compounds containing tervalent silicon atoms are octaphenylsilicotetrasilane (J., 1923, **123**, 2590) and octa-*p*-tolylsilicotetrasilane (Steele and Kipping, J., 1929, 2545), prepared from the dichlorides  $R_2SiCl_2$ , it seemed of interest to try to obtain aliphatic analogues of these substances, especially as, at the same time, several outstanding problems relating to certain very sparingly soluble products (J., 1924, **125**, 2291) might be elucidated. As, however, the simple dialkyl derivatives of silicon tetrachloride are not very easily isolated, it was thought that dicyclohexylsilicon dichloride would be a more suitable starting point for the attainment of the objects in view.

Silicon tetrachloride was therefore treated with an ethereal solution of magnesium cyclohexyl bromide (about  $2\frac{1}{2}$  mols.), and the crude product, isolated in the usual way, was submitted to distillation (35 mm.). Except for dicyclohexyl and an unexpectedly small yield of impure cyclohexylsilicon trichloride, hardly any volatile product was obtained; at a certain temperature the oil began to froth and quickly changed into a bulky yellow solid, which was neither Grignard compound nor magnesium salt, and during this transformation, cyclohexene, dicyclohexyl, and hydrogen chloride were formed.

The attempted distillation of the crude oil under 1—2 mm. gave practically the same results as under the higher pressure; some

trichloride and a very little impure *dicyclohexylsilicon* dichloride were found in the distillate, but most of the product remained as a brittle solid. It was evident that the results of the interaction of silicon tetrachloride and magnesium *cyclohexyl* bromide, or of the distillation of the *cyclohexyl* derivatives of silicon tetrachloride, must be entirely different from those observed in any previous study of alkyl or aryl derivatives of the tetrachloride.

It was then found that the crude distilled dichloride, and also the non-volatile products, contained compounds which gave hydrogen with alkali; during the original reaction, or the subsequent distillation, therefore, silicon atoms had become directly united.

From the volatile products, *cyclohexylsilicon* trichloride was isolated without difficulty; on hydrolysis it gave a non-crystalline material, which consisted of a mixture of at least three condensation products derived from the hydroxide  $C_6H_{11}\cdot Si(OH)_3$ . When dried over sulphuric acid, these different substances gave "*cyclohexylsiliconic acid*" having approximately the composition  $(C_6H_{11}\cdot SiO\cdot OH)_n$ , which was insoluble in all ordinary solvents but gave a soluble crystalline salt with sodium ethoxide; when heated at  $150^\circ$ , the acid underwent further condensation, giving a product having the composition of the "anhydride"  $[(C_6H_{11}\cdot SiO)_2O]_n$ . These results correspond closely with those obtained by Meads and Kipping in their study of the phenyl-, benzyl- and propyl-"siliconic acids" (J., 1914, **105**, 679; 1915, **107**, 459).

The dichloride  $(C_6H_{11})_2SiCl_2$  was not obtained free from *dicyclohexyl*; on hydrolysis it gave a non-crystalline solid, consisting of a mixture of condensation products of  $(C_6H_{11})_2Si(OH)_2$ , soluble in various organic solvents; when precipitated from its ethereal solution with glacial acetic acid, this substance melted at  $140$ – $145^\circ$ , but it underwent further condensation when kept or when heated at  $100^\circ$ , giving an anhydrous *dicyclohexylsilicanediol*  $[(C_6H_{11})_2SiO]_7$ . This final condensation product, therefore, is a mixture of compounds of the same order of complexity as those obtained from diethylsilicon dichloride (Martin and Kipping, J., 1909, **95**, 302), which gave an average molecular weight corresponding with  $[SiEt_2O]_7$ .

For the investigation of the non-volatile products of the original interaction, distillation was stopped just below that temperature at which frothing occurred; the residue was treated with ether, which precipitated an insoluble solid. The soluble matter from the ethereal solution gave on hydrolysis a mixture of at least two substances, one insoluble, the other soluble in ether. The former gave analytical data which corresponded with those required for a mixture of condensation products of the hydroxides  $C_6H_{11}\cdot Si(OH)_2$  and  $C_6H_{11}\cdot Si(OH)_3$ .

$\text{C}_6\text{H}_{11}\cdot\text{Si}(\text{OH})_2$ . The latter seemed to be a tetracyclohexylsilico-  
 $(\text{C}_6\text{H}_{11})_2\text{Si}\cdot\text{OH}$

ethanediol,  $(\text{C}_6\text{H}_{11})_2\text{Si}\cdot\text{OH}$ , which when heated at  $100^\circ$  was converted into a condensation product having a molecular weight of about 3000, corresponding with  $[(\text{C}_6\text{H}_{11})_4\text{Si}_2\text{O}]_7$ .

From these results it would seem that the interaction of silicon tetrachloride and magnesium cyclohexyl bromide takes place normally, giving cyclohexylsilicic trichloride, dicyclohexylsilicon dichloride and probably some tricyclohexylsilicic chloride. The yield of the dichloride, obtained by distillation, however, is very small and the main portion of the product which has been heated at  $150$ – $180^\circ$  consists of derivatives of silicoethane. Further, the quantity of dicyclohexyl obtained on distillation seems to be greater than that which could have been formed in the preparation of the Grignard reagent under the known conditions. It is inferred, therefore, that some of the original products of the reaction are converted at  $150$ – $180^\circ$  into derivatives of silicoethane by changes such as the following:

This inference is confirmed by the fact that the distilled mixture of dicyclohexyl and dicyclohexylsilicon dichloride gives, when heated, a solid residue similar to that referred to above. Further, since the crude product, before distillation, contains a small proportion of compounds in which silicon atoms are directly united, the formation of silicoethane derivatives occurs to some extent at or below  $100^\circ$ .

Many analyses of the solid produced during distillation have been made but without any definite results. This product contains only about 1 atom of chlorine to 4 silicon atoms and less than 1 cyclohexyl group to each silicon atom. From the hydrogen values of many samples it must be concluded that the elimination of hydrogen chloride and cyclohexene from the silicoethane derivatives is not accompanied by a further direct combination of silicon atoms, but rather by a fission of some of the  $\text{Si-Si}$  links. Its products of hydrolysis differ but little in composition from the original solid, and when treated with sodium hydroxide solution they give apparently sodium silicate and the sodium salt of "cyclohexylsilicic acid," without the production of any appreciable quantity of a fission product which is insoluble in aqueous alkali.

Until some other *cyclohexyl* derivatives of silicane have been studied, any suggestions as to the natures of these complex products would be of little value; it is hoped that work now in progress may afford some information.

#### EXPERIMENTAL.

*The Grignard Reagent.*—In the preparation of magnesium *cyclohexyl* bromide the yield is never theoretical; \* the best results (yield, 50–60%) were obtained as follows. Into a mixture of magnesium (18 g.) and ether (150 c.c.) containing a crystal of iodine, about 6 c.c. of a mixture of *cyclohexyl* bromide (120 g.) and ether (90 c.c.) are run. As soon as the initial vigorous reaction has somewhat subsided, the remainder of the bromide solution is added during 4–5 hours; the whole is then heated on a water-bath for  $\frac{1}{2}$  hour. Only about 5% of the magnesium remains undissolved and there is no deposition of magnesium salt.

*The Reaction with Silicon Tetrachloride.*—The solution of the Grignard compound ( $2\frac{1}{2}$  mols.) is dropped into an ice-cold, well-stirred solution of silicon tetrachloride (35 g.) in dry ether (50 c.c.). Magnesium halide begins to separate when about  $\frac{1}{3}$  of the reagent has been added, occasionally in the solid form, but more often as a brown or green oil, which in some cases does not crystallise even when, after the addition of all the Grignard reagent, the contents of the flask are heated on a water-bath under reflux during 3 hours. This oil, which passes through filter paper, contains about 60% of ether and probably consists of a saturated solution of ether in an etherate of magnesium chlorobromide of the class of compound described by Menshutkin (*J. Russ. Phys. Chem. Soc.*, 1907, **39**, 1548).

After having been heated until the deposition of magnesium salt seems to be at an end, the clear ethereal solution gives on evaporation a further quantity of magnesium salt as a purple crystalline mass, the yellowish liquid turning emerald-green; the latter is filtered, the residue washed with ether, and the combined filtrate and washings are again evaporated. These processes must be repeated three or four times before the solution ceases to give a deposit of magnesium halide. The liquid product, which is now light yellow, is submitted to distillation (35 mm.). At first a little *cyclohexene* passes over and then a considerable fraction is collected at 120–135°; this

\* Tschitschibabin (*Ber.*, 1905, **38**, 562) prepared the corresponding chloride in dry hydrogen, with a cooled reaction vessel, and used it to prepare esters, of which the yield was only 40%. Hell and Schaal (*Ber.*, 1907, **40**, 4162) observe that in the preparation of magnesium *cyclohexyl* bromide, the maximum yield of Grignard compound is about 60%; Adams and Noller ("Organic Syntheses," Vol. VI) give 61–65%.

contains *cyclohexylsilicon trichloride* and *cyclohexyl bromide*. The next fraction, collected up to  $150^{\circ}$ , consists almost entirely of *dicyclohexyl* but contains a little *dicyclohexylsilicon dichloride*. The temperature then rises rapidly to  $170$ – $180^{\circ}$  but only a very small quantity of liquid distils, and there is violent frothing, owing doubtless to the evolution of hydrogen chloride, with formation of a bulky solid. When the heating is discontinued, before frothing commences, while the whole contents of the flask are still liquid, the residue is soluble in dry ether with the exception of a small proportion of a yellowish solid, and the products in the ethereal solution, on hydrolysis, give a small proportion of the oxide  $[(C_6H_{11})_2SiO]_n$ , together with compounds containing linked silicon atoms. When, however, the heating is continued, the contents of the flask solidify, no dichloride distils, none can be extracted from the residue, and no diol is obtained by the hydrolysis of either the distillate or the residue.

When the crude product is distilled under 3–4 mm. pressure, the first fraction collected below  $120^{\circ}$  contains *dicyclohexyl* and *cyclohexylsilicon trichloride*; the next fraction, from  $140$ – $155^{\circ}$ , contains *dicyclohexyl* and *dicyclohexylsilicon dichloride*; a very small fraction passes over from  $155$ – $180^{\circ}$  and consists principally of the dichloride. At this stage the greenish, very viscous residue is almost entirely soluble in dry ether, but, if heating is continued, frothing occurs and the contents of the flask gradually become solid.

*cycloHexylsilicon Trichloride and "cycloHexylsiliconic Acid."*—The product collected from  $120$ – $135^{\circ}$  (35 mm.), fractionated at atmospheric pressure, afforded a colourless fuming liquid, b. p.  $208$ – $211^{\circ}$  (Found : Cl, 48.6.  $C_6H_{11}Cl_3Si$  requires Cl, 48.9%).

When this *trichloride* is dropped into well-stirred ice-cold water, a white solid is formed, but a considerable proportion of the hydrolysis product remains in solution, and only a small fraction of this dissolved matter can be extracted with ether. The solid, insoluble in water, when freshly precipitated is partly soluble in ether, and the ethereal solution on evaporation gives a colourless glue-like mass which rapidly hardens to a resin and becomes insoluble in ether. The original solid left at the ordinary temperature also becomes wholly insoluble in ether and other solvents; further, it is no longer completely soluble in cold sodium hydroxide solution. The aqueous solution of the original product of hydrolysis gives on evaporation a gelatinous precipitate which dries in the air to a white powder insoluble in water and in ether. Three samples of the preparation insoluble in water and in ether, dried over sulphuric acid during 24 hours and then for an hour at  $100^{\circ}$ , gave Si = 19.2, 19.0, and 19.0 (Calc. for  $C_6H_{11}SiO \cdot OH$  : Si, 19.4%).

Two such samples were heated first at 100° during 24 hours and then at 150° during 24 hours until constant in weight; the average loss (6.1%) corresponded with that (6.2%) required for  $2C_6H_{11} \cdot SiO \cdot OH = (C_6H_{11} \cdot SiO)_2O + H_2O$  and the heated products gave Si, 20.9 and 20.8 respectively [Calc. for  $(C_6H_{11} \cdot SiO)_2O$ : Si, 20.7%].

"*cycloHexylsiliconic acid*" dissolves slowly in warm 5–10% sodium hydroxide solution, from which it is immediately precipitated at the ordinary temperature or at 0° by ammonium chloride, but only after some time by dilute hydrochloric acid; only a very small proportion of this precipitate is soluble in ether and this rapidly becomes insoluble when it is kept. The insoluble form of the acid does not melt, but chars at a high temperature. When a solution of the sodium salt in 5% caustic soda is boiled, a slight odour of *cyclohexane* can be detected but decomposition is very slow as in the case of other alkylsiliconic acids (Meads and Kipping, J., 1914, 105, 688). With more concentrated solutions decomposition takes place more rapidly; after having been refluxed during 1 hour the products, precipitated by ammonium chloride and dried at 180–200°, gave the following results: From 8% NaOH, Si = 26.5; 20% NaOH, Si = 30.1; 30% NaOH, Si = 39.1; 40% NaOH, Si = 45.1 [ $(C_6H_{11} \cdot SiO)_2O$  requires Si, 20.7%.  $SiO_2$  requires Si, 46.6%].

The slow evaporation over sulphuric acid of a solution of the acid in alcohol containing the theoretical quantity of sodium ethoxide gave crystals, some cubic, some having a hexagonal outline, which quickly deliquesced and decomposed on being exposed to the air, changing into small globules of a glue-like substance.

*Dicyclohexylsilicon Dichloride and Anhydrodicyclohexylsilicanediol*.—The quantity of *dichloride* in the two crude fractions 140–155° and 155–180° (p. 1024) was so small that the compound could not be isolated; a fraction collected from 140–145° after several distillations gave Cl = 23.9 [ $(C_6H_{11})_2SiCl_2$  requires Cl, 26.7%]. When a portion was heated (760 mm.), a little *dichloride* and *dicyclohexyl* distilled but as heating was continued most of the oil was converted into a glue-like mass, which finally changed to a bulky solid.

*Dicyclohexylsilicanediol* was obtained by hydrolysing the crude *dichloride* and then separating the *dicyclohexyl* by distillation in steam. It was more conveniently prepared by hydrolysing the oil which remains when distillation is stopped as soon as *trichloride* ceases to pass over. The pasty product, freed from *dicyclohexyl*, is a pale yellow, dough-like mass most of which dissolves in ether, leaving a pale yellow solid quite insoluble in that solvent. The latter gives hydrogen with caustic soda and is described later.

The ethereal solution is agitated with dilute caustic soda solution until hydrogen evolution ceases, washed with water, and evaporated; the pale glue-like residue when left in the air changes into a brittle resin, which softens at about  $200^{\circ}$ , gradually liquefies at higher temperatures, and then chars. When glacial acetic acid or alcohol is added to a cold ethereal solution of the glue-like substance, a white, apparently amorphous, granular solid is precipitated under certain conditions; this product melts indefinitely at  $145-150^{\circ}$  and, when left during about  $\frac{1}{2}$  hour in the acid solution, becomes a glue-like mass; when kept during a day or two, it changes into the resinous form, which decomposes at  $200-250^{\circ}$ .

The precipitated powder was dried in the air and at  $100^{\circ}$  until constant in weight; four different samples gave  $\text{Si} = 13.3; 13.0; 13.2; 13.4$  [Calc. for  $\{(\text{C}_6\text{H}_{11})_2\text{SiO}\}_n$  :  $\text{Si}$ , 13.3%]. Cryoscopic determinations gave (a) in benzene,  $M$ , 1438 and 1481; (b) in camphor,  $M$ , 1450 and 1460.

These results show that the simple diol is unstable; the physically different preparations mentioned above are doubtless mixtures of condensation products like those obtained from other diols and the fact that the average molecular weight is as high as 1455 points to the presence of very complex compounds corresponding with some of those obtained from diphenylsilicanediol (Kipping and Murray, *J.*, 1928, 1427).

*Derivatives of Silicoethane.*—The very viscous, dark green residue which is obtained when the distillation of the crude product is discontinued at about  $180^{\circ}$  is treated with dry ether, which precipitates a small quantity of yellowish solid. The filtered solution gives on evaporation a very thick oil, which when heated under reduced or atmospheric pressure is converted into a yellow solid with evolution of hydrogen chloride, giving a distillate consisting of *cyclohexene*, *dicyclohexyl*, and a small proportion of some compound which evolves hydrogen with aqueous alkalis; the crude oil was analysed (Found:  $\text{Cl}$ , 21.4%; 1 g. gave 52 c.c. of hydrogen. Two other preparations gave hydrogen values of 51.2 and 52.7 respectively). These results are considered later (p. 1028).

The oil hydrolysed with cold water gives a creamy mass which hardens to a crisp solid. A very variable quantity, sometimes as much as 40%, of this product is soluble in ether and the proportion seems to depend on the stage at which distillation has been stopped. The insoluble portion is a granular infusible powder insoluble in all the solvents which were tried. Three different preparations were dried at  $100^{\circ}$  and analysed (Found:  $\text{Si}$ , 19.0, 18.8, and 17.3% respectively). They all evolved hydrogen with caustic alkalis and gave respectively the following values: 70, 69, and 67.4 [Calc. for

$\text{C}_6\text{H}_{11}\cdot\text{SiO}$  : Si, 22%; hydrogen value 80. Calc. for  $\frac{\text{C}_6\text{H}_{11}\cdot\text{SiO}}{(\text{C}_6\text{H}_{11})_2\text{Si}\cdot\text{OH}}$  :  
 $\text{C}_6\text{H}_{11}\cdot\text{SiO}$  : Si, 16.9%; hydrogen value 66].

These results agree with the view that the ether-soluble residue from the distillation contains a mixture of di- and tri-*cyclohexyl* derivatives of silicon hexachloride and that this insoluble substance is a mixture of the condensation products formed when they are hydrolysed. The proportions of the two chlorides would no doubt depend on the temperature at which distillation had ceased and the composition of the mixed products of hydrolysis would vary accordingly.

That this insoluble product contains linked silicon atoms is proved by its behaviour towards alkalis; that it contains both  $\text{R}_2\text{Si}<$  and  $\text{RSi}\leq$  groups is proved by the fact that after fission has occurred the alkaline solution contains in suspension a glue-like substance, soluble in ether, which has all the (rather indefinite) properties of the oxide  $(\text{C}_6\text{H}_{11})_2\text{SiO}$ . The alkaline solution treated with acids gives a precipitate of "*cyclohexylsiliconic acid*."

The product of hydrolysis which is soluble in ether was obtained as a glue-like mass by the evaporation of the solution. It dissolved freely in ether but was less readily soluble in acetone, from which it separated again in a glue-like form. As it might have contained a small proportion of the oxide,  $(\text{C}_6\text{H}_{11})_2\text{SiO}$ , it was fractionally extracted with cold acetone, in which the latter is readily soluble, and then dried over sulphuric acid until constant in weight (sample I); the last acetone extract was evaporated and the residue dried in like manner (sample II) [Found: (I) Si, 13.2%; hydrogen value, 53. (II) Si, 12.4%; hydrogen value, 50. Calc. for  $(\text{C}_6\text{H}_{11})_4\text{Si}_2(\text{OH})_2$ : Si, 13.3%; hydrogen value, 53.5]. That the compound contains the group  $\text{SiR}_2$  was proved by the fact that, when it was treated with aqueous alkali until hydrogen ceased to be evolved, it did not dissolve but gave a product which behaved in all respects like the oxide and contained 12.1% of silicon (Calc. for  $\text{SiR}_2\text{O}$ : Si, 12.3%).

The less soluble portion (I) of this tetracyclohexyl derivative was dissolved in ether, and a little alcohol added to the solution. There was an immediate precipitate of a colourless infusible solid, which, dried over sulphuric acid until constant in weight, gave a hydrogen value of 56.5 and *M* (cryoscopic) in benzene 2980 and in camphor 2900. This product was still soluble in ether, acetone and other solvents, but it could not be obtained in crystals. These results indicate that 7 mols. of the dihydroxide have undergone condensation with the loss of 6 or 7 mols. of water to form

$\text{HO}\cdot\text{Si}_2\text{R}_4\cdot\text{O}[\text{Si}_2\text{R}_4\cdot\text{O}]_5\cdot\text{Si}_2\text{R}_4\cdot\text{OH}$   
 or the closed-chain compound  $[\text{Si}_2\text{R}_4\text{O}]_7$ .

The analytical data given above for the original oily residue (p. 1026) and the results of the investigation of its products of hydrolysis accord with the view that the oil consists principally of the two compounds  $\text{SiR}_2\text{Cl}\cdot\text{SiR}_2\text{Cl}$  and  $\text{SiR}_2\text{Cl}\cdot\text{SiRCl}_2$  with a very variable proportion of  $\text{SiRCl}_2\cdot\text{SiRCl}_2$ .

*The insoluble residue.* The yellow porous infusible solid which remains when the distillation of the crude original product is continued until liquid ceases to pass over, is not present in the original oil; during its formation, hydrogen chloride, cyclohexene and di-cyclohexyl are produced. As it was insoluble in all organic solvents which were tried, it was directly analysed, 6 different preparations being used. The percentage of silicon ranged from 22.9 to 25.5 and the hydrogen values from 45—52.5; a chlorine determination, in one sample only, gave  $\text{Cl} = 9.0\%$ . It is noteworthy that the hydrogen values are no greater than that of the oil from which it has been formed, in spite of the loss of halogen and hydrocarbon radicals.

When left in contact with aqueous alcohol during many hours and then washed, crushed and dried, the solid gave a cream-coloured powder, insoluble in all the common solvents. Several preparations were analysed, but, as was to be expected in view of the small proportion of halogen which was displaced by hydroxyl, the silicon percentages and the hydrogen values were practically the same as those of the non-hydrolysed solid. The only other evidence as to the nature of this product was obtained by warming the solid with acetone and sodium hydroxide until hydrogen ceased to be evolved; with the exception of a small and variable proportion of glue-like matter, the solid was thus converted into products soluble in aqueous alkali, and these were fractionally precipitated by passing carbon dioxide into the solution. The three precipitates thus obtained, when dried, contained 29.5, 22.3 and 19.8% of silicon respectively; since  $\text{C}_6\text{H}_{11}\cdot\text{SiO}\cdot\text{OH}$  requires Si, 19.4% and the sodium hydroxide solution was not sufficiently strong to decompose the silicic acid, it must be concluded that some of the silicon atoms in the solid are not combined with cyclohexyl groups.

CXXVIII.—*Organic Derivatives of Silicon. Part XLIII. The Formation of Tri- and Tetra-phenylsilicane by the Action of Sodium on Triphenylsilyl Chloride.*

By FREDERIC STANLEY KIPPING and JOHN FRANCIS SHORT. ]

THE action of sodium on phenylsilicon trichloride in boiling xylene solution in an atmosphere of nitrogen results in the production of a very complex mixture, the soluble components of which contain from 6 to 50 atoms of silicon in their molecules; some of these components, submitted to fission with alkalis, give diphenylsilicanediol and therefore contain  $>\text{SiPh}_2$  groups (Kipping, Murray, and Maltby, J., 1929, 1180). In the absence of a solvent in the presence of dry air the trichloride is almost entirely converted at about  $180^\circ$  into a product which is insoluble in all ordinary solvents; but in the absence of air the reaction seemed to proceed differently (*loc. cit.*, footnote, p. 1184).

In the course of further experiments in which the trichloride was heated with the metal in a stream of pure nitrogen, tri- and tetraphenylsilicane were obtained.

The formation of the last-named compound is probably due to the prior production of sodium phenyl, which then reacts with the unchanged trichloride; the same suggestion was made to account for the presence of  $>\text{SiPh}_2$  groups in some of the compounds obtained in xylene solution (*loc. cit.*, p. 1183). The related observations on the formation of tri- and tetra-benzyl derivatives from dibenzylsilicon dichloride and sodium (Steele and Kipping, J., 1928, 1431) seem to show that aryl groups generally, directly combined with silicon, may give sodium aryl compounds; the alternative view that aryl chloride separates and then reacts with the unchanged silicon halide in the presence of sodium seems to be less probable; but, however produced, the unexpected formation of tetraphenylsilicane in this and other reactions (Kipping and Murray, J., 1929, 360) affords an interesting contrast to the non-formation of tetraphenylmethane under conditions which might be expected to give it.

The production of triphenylsilicane from the trichloride is difficult to explain. It was at first thought that the hydrogen in this compound might be derived from sodium hydride, which is present in the metal in very small proportion; but when the trichloride is heated at its boiling point with sodium hydride in the absence of air during many hours there is no sign of any reaction. As it also seems impossible that the hydrogen can be derived from any phenyl-

ethoxysilicon dichloride present in the purified trichloride (J., 1929, 1184), it is necessary to assume that it is formed from phenyl groups by changes such as  $2 >\text{SiPh}_2 \rightarrow >\text{SiPh}\cdot\text{C}_6\text{H}_4\cdot\text{SiPh}_2 + \text{H}$ . This assumption was made in order to account for the production of triphenylsilicane from octaphenylcyclosilicotetrane (Kipping and Murray, *loc. cit.*) and considering the high temperature at which that change occurred it seemed to be a reasonable one; there was also some collateral evidence of the presence of phenylene groups in some of the products. In the experiments with the trichloride the temperature hardly exceeds  $200^\circ$ , unless locally, and such an explanation of the origin of the hydrogen is less probable, but there seems to be no alternative.

The yields of the tri- and tetra-phenyl derivatives cannot be given exactly; they both seem, however, to be less than 3% of the weight of the chloride.

#### EXPERIMENTAL.

To freshly distilled phenylsilicon trichloride (10—15 g.) contained in a 400 c.c. flask, large clean blocks of sodium ( $4-4\frac{1}{2}$  atoms) are added and a stream of oxygen-free nitrogen, dried finally with phosphoric oxide and sodium wire, is passed through the apparatus, which is provided with an upright quill-tube air-condenser about 30" long. The escaping gas is led through two wash-bottles containing benzene (or xylene) and after passing a mercury seal is bubbled through water. When all the air has been expelled, the flask is heated in an oil-bath and the nitrogen stream is reduced to about 1 bubble per second. Just below the boiling point of the trichloride the bright metal becomes coated with a brown crust and appears to increase considerably in volume. Gentle agitation releases the molten metal, which then becomes encrusted as before, and in the course of an hour or so a film of oil is usually visible in the condenser; the heating at about  $190^\circ$  is continued until the contents of the flask have become almost solid (about 10—20 hours). In some experiments, in which the temperature was finally raised to about  $230^\circ$ , crystals of tetraphenylsilicane were deposited on the upper portions of the flask and drops of oil, collected from the lower end of the air-condenser, were found to consist almost entirely of triphenylsilicane. If the flask is very vigorously shaken when the reaction has well started and the temperature has risen to about  $160^\circ$ , a great development of heat occurs and the contents of the flask are rapidly transformed into a granular brown solid.

In an experiment in which sublimed sodium hydride was used instead of sodium there was no sign of any reaction and the surface of the hydride was not coated with any crust even when the contents of the flask had been gently boiled during some 8—10 hours.

The oily film which, when sodium was used, coated the whole length of the condenser, and in which six-sided prisms were sometimes detected, was readily soluble in cold acetone, most of the crystalline matter being undissolved; this solution was practically free from chlorine and on evaporation yielded about 0.2 g. of a colourless viscous residue which did not crystallise at 0°. This product had the properties of triphenylsilicane (J., 1929, 364); when treated with aqueous alkali and a little acetone, it was rapidly attacked at the ordinary temperature with the evolution of hydrogen and formation of triphenylsilicol. The latter was fully identified by converting it into triphenylsilicyl oxide and crystallising the product from benzene; the highly characteristic rhomboidal crystals, *m. p.* 222°, of the oxide, which became opaque at 100°, were obtained. Small additional quantities of crude triphenylsilicane may be extracted from the main product with light petroleum (*b. p.* 30–40°).

The crystals sparingly soluble in acetone from the air-condenser and those forming a sublimate in the reaction flask were recrystallised from boiling acetone; the product, usually less than 0.1 g., was thus obtained in highly lustrous needles which were proved to be those of tetraphenylsilicane by direct comparison and by mixed melting-point determinations.

The products which were collected in the benzene wash-bottle are still under investigation; it seems that they contain either silicochloroform or silicon dichloride; and the water with which the escaping nitrogen was finally washed contains hydrochloric acid.

The main product of the reaction has not been thoroughly investigated, as it is no doubt a very complex mixture similar to that formed from the trichloride in boiling xylene solution; further, it is very difficult to decompose completely all the silicon halide and after 15–20 hours' heating the mixture still contains halogen compounds soluble in benzene which would make its investigation even more troublesome than that of the halogen-free products previously described. In order, however, to try to ascertain the approximate yield of the tetraphenyl derivative the products soluble in cold benzene were fractionally crystallised from that solvent and then from acetone; most of the fractions thus obtained were glue-like in consistency, but some of the more soluble portions seemed to be partly crystalline and from these after many operations there was isolated about 0.2 g. of crystalline matter. This product melted at 229–230° and gave with pure silicon tetraphenyl a mixture which melted from 230–232°, but it separated from solvents, including acetone, in microscopic nodules, whereas tetraphenylsilicane always crystallises from that solvent in highly lustrous needles; when warmed with acetone and aqueous alkali, it gave a little hydrogen

and therefore contained some linked silicon atoms, but after this impurity had been eliminated almost the whole of the substance was recovered apparently unchanged in crystalline form and in melting point. Since it had been found that tetraphenylsilicane sublimed readily, this nodular material was heated at about 220°; pure tetraphenylsilicane sublimed in lustrous needles, leaving only a very small proportion of gelatinous matter. Several of the more soluble fractions of the main products were treated with acetone and aqueous alkali until the hydrogen evolution ceased and after evaporation of the acetone the insoluble matter was again fractionated, but only very small quantities of tetraphenylsilicane were thus obtained. It seems, therefore, that the total yield of this compound is not very much greater than that of the triphenyl derivative.

### CXXIX.—*The Mechanism of, and Constitutional Factors controlling, the Hydrolysis of Carboxylic Esters. Part I. The Constitutional Significance of Hydrolytic Stability Maxima.*

By CHRISTOPHER KELK INGOLD.

ALTHOUGH the mass of data, accumulated by Victor Meyer, Kellas, Sudborough, Reid, and others, relating to the rates of hydrolysis of carboxylic esters and amides, forms one of the main pillars of the theory of steric inhibition, an examination of the results reveals the existence of a large number of anomalies of which no explanation has yet been given. The point may be exemplified by reference to the acid hydrolysis of two simple series, one of ethyl esters (Löwenherz, *Z. physikal. Chem.*, 1894, **15**, 388), and the other of acetates (Palomaa, *Ann. Acad. Sci. Fennicæ*, 1913, *A*, **4**, 2; 5, 4; Skrabal and Hügetz, *Monatsh.*, 1926, **47**, 17; and others), for which the data\* fail to show the continuous gradations which might have been expected.

	$k \times 10^3$ (40°).		$k \times 10^3$ (25°).

		tert.-Butyl acetate .....	7.5 „

On the other hand, it has recently been proved that the hydrolysis of carboxylic esters is just as susceptible to polar influence as are

\* It will be the uniform practice in these papers to employ minutes as time units and to use  $\log_e$ , not  $\log_{10}$ , in integration formulæ for velocity coefficients. Data from the literature are corrected, where necessary, to conform with these conventions.

most other reactions. Probably the clearest demonstration of this is to be found in the circumstance that Kindler's results (*Annalen*, 1926, 450, 1) for the speed of hydrolysis of benzoic esters containing various substituents in the *m*- and *p*-positions are in excellent agreement with the purely electropolar scheme which has been evolved (Ingold, *Ann. Reports*, 1927, 24, 155; 1928, 25, 146; Ingold and Rothstein, J., 1928, 1217; compare Williams, this vol., p. 37) for the interpretation of the influence of *m*- and *p*-nuclear substitution on aromatic side-chain reactions generally. In such a group of examples, complication is at a minimum: the electronic conductivity of the benzene ring guarantees the facile transmission of polar influences, whilst its configuration and spatial rigidity render steric inhibition practically inoperative. The clear implication, however, is that in the general case of ester hydrolysis, in which spatial effects are obviously of importance, internal polar factors will also play a part, and that this may explain the anomalies illustrated.

The theoretical object contemplated in this series of communications is the development of methods for the separation of the two factors presumed to be present in general on the basis of the arguments indicted. An analogy for the procedure adopted is provided by a contemporaneous investigation (Gane and Ingold, J., 1929, 1691; and earlier) in which a similar problem is envisaged, *viz.*, the separation of the spatial and internal polar factors which together control the strengths of polybasic acids. Here the analysis was greatly facilitated by the consideration, in the first instance, not of the dissociation constants themselves, but of a function of them, presumed, on the basis of an approximate theory, to be related mainly to *one* of the operating factors.

The development of an analogous procedure for the hydrolysis of esters necessitates some consideration of the theory of the dynamics of homogeneous catalysis as it has been elaborated by Brönsted and Dawson especially. It may be stated that our investigation is based on—indeed, was rendered possible by—Dawson's elegant methods for the analysis of superimposed catalytic effects; and, further, that due consideration has of necessity been given to certain highly important points raised by Brönsted in the course of his work.

The Arrhenius-Ostwald theory of catalysis by hydrogen and hydroxyl ions (symbolised,  $v = v_H + v_{OH}$ ) has more recently been extended, in several well-defined stages, to include catalysis by a large variety of molecules and ions. The "dual" theory of catalysis ( $v = v_H + v_{OH} + v_m$ ) envisaged catalysis by the undissociated molecules of acids (Acree and Johnson, *Amer. Chem. J.*, 1907, 37, 410; 38, 258; Senter, J., 1907, 91, 460; Lapworth, 1910,

97, 19; Goldschmidt and Thuesen, *Z. physikal. Chem.*, 1910, 70, 627; 1912, 84, 30; *Z. Elektrochem.*, 1911, 17, 684; Bredig, Miller, and Braune, *ibid.*, 1912, 18, 535; Snethlage, *ibid.*, p. 539; Taylor, *ibid.*, 1914, 20, 201; Dawson, Powis, and Reiman, J., 1913, 103, 2135; 1915, 107, 1426), and the most important step in its super-session by a still more general theory ( $v = v_H + v_{OH} + v_m + v_a$ ) consisted in the recognition of catalysis by the anions of acids (Brönsted, Pedersen, and Drus, *Z. physikal. Chem.*, 1924, 108, 185; 1925, 117, 299; Dawson and Carter, J., 1926, 2282). Many claims have been made for the recognition of a small but distinct catalytic effect of the water molecule on reactions in aqueous solution, but few are substantial ( $v = v_H + v_{OH} + v_m + v_a + v_{H_2O}$ ); the established cases include the mutarotation of glucose (Hudson, *J. Amer. Chem. Soc.*, 1907, 29, 1571; Brönsted and Guggenheim, *ibid.*, 1927, 49, 2554) and the iodination of acetone (Dawson and Key, J., 1928, 543).

Brönsted and Guggenheim discussed their results on the mutarotation of glucose in relation to the conception in accordance with which acids and bases are defined by the equation

{e.g.,  $[\text{Co}(\text{NH}_3)_5\text{OH}]^{2+}, \text{NH}_3, \text{OH}^-$ } {e.g.,  $\text{NH}_4^+, \text{H}^+, \text{CO}_2\text{H}, [\text{CO}_2\text{CO}_2\text{H}]^-$ },

independently of their state of electrification. (In this scheme  $\text{OH}^-$  appears as a special instance of a base, and the hydron,  $\text{H}_3\text{O}^+$ , as a special case of an acid; water is remarkable as belonging to both categories.) They showed that the catalytic efficiencies of a series of bases (including  $\text{OH}^-$ ) increased with the strength of the base, and that the logarithmic plot of the catalytic coefficients against the equilibrium constants of the reaction formulated above approximated to a straight line having a certain slope. Similarly, the catalytic effects of a series of acids (including  $\text{H}_3\text{O}^+$ ) increased with the strength of the acid, and an analogous plot of the data yielded another straight line of different slope. Evidently there are two catalytic mechanisms corresponding to the two lines: in acid catalysis the reactant receives from the catalyst a positive charge, and in basic catalysis it confers on the catalyst a positive charge. These conditions are fulfilled by both Lowry's (J., 1925, 127, 1371) and Baker's (J., 1928, 1583) theories of catalytic effects on mutarotation in the sugar series, but the general conclusion must hold independently of the accuracy of the assumed mechanistic details; and it is clear, moreover, that the actual mechanism of catalysis by hydrons is also that of catalysis by acids, and that the mechanism of catalysis by hydroxyl ions applies equally to catalysis by bases, in the generalised interpretation of the terms acid and base. Again, since the coefficients representing the catalytic

activities of ten acids and five bases on the iodination of acetone (Dawson and others, J., 1926, 2282; 1928, 543, 2844; 1929, 1884, 2530) yield a closely similar bilinear plot, it can be claimed that there is experimental evidence for extending the same two mechanisms, with their distinctive electropolar characteristics, to prototropic change generally, for it is usually accepted that the prototropy of acetone is here involved. Furthermore, Dawson and Lowson's results (J., 1927, 2107; 1928, 2152; 1929, 393, 1229) for the effect of three acids and two bases on the hydrolysis of ethyl acetate adumbrate yet another diagram of the same type, so that the principle of a dualistic mechanism of polar catalysis in relation to the generalised conception of acids and bases may evidently be extended to the hydrolysis of carboxylic esters. It should be stated that Lowry (*loc. cit.*), on theoretical grounds, suggested a close relation between the catalysis of sugar mutarotation and that of ester hydrolysis. Probably a still wider generalisation would be justifiable.

The explicit discussion will now be confined to catalysis by hydrogen and hydroxyl ions in ester hydrolysis, the implication being that the statements made are applicable to acid and basic catalysis generally, except in so far as quantitative modification is necessitated by the specific nature of an acid or base.

Consider the  $n$ th ester of an isotypic series. (We cannot yet define the word "isotypic," which is inserted to retain the right to exclude certain cases: the theory here advanced is an approximate one, and whilst the comparison to be instituted *might* embrace all carboxylic esters, except, perhaps, a few special classes such as lactones or 1:1-alkylidene di-esters, it might, on the other hand, prove to be much more restricted.) First, the formula of the series may be taken as  $R \cdot CO \cdot OR'$  in which  $R$  is variable and  $R'$  constant. Let  $k_H$  and  $k_{OH}$  be the catalytic coefficients expressing the rates of hydrolysis of the typical member at a given temperature by hydrogen and hydroxyl ions respectively. Now, it is possible to suppose that the *polar* effect of the variable group  $R$  on the constant residue  $\cdot CO \cdot OR'$  is capable of being quantitatively *imitated* by a group  $G$  of such a form that, when  $R$  is varied, the variations of  $G$  necessary to preserve the imitation do not alter the *steric* value of  $G$  in relation to the residue  $\cdot CO \cdot OR'$ . (For example,

$G$  might be of such a form as  $A$  ,  $A$  , or  $A$  , where  $A$  is variable, and  $B$  constant.) Let

$k_H^G$  and  $k_{OH}^G$  be the corresponding catalytic coefficients for the hydrolysis of  $G \cdot CO \cdot OR'$ . These coefficients,  $k_H^G$  and  $k_{OH}^G$ , may now be regarded as the polar constituents of those,  $k_H$  and  $k_{OH}$ , of the

series  $R \cdot CO_2R'$ ; they are the values which  $k_H$  and  $k_{OH}$  *would* assume in the presence of a *constant* steric effect arbitrarily fixed by the choice of the form of  $G$ . For the  $n$ th ester considered, let  $k_H = k_H^0/S$ , where  $S$  is a factor introduced to express the effect of steric inhibition in the hydrolytic reaction involving hydrogen ions;  $S$  will clearly depend on  $n$ , that is, on the nature of  $R$ . The value of  $k_{OH}$  will not, of course, be  $k_{OH}^0/S$  because the mechanism of the reaction with hydroxyl ions is different; a different connecting factor will, in general, be required, and may be expressed by  $CS$  in the relation  $k_{OH} = k_{OH}^0/CS$ . Now the basic assumption here made is that, because the difference between hydrogen- and hydroxyl-ion catalysis repeats itself throughout the series of esters of which the hydrolysis is being considered,  $C$  will be independent of  $n$  to a first approximation; in other words, that  $S$ , having been defined for *each* ester by reference to hydrion catalysis, takes sufficient account, for another kind of catalysis, of the varying nature of the esters, leaving the constant  $C$  to take charge, as it were, of the (constant) nature of the second catalyst. It is not expected that  $C$  will be *exactly* constant; but the larger  $C$  is—that is, the more diverse the mechanisms with regard to their susceptibility to steric effects—the more nearly true should be the suggested relation. The constancy of  $C$  being assumed, it follows that  $C(k_{OH}/k_H) = k_{OH}/k_H^0$ , that is, that  $k_{OH}^0/k_H^0$  is a function of polarity only. Similarly, if  $R$  is kept constant and  $R'$  is made to vary,  $C'(k_{OH}/k_H) = k_{OH}^0/k_H^0$ . Finally, both  $C$  and  $C'$  are *arbitrary* constants, since they depend on the forms chosen for  $G$  and  $G'$ ; therefore, the general relationship for all the isotypic esters,  $R \cdot CO_2R'$ , with variable  $R$  and  $R'$ , is that  $k_{OH}/k_H$  is directly proportional to its polar constituent.†

This view, namely, that  $k_{OH}/k_H$  is, probably within wide limits, a function of polarity only, and is untrammelled by the complications due to steric hindrance which affect  $k_{OH}$  and  $k_H$  separately, may be tested by reference to experimental data; and it is convenient to use two types of data for this purpose.

The first uses the theory of the  $v$ - $p_H$  isotherm. That the velocity of an aqueous reaction catalysed by hydrogen and hydroxyl ions must pass through a minimum (at  $p_H = p_H^*$ ) is obvious *a priori*, but was first observed by Wijs for the hydrolysis of methyl acetate

† It will be observed that this conclusion is reached without specific assumptions relating to mechanism. It is necessary only that the mechanisms obtaining should admit the validity of the basic hypothesis, namely, that the relative steric effects on velocity are expressible as the product of two coefficients singly dependent, respectively, on the ester and the catalyst. This granted, it follows that the conclusion drawn should apply to a pair of acid or of basic catalysts, *e.g.*, to  $k_{\text{weak acid}}/k_H$  or to  $k_{\text{weak base}}/k_{OH}$ , as well as to a pair composed of one catalyst of each kind.

(*Z. physikal. Chem.*, 1893, **11**, 492; **12**, 514); and the symmetry of the  $v$ - $p_H$  curve, which is important for the location of the stability maximum, *i.e.*, of  $p_H^*$ , seems to have been first shown by Euler and Hedelius (*Biochem. Z.*, 1920, **107**, 150; compare Euler and Svanberg, *Z. physikal. Chem.*, 1921, **115**, 139, and Euler and Laurin, *Arkiv Kemi, Min. Geol.*, 1920, **7**, No. 30, 1) for the mutarotation of glucose. Dawson, partly with Dean and Hoskins (J., 1926, 2872, 3166; 1927, 213, 1148, 1290), has directed attention to the consequences of applying the (concentration) mass law, amongst which are (a) that the  $v$ - $p_H$  isotherm should be symmetrical because it should be a catenary, (b) that  $-2p_H^* - \log K_w = \log (k_{OH}/k_H)$ , where  $K_w$  is the ionic product of water, and (c) that, when the  $p_H$  variation is produced by a series of buffers of which either the acidic or the saline component is kept constant in concentration, catalysis by the buffer constituents causes some displacement of  $p_H^*$ , but preserves the catenary form of the curve. We are not here concerned with the point (Brönsted and Guggenheim, *loc. cit.*) that relations cannot be absolute which neglect effects due to ionic environment in buffers, because, in applying (b) to calculate  $k_{OH}/k_H$  from observed values of  $p_H^*$ , the fact has to be faced that the available data for  $p_H^*$  neglect the correction for buffer constituents altogether (this defect in method is remedied in Part II). However, despite the approximate character of the data (Karlsson, *Z. anorg. Chem.*, 1921, **119**, 69; 1925, **145**, 1; Bolin, *ibid.*, 1925, **142**, 201; 1928, **177**, 227; compare Dawson, J., 1927, 1148), the examples to which they apply are so diverse that the general character of the suggested relation between  $k_{OH}/k_H$  and polarity can be observed over a greater range of structural variation than it is at present possible to traverse in any other way. From the first series in Table I, it will be seen that  $k_{OH}/k_H$  increases regularly, as it should, with the efficacy of the electron-sink; it is also noteworthy that the polar group may act from either of the residues attached to  $-CO\cdot O-$ . Ester No. 2 was glycerol monoacetate, but is formulated, for convenience in tabulation, as though it were glycol monoacetate, for the polar effect of the terminal  $\cdot CH_2\cdot OH$  group is expected to be negligible. Ester No. 5 was actually ethyl aminoacetate; but the velocity minimum occurs at  $p_H$  3.5, *i.e.*, in *acid* solution, so that the entity to which  $k_{OH}/k_H$  refers is the ammonium kation, and this agrees with the very high value of  $k_{OH}/k_H$ . The value of  $k_{OH}/k_H$  for methyl formate, regarded as the parent of the second series in Table I, is not known; but it is known qualitatively to be considerably greater than for ethyl formate. In this series, the value of  $k_{OH}/k_H$  diminishes, as it should, with the efficacy of the electron-source, which, as before, may act from either of the groups attached to  $-CO\cdot O-$ .

5	CH <sub>3</sub> →	CH <sub>3</sub> →CH <sub>2</sub> →CH <sub>2</sub> →	5.65	25	1.0	0.5

In the above examples there is a certain variety in the types of polar substituents, and, accordingly, a very great diversity in the

Rates of hydrolysis of methylacetic esters as function of structure.

values of  $k_{OH}/k_H$ ; and one of the advantages of this method of estimating  $k_{OH}/k_H$  is that the ease with which the ratio is determined is independent of its order of magnitude, at least between  $10^2$  and  $10^7$ . When the order of magnitude of the ratio becomes greater than  $10^8$ , difficulties enter the independent *direct* determination of  $k_{OH}$  and  $k_H$  at the same temperature,† and, therefore, the range

† The numerous alleged determinations of  $k_{OH}$  in buffers, but without correction, or data permitting the application of a correction, for the buffer constituents, are, of course, valueless, except as indications of order of magnitude.

of polar substituents which can be examined by reference to data of this kind is more restricted; on the other hand, the values of  $k_{OH}/k_H$  thus obtained should be more accurate than those derived from stability maxima in the absence of a correction for the buffer, and should therefore suffice to distinguish the effects of finer polar differences. In illustration, reference may again be made to the apparently anomalous series of simple alkyl acetates tabulated at the outset. The calculated values of  $k_{OH}/k_H$  are as shown in Table II, and it will be seen that in these values there is no perceptible anomaly; if plotted against the number of  $\beta$ -methyl groups,  $k_{OH}/k_H$  and  $p_H^*$  both give smooth uninflected curves of small curvature (see fig.).

Having explained the *a priori* considerations on which this series of investigations will be based, and illustrated their reasonableness by reference to existing data, the object of this introductory communication is accomplished. Any estimate of the extent to which the method outlined can be pressed in the analytical separation of the two main constitutional influences which affect the stability of esters towards hydrolysis must await a wider range of data such as will be provided in ensuing papers.

THE UNIVERSITY, LEEDS.

[Received, March 5th, 1930.]

### CXXX.—*The Mechanism of, and Constitutional Factors controlling, the Hydrolysis of Carboxylic Esters. Part II. Hydrolytic Stability Maxima of some Glyceric Esters.*

By CONSTANCE MARY GROOCCOCK, CHRISTOPHER KELK INGOLD,  
and ARTHUR JACKSON.

IN selecting a method for the determination of catalytic data of the type of which the significance is discussed in Part I, our object was to combine wide applicability with some approach to accuracy,

The first consideration suggested the location of hydrolytic stability maxima, since, as has already been shown, this is the only method which remains practicable when strongly electron-attracting substituents adjoin the ester residue.

The second desideratum required that such a process be used only in conjunction with an adequate method for eliminating catalytic influences associated with the buffers used to define the  $p_H$ . These influences consist of (a) the superimposed catalysis of the buffer acid and buffer base, and (b) the effect of the buffer-ion environment on the activity of all the catalytic entities. A method for their elimination has been devised and is described later.

A third preliminary consideration was necessitated by the sparing solubility of the majority of esters,  $R \cdot CO_2R'$ , in water. The objections to the use of a mixed solvent, such as aqueous alcohol, for our purpose are obvious and are of a type not easy to surmount; it was therefore decided to avoid the difficulty by varying the radicals  $R$  and  $R'$  separately and using a poly-hydroxylated group for the radical which is kept constant throughout any given series. In this paper, for example, we record the results obtained with a series of glyceric esters  $CH_2(OH) \cdot CH(OH) \cdot CO \cdot OR$  ( $R$  variable).

Previous investigators who have undertaken experiments with the object of locating the hydrolytic stability maxima of esters in buffer solutions appear always to have aimed at using a sufficient buffer concentration to stabilise the  $p_H$  against disturbance from the acid liberated from the hydrolyte in the course of the experiment. This method involves two difficulties. First, the necessary concentration of buffer materials (which have to be neutralised in the course of the analytical work) is often such that the titre which measures the progress of hydrolysis is of the order of 1% of the total titre; and this sets a rather low limit to the accuracy obtainable in analysis. Secondly, in the present state of electrolytic theory there is no method for extrapolating to zero buffer concentration the velocity data obtained with concentrated buffer solutions, which is sufficiently trustworthy to obviate the necessity for an empirical check by reference to experimental data for low buffer concentrations; and this necessary empirical control is clearly impossible in a method in which, at the lowest buffer concentrations which are consistent with its principles, the buffer substances are still by far the main constituents of the solution. The first of these objections could, of course, be minimised by the use of gravi-volumetric methods of analysis; but since there seemed no way of overcoming the second, we rejected the method in favour of the following process.

An aqueous solution of the glyceric ester (concentration  $E_0$ ) was treated with sufficient carbonate-free sodium hydroxide to hydrolyse

a small proportion of it. At the temperature used, saponification occurred almost instantly with formation of sodium glycerate (concentration  $c$ ), and in a few moments the solution passed through the neutral point and became faintly acid. It is easily seen that, from the moment of neutrality onwards, all effects on the dynamics of the reaction will be substantially the same as if sodium glycerate had been added at that moment to an ester solution of concentration  $E = E_0 - c$ . This sodium glycerate constituted the (constant) salt constituent of the buffer series,  $c\text{NaA} + x\text{HA}$ . The glyceric acid liberated in concentration  $x$  during the continuation of hydrolysis furnished the (variable) acid constituent of the buffer series, and also the measure of the decomposition of the hydrolyte.

In considering the dynamics of a hydrolysis subject to this kind of  $p_H$  control, it is convenient to treat effects (a) and (b) (see p. 1040) separately. First, we shall disregard effects due to buffer-ion environment. In symbolising the dynamics we shall follow the procedure developed by Dawson.

Application to the fundamental equation

$$v = v_H + v_{OH} + v_m + v_a + v_w = k_H[H^+] + k_{OH}[OH'] + k_m[HA] + k_a[A'] + k_w[H_2O]$$

of the mass-law relations

$$[A'] = c + [H^+] \text{ and } [HA] = c[H^+]/K + [H^+]^2/K \quad (1)$$

leads to

$$v = \left(k_H + \frac{k_m c}{K} + k_a\right)[H^+] + \frac{k_{OH} K_w}{[H^+]} + \frac{k_m}{K} [H^+]^2 + (k_a c + k_w [H_2O]) \quad (2)$$

of which

$$v = \left(k_H + \frac{k_m c}{K}\right)[H^+] + \frac{k_{OH} K_w}{[H^+]} + (k_a c + k_w [H_2O]) \quad (3)$$

is an approximate form. The approximation consists in the neglect of  $[H^+]$  in comparison with  $c$ , and so long as the former is of the order  $10^{-4.5}$  and the latter of order  $10^{-1}$  this is justifiable. The quantities,  $v = u$  and  $[H^+] = h$ , characterising the relation  $dv/d[H^+] = 0$  are given by

$$u = 2 \left\{ k_{OH} K_w \left( k_H + \frac{k_m c}{K} \right) \right\}^{\frac{1}{2}} + (k_a c + k_w [H_2O]) \quad (4)$$

and

$$h = \left\{ k_{OH} K_w \left( k_H + \frac{k_m c}{K} \right) \right\}^{\frac{1}{2}} \quad (5)$$

and, if  $w$  is written for that part of  $v$  which is independent of  $[H^+]$ , the approximate equation (3) for  $v$  takes a form equivalent to that

used by Dawson to express the symmetry of the  $v$ - $p_H$  relation, viz.,

$$2 \frac{v-w}{u-w} = \frac{[H^*]}{h} + \frac{h}{[H^*]} \quad (6)$$

In using this form for the purpose of deriving an equation for the experimentally determined  $x$ - $t$  relation, we should substitute for  $v$  and  $[H^*]$ , using

$$dx/dt = v(E-x) \quad (7)$$

and

$$K(x - [H^*]) = [H^*](c + [H^*]) \quad (8)$$

but if the second of these equations is replaced by  $[H^*] = Kx/c$ , the approximation (except at the commencement of the reaction) is of the same order as that introduced above, and the differential equation takes the comparatively simple form

$$\frac{dx}{dt} = (E-x) \left\{ \frac{1}{2}(u-w) \left( \frac{Kx}{hc} + \frac{hc}{Kx} \right) + w \right\} \quad (9)$$

The manner in which the solution of equation (9) should be expressed in order that it may be real depends on the relative magnitudes of  $u$  and  $2w$ . In our experiments  $u$  was always greater than  $2w$ , and the real form of the solution for this case is

$$t \left\{ \frac{E^2 K^2}{h^2 c^2} + \frac{2EKw}{(u-w)hc} + 1 \right\} = EK \log_e \left[ \frac{E}{E-x} \left\{ \frac{K^2 x^2}{h^2 c^2} + \frac{2Kwx}{(u-w)hc} + 1 \right\} \right] \\ - \frac{(u-w)hc - EKw}{\sqrt{u^2 - 2uw}} \left\{ \tan^{-1} \frac{\frac{(u-w)Kx}{hc} + w}{\sqrt{u^2 - 2uw}} - \sin^{-1} \frac{w}{u-w} \right\} \quad (10)$$

From numerical data conforming to this equation it is obviously possible to construct the curve of equation (3) or its equivalent (6), and also the  $(dx/dt)$ - $x$  curve (equation 9).

It is now necessary to consider the effect of varying  $c$ . Since, for a given value of  $[H^*]$ , equation (2) may be written

$$v = A + \left( \frac{k_m [H^*]}{K} + k_a \right) c \quad (11)$$

it follows that, in so far as the mass law expresses the situation,  $v$  is a linear function of  $c$  for constant  $[H^*]$ , and  $dv/dc$  is a linear function of  $[H^*]$ . If, therefore, we use a family of experimentally obtained  $x$ - $t$  curves to plot a corresponding family of  $v$ - $[H^*]$  curves, and then employ them to construct a family of  $v$ - $c$  curves, the last should be straight lines. Their intercepts on the axis  $c = 0$  should yield the data required for the construction of a  $v$ - $[H^*]$  curve corresponding with  $c = 0$ , and their slopes should give a  $(dv/dc)$ - $[H^*]$  curve, of

which the slope measures  $k_m/K$  and the intercept on the axis  $[H^+] = 0$  measures  $k_a$ . The mass-law expression for the  $(v-[H^+])_{c=0}$  curve is

$$v_0 = (k_H + k_a)[H^+] + \frac{k_{OH}K_w}{[H^+]} + \frac{k_m}{K}[H^+]^2 + k_w[H_2O]. \quad (12)$$

but the practical simplification which results from applying the above procedure to our experimental data is greater still, because, although only rough estimates of  $k_a$  and  $k_m$  are possible, it transpires that  $k_a/k_H$  is of the order  $10^{-4}$ , and that in the neighbourhood of the stability maximum  $k_m[H^+]/K$  is of the same order as  $k_a$ ; that is, there are reasons, justifying the omission of the terms  $k_a[H^+]$  and  $k_m[H^+]^2/K$  from equations (2) and (12), which are independent of the reason that applies in the case of equation (2) when  $c$  is great in comparison with  $[H^+]$ ; the last reason therefore still holds good when  $c = 0$ , and the equation for the  $v_0-[H^+]$  curve may be expressed

$$v_0 = k_H[H^+] + \frac{k_{OH}K_w}{[H^+]} + k_w[H_2O] \quad (13)$$

If  $w_0$  is written for  $k_w[H_2O]$ , the corresponding data for the stability maximum in the absence of buffer substances are

$$u_0 = 2\sqrt{k_H k_{OH} K_w} + w_0 \quad (14)$$

$$h_0 = \sqrt{k_{OH} K_w / k_H} \quad (15)$$

and, in terms of these quantities, the equation for  $v_0$  is

$$2 \frac{v_0 - w_0}{u_0 - w_0} = \frac{[H^+]}{h_0} + \frac{h_0}{[H^+]} \quad (16)$$

The above outline of the method we have adopted in order to eliminate from our results effects due to the catalytic activity of the constituents of the buffers, leaves untouched the question of correcting for disturbances due to the effect of ion-environment on catalytic activity. Brönsted, in particular, has drawn attention to the importance of these influences in homogeneous catalysis. Now, Dawson and his collaborators have also envisaged this problem, and, although we must agree with Brönsted that recognition of the disturbances mentioned is equivalent to an admission that mass-law relations are inapplicable, what is of more importance is that Dawson has found a simple method of giving a quantitative account of the actual catalytic relations; and his method may be expressed in the statement that the *form* of the mass-law equations holds good provided that the coefficients are no longer regarded as constants, but are replaced by suitable *functions of the ionic strength*. Dawson and Key, for instance, investigated the effect of neutral salts on the catalysis of the iodination of acetone (J., 1928, 1248), and found

that, with one exception, the deviations from constancy which it was necessary to ascribe to the catalytic coefficients were barely detectable. For the one coefficient (namely,  $k_H$ ) for which the variation could be measured, it was found to be represented by a linear function of the ionic strength over a very much greater range of ionic strength than any with which we are concerned. It can readily be shown (i) that, if conditions which are similar in regard to the orders of magnitude of the quantities involved hold also for ester hydrolysis, then the main effect on the relations which equation (11) purports to express will be represented by an alteration in the slope of the  $v$ - $c$  curves (because, of course,  $A$  contains  $k_H$ ); and (ii) that the variations attributable to  $k_m$  and  $k_a$  are unlikely in practice to impart any perceptible curvature to these graphs within the range of concentration used in our experiments. Again, Dawson and Lowson have made a study of salt effects on the hydrolysis of ethyl acetate in which they have considered especially the deviations with increasing salt concentration which must be ascribed to the dissociation constants of weak acids (J., 1929, 1217). They found that the variability with which it is necessary to credit these constants is of the type required by the Debye-Hückel theory of electrolytes, although there remained a divergence from that theory in the matter of the numerical value of one of the constants of the equation connecting  $K$  with  $c$ . The effect of influences of this nature on the relations which equation (11) is supposed to represent can be qualitatively deduced, although they are somewhat complicated. There will be, for instance, an effect on the explicit  $K$ ; this is calculated to impart to the  $v$ - $c$  curves a convexity towards the  $c$ -axis, which might be large enough to be perceptible on the acid side of the stability maximum, but would be extremely slight on the alkaline side. On the other hand, there will be an indirect effect on  $v$  arising from the fact that  $v$  is a function of  $[H^+]$ , which is a function of  $K$ ; and this should produce a slight convexity towards the  $c$ -axis on the acid side of the stability maximum. Similarly, opposing effects, relating primarily to the alkaline side of the stability maximum, can be foreseen; and the general conclusion which emerges from a consideration of the probable orders of magnitude of the quantities involved is that the main effect of the disturbances considered would again be represented by an alteration of the slope of the  $v$ - $c$  curves, although small departures from linearity remain theoretically possible. Further details with regard to the theoretical aspect of this matter need not be discussed, because we find that, for the range of salt concentration employed, the  $v$ - $c$  curves are, in fact, straight lines to within the limits of consistency of the data. It is, therefore, clear that the process of linear extrapolation outlined above must

yield velocity values ( $v_0$ ) which are not only independent of contributory catalysis by the buffer constituents, but are also free from the disturbing effects of buffer-ion environment on catalytic activity; in other words, the  $v_0$ -[H<sup>+</sup>] curve obtained from the experimental data by the method indicated should be represented, to a degree of accuracy determined only by the data themselves, by equations (13—16), in which all the quantities pertain to salt-free aqueous solutions.

There is one disturbing factor which cannot be eliminated by any such method as that outlined, and that is the effect of the ester itself in modifying the properties of the aqueous medium. Knowing nothing about this, we have been forced to neglect it; but inasmuch as it is proposed later to compare the results obtained, we have endeavoured to arrange that effects due to the ester shall be kept as nearly constant as possible throughout the series by using, in every case, solutions of uniform ester concentration.

Eight esters of *dl*-glyceric acid with alcohols of simple constitution have been examined by the method described. The results are summarised in Section E of the experimental part of this paper (see especially Table IX and Figs. 4 and 5). Discussion of the data is postponed until the results of further experiments, now in progress, are available for collective consideration.

#### EXPERIMENTAL.

(A) *Materials*.—*dl*-Glyceric acid was prepared by oxidation of glycerol with nitric acid ("Beilstein," 4th Aufl., III, 395). Its esters with aliphatic alcohols have hitherto usually been obtained by heating the acid with the alcohol at 180—190° (Frankland and McGregor, J., 1893, 63, 512; Frankland and Price, J., 1897, 71, 253), but we found that esters prepared by this method turned brown on keeping. The esters were therefore prepared by boiling the acid (it is not necessary that it should be absolutely anhydrous) with an excess of the alcohol containing 1% of hydrogen chloride. Careful fractionation under diminished pressure yielded stable, colourless esters of constant b. p., which, however, contained traces of chlorine compounds. These were removed by distillation under reduced pressure with freshly prepared silver oxide. The esters appeared to be somewhat hygroscopic, and, accordingly, precautions were taken to prevent access of moisture. Purity was checked by quantitative saponification ( $G$  = glyceryl group). The italics in Table I indicate the esters which are new.

(B) *Calibration*.—In order to obtain a convenient rate of reaction in the neighbourhood of the stability maxima it was found necessary to use a temperature considerably above that of the room. Since

the titrations were carried out at room temperature, the ordinary methods for the intercalibration of volumetric apparatus were inapplicable on account of thermal expansion. We therefore standardised the barium hydroxide solution used for the acidimetric measurements by a method which included an automatic relative calibration of the series of flasks and pipettes used against the already internally calibrated burette. The procedure may be illustrated as follows.

Pure succinic acid (1.2832 g.) was placed with distilled water in a flask, A, which had a mark on the neck, and the solution was made up with water to the mark at 70.2°. At this temperature a sample was withdrawn with a nominally 25 c.c. pipette, (a), and titrated, in the presence of an approximately standard quantity of phenolphthalein, with nominally *N*/40-barium hydroxide, 39.38 ml. of which were required to produce the tint which throughout these experiments was accepted as an indication of the end-point. The capacity of the flask, up to its mark, at the same temperature, was determined gravimetrically, allowance being made for the buoyancy of water in air, and found to be 539.2 ml. It follows that each ml. of titre corresponds with the presence of 0.0010265 g.-equiv. of acid per litre in a solution the sample of which has been withdrawn at the temperature stated from flask A by pipette (a). This temperature was used throughout the velocity measurements. Flasks B—F were treated similarly in relation to pipette (a); later, another set G—K were treated likewise in relation to a second pipette (b).

(C) *Details of a Typical Experiment* (Expt. L, 1.15).—A mixture of methyl glycerate (see Table I) (42.004 g.), warm distilled water (about 400 c.c.), and 0.9746*N*-sodium hydroxide (83.01 ml.) in flask A was placed in the thermostat, and, after temperature equilibrium had been attained, the whole was made up to the mark. At intervals extending over about a week, samples were withdrawn with pipette (a) and titrated in the manner described in Section B. The results are given in the 2nd, 3rd, and 4th columns of Table II, *t* being the time (in minutes) and *x* the normality of the acidity.

From the data given it can be calculated that  $E = 0.4988$  and  $c = 0.1500$ . The times recorded in the 5th column of Table II are calculated from an equation equivalent to (10), the values used being  $K = 2.28 \times 10^{-4}$ ,  $u = 2.37 \times 10^{-5}$ ,  $w = 0.37 \times 10^{-5}$ , and  $h = 8.81 \times 10^{-5}$ . The value of  $K$  is taken from Ostwald's measurements at  $25^\circ$  (*Z. physikal. Chem.*, 1889, 3, 192), and its selection is admittedly arbitrary, because, apart from other considerations (see below), the temperature is not that of our experiments. No determinations of  $K$  appear to have been made at higher temperatures, and we have not attempted to introduce a temperature correction by means of special experiments, for the following reasons. First, judging from such evidence as is available, the thermal variations in the dissociation constants of simple monocarboxylic acids are so slight that they are difficult to estimate with accuracy, either from conductivities, or from heats of neutralisation, except on the basis of an elaborate investigation. Secondly, the correction, if it could be estimated, would probably be smaller than the uncertainty in the value for the basic temperature,  $25^\circ$ ; Böeseken, for instance, records  $2.8 \times 10^{-4}$  for this temperature (*Rec. trav. chim.*, 1918, 37, 169). Thirdly, as is pointed out in the introduction, our experiments are necessarily affected by the circumstance that our buffer-free solvent is, not water, but an aqueous solution of the ester; whilst this disturbing influence inevitably affects  $K$  (and there is no point in attempting to eliminate it, since the same cannot be done for the other coefficients and constants involved), it would be superfluous to endeavour to eliminate from  $K$  the (probably smaller) disturbance

due to temperature. In the circumstances, the best course seemed to be to adopt a definite value of  $K$  and keep to it throughout the work; and since the effects mentioned would probably tend to reduce  $K$ , we have chosen the lower of the two recorded values. Errors due to an incorrect value of  $K$  should, we think, be constant throughout the series of experiments, because, as has been explained, all effects (including the one on  $K$ ) due to the main *variable* factor, namely, the salt concentration, are eliminated during the reduction of our

FIG. 1.

results to those which should pertain to the buffer-free medium. The  $x-t$  curve plotted from the figures in Table II runs generally upwards and to the right, but contains a point of inflexion (minimal slope) in the neighbourhood of the 10th observation. Of the three values  $u$ ,  $w$ , and  $h$  selected to give that degree of agreement with equation (10) which is indicated in the 6th column,  $u$  is mainly responsible for the general slope,  $w$  controls the degree of acuteness of the inflexion, and  $h$  its position. It should be added that, since there is a certain indefiniteness about the time of starting, and also because the integrated formula is not accurate near the commencement of the reaction, the first observation was treated as the effective

starting point for computation; \* this is indicated by the parenthesis at the top of the table.

The general nature of the  $x-t$  relation can be more clearly exhibited by using the differences between neighbouring observations to calculate  $v$  from equation (7) and the means of such observations to obtain corresponding values of  $[H^+]$  (or  $p_H$ ) from equation (8). The results of this calculation are given in Table III, the figures in the last two columns of which are graphically represented in Fig. 1.

In the table, col. 1 enables the pair of observations used to be identified in Table II; cols. 2 and 3 record respectively the differences of time and of acidity; col. 4 gives the mean acidity for each interval; and cols. 5 and 6 record the mean molecular concentrations of glyceric acid and of glyceric ester for each interval. It will be seen that only about one-fifth of the total possible reaction has been followed (in the majority of our experiments the fraction is smaller), and for this reason, having regard to Dawson and Lowson's investigation of the effect of reversibility on the dynamics of the hydrolysis of ethyl acetate (J., 1927, 2107), we need not fear serious disturbance from the retrograde reaction.

TABLE III.

19-20	744	0.01052	0.1047	0.1045	0.3941	3.58	3.80

It will be obvious from Fig. 1 that the experimental data correspond with a curve approximating more or less closely to the usual

\* To do this we replace  $t$  (equation 10) by  $t - t_1$ , remove the term  $\sin^{-1}$  (an integration constant), and subtract from the right-hand side of the residual equation an expression identical with that side except that  $x_1$  replaces  $x$ , ( $x_1$ ,  $t_1$ ) being the first observation.

catenary form; the main purpose of the figure, however, is to exhibit the fact that the accuracy of the individual observations is insufficient to enable directly read differences to define the  $v$ - $p_H$  curve with any approach to precision (the curve drawn is constructed as described below). Our practice in this and the other experiments has therefore been to plot the  $x$ - $t$  observations, and to read  $dx/dt$  from the curve. We regard this method of eliminating the casual errors of individual observations as allowable because it is a close graphical analogue to many accepted legitimate methods of attaining the same end, as, for instance, the averaging of a column of individually calculated velocity coefficients derived by the application of an integrated formula to a series of observations tracing the progress of a reaction; indeed, the latter process is, if anything, more difficult to defend because integration itself involves an averaging of errors which might seriously affect direct application of the data to the differential equation to which they should correspond. In applying the graphical process indicated, we found it convenient to plot  $1000x \cos \theta - 0.01t \sin \theta$  against  $100x \sin \theta + 0.001t \cos \theta$ , where  $\theta$  is an angle shown to be suitable by a preliminary rough plot of  $x$  against  $t$ . This method avoids the use of an inconveniently extended scale; the effect is much as if the  $x$ - $t$  data were plotted on a sheet of rubber which was then stretched 10-fold in a direction at right-angles to the general direction of the curve in order to bring into relief the deviations of the points from the curve. For the experiment now considered  $45^\circ$  is a suitable value for  $\theta$ . Proceeding in this way, we obtained the data shown in Table IV, the headings of the first five columns of which are self-explanatory. The velocity values in col. 6 are calculated from equation (6) by use of the values of  $u$ ,  $w$ , and  $h$  given above. Col. 7 shows the deviations, which are seen to be small and casual in character.

TABLE IV.

 $v \times 10^5$ .

0.0725	1.201	3.95	0.4263	2.82	2.82	$\pm 0.00$
0.0924	1.268	3.86	0.4064	3.12	3.17	$-0.05$
0.1065	1.377	3.79	0.3923	3.51	3.52	$-0.01$

The data in the third and fifth columns enable the  $v$ - $p_H$  curve to be located to within  $\pm 0.01$  unit of  $p_H$  and of  $v \times 10^5$ , except at a distance from the stability maximum where the uncertainty of  $v$  is somewhat greater. The curve is practically symmetrical about the ordinate  $p_H = 4.24$ .

FIG. 2.

(D) *Summary of a Typical Group of Experiments (Group L1).*—This group consists of four experiments of the same nature as that particularised in Section C. 0.5*M*-Methyl glycerate (*E*) was employed throughout, but the concentration of sodium glycerate (*c*) was different in each experiment, being 0.050 in the first, 0.075 in the second, 0.100 in the third, and 0.150 in the fourth. The second experiment was carried out about a year before the other three, which were done contemporaneously; this is mentioned in order to show that during the rather long period over which the measurements

recorded in this paper have extended, a satisfactory constancy of conditions has been maintained.

Proceeding as described in the previous section, we obtained the values of  $v$  and  $p_H$  shown in Table V. The plot of these results is exhibited in Fig. 2 (full-line curves).

TABLE V.

$c = 0.050.$		$c = 0.075.$		$c = 0.100.$		$c = 0.150.$	
$p_H.$	$10^5 v.$	$p_H.$	$10^5 v.$	$p_H.$	$10^5 v.$	$p_H.$	$10^5 v.$

4.39	2.17	4.46	2.40	4.40	2.32	4.43	2.58
4.31	2.01	4.35	2.18	4.35	2.25	4.37	2.43
4.24	1.96	4.26	2.07	4.29	2.21	4.31	2.40
4.17	1.97	4.18	2.08	4.25	2.18	4.26	3.37
4.12	1.98	4.11	2.09	4.19	2.19	4.22	3.38
4.00	2.10	4.00	2.30	4.12	2.20	4.16	2.40
3.92	2.36	3.87	2.70	4.05	2.33	4.09	2.49
3.79	2.70	3.70	3.50	3.96	2.54	4.02	2.64
3.73	3.13	—	—	3.85	2.85	3.95	2.82
3.63	3.71	—	—	3.79	3.17	3.86	3.12
—	—	—	—	3.74	3.40	3.79	3.51

It will be seen from the figure that as  $c$  increases, the minimal velocity increases and becomes displaced towards regions of lower hydron concentration, as might have been expected on the basis of equations (4) and (5).

From these curves the  $v$ - $c$  curves can readily be plotted. They are shown in Fig. 3 for each 0.1 unit of  $p_H$  from  $p_H$  4.6 to  $p_H$  3.8 inclusive, the numerals showing the  $p_H$  value to which each point corresponds. When points relating to the same  $p_H$  are joined, straight lines are obtained which, on production to the axis of velocities, yield the velocity data which should pertain to the salt-free solution.

The data obtained from the intercepts on the axis of velocities are shown in connexion with the lowest (broken) curve of Fig. 2. They are compared in Table VI with the requirements of equation (16), in which the values used are  $h_0 = 6.76 \times 10^{-5}$ ,  $u_0 = 1.76 \times 10^{-5}$ , and  $w_0 = 0.06 \times 10^{-5}$ .

TABLE VI.

$p_H$ .....	4.6	4.5	4.4	4.3	4.2
$10^5 v_0$ .....	2.66	2.29	1.99	1.82	1.76
$10^5 v_0$ (calc.) .....	2.67	2.27	1.99	1.83	1.76
Diff. ....	-0.01	+0.02	$\pm 0.00$	-0.01	$\pm 0.00$
$p_H$ .....	4.1	4.0	3.9	3.8	
$10^5 v_0$ .....	1.76	1.89	2.09	2.42	
$10^5 v_0$ (calc.) .....	1.78	1.89	2.08	2.43	
Diff. ....	-0.02	$\pm 0.00$	+0.01	-0.01	

It is noteworthy that the slopes of the  $v$ - $c$  curves are approximately constant at  $p_H$ 's above 4.3, but on the acid side of this value they increase more and more rapidly as the  $p_H$  decreases. It is possible from the limiting slope and the divergences of slope, to make rough estimates of  $k_a$  and  $k_m$  respectively, although, of course, the experi-

FIG. 3.

ments were not designed with the object of measuring those quantities, and are not of the most suitable kind for that purpose. It appears, however, that  $k_a$  and  $k_m$  are both of the order of a few units times  $10^{-5}$ .

(E) *Short Summary of Results.*—The  $v$ - $p_H$  data ( $10^5 v$ ) for the esters and salt concentrations employed, obtained as illustrated in Sections C and D, are collected in Table VII. The extrapolated

velocity values ( $10^5 v_0$ ) for buffer-free solution are in Table VIII, and are shown graphically in Figs. 4 and 5.

The curves shown in conjunction with the  $v$ - $p_H$  data in Figs. 4 and 5 are graphs of equation (16) corresponding with certain assumed values of  $u_0$ ,  $h_0$ , and  $w_0$ . The assumed values of  $w_0$  are relatively

FIG. 4.

very small (of the order  $10^{-7}$ ) and the curves are not sensitive to their absolute magnitudes; conversely, the data shown in connexion with the curves do not enable the values of  $w_0$  to be fixed with any approach to precision. They do show, however, that the catalytic influence measured by  $w_0$ , viz., that of water molecules, is only of minor importance in the hydrolysis of carboxylic esters. We think

that Skrabal and Zahorka's claim (*Monatsh.*, 1929, **53**, **54**, 562) to have shown that 36% of the minimal velocity of hydrolysis of ethyl acetate at 25° is due to water catalysis is vitiated by the omission

to make allowance for buffer effects; probably the major portion of the percentage mentioned is to be laid to the account of the constituents of the buffers employed.

The values  $u_0$  and  $h_0$  correspond with the co-ordinates of the minima

of the curves. They are given in Table IX, together with the corresponding values of  $p_H^* = -\log_{10} h_0$ , and of  $k_{OH}/k_H = h_0^2/K_w$ . In the calculation of  $k_{OH}/k_H$  it is necessary to assume a figure for  $K_w$ , and  $10^{1.23-1.4}$  has been adopted as the result of interpolation from existing data. The value is inevitably arbitrary for the reason mentioned on p. 1045, but, as is there explained, there is reason to believe that its arbitrariness will not affect the purpose for which these measurements have been made.

THE UNIVERSITY, LEEDS.

[Received, March 5th, 1930.]

### CXXXI.—*The Anomalous Fifth Carbon Atom in n-Fatty Nitriles.*

By ROBERT AVERY FULTON and WILLIAM BELL LEE.

IN some series of straight-chain carbon compounds the 5th, 10th, and 15th members exhibit maxima or minima in many physical and chemical properties (Lee, *Trans. Faraday Soc.*, 1927, **23**, 79; Lee and van Rysselberge, *J. Physical Chem.*, 1929, **33**, 1543), and similar anomalies have been noted in molecular rotatory power by Pickard and Kenyon. Moreover, in homologous series of such compounds the alternation of physical properties between the odd and the even members is well known. Müller (*Proc. Roy. Soc.*, 1929, *A*, **124**, 317) postulates a plane, or nearly plane, zigzag structure of the carbon chain in such cases, but Henderson (*Proc. Roy. Soc. Edin.*, 1928, **48**, 20), from X-ray investigations of the dibasic acids of the oxalic acid series, concluded that the carbon chain was in spiral form.

The systematic and comparative experiments recorded below, which were made by one of us (R. A. F.) on six consecutive members of the series of nitriles of the *n*-fatty acids, demonstrate that a well-defined anomaly exists in the chemical reactions of the  $C_5$  nitrile. If a helicoidal configuration of the carbon atoms be assumed, every fifth carbon atom would correspond to one complete turn of the helix.

*Experiments in Liquid Ammonia Solution.*—Equimolecular quantities of the normal nitriles (from acetonitrile to hexonitrile) and of potassamide were electrolysed in liquid ammonia solution. The materials were carefully purified, and in all the experiments the conditions, *e.g.*, concentration, temperature ( $-33^{\circ}$ ), and current density (0.5 amp./sq. cm.), were kept as nearly as possible the same. The electrolysis was carried out in an apparatus similar to that used by Kolbe and others. The gases evolved in the reactions were analysed by low-temperature fractionation according to the method of Burrell (*U. S. Bureau of Mines Bulletin*, No. 104), and the analyses were accurate to approximately 0.1%.

Attention is focused entirely on the anode reactions, and the electrolysis is essentially that of the potassium salt of the "ammono"-fatty acid (Franklin; see *e.g.*, Cornell, *J. Amer. Chem. Soc.*, 1928, **50**, 3311) formed thus:  $\text{CH}_3\cdot\text{CN} + \text{KNH}_2 = \text{CH}_3\cdot\text{C}(\text{NH})\cdot\text{NHK}$ . Ammonocarbonic acid was always one of the products, and, except in the case of the ammonoacetate, hydrogen also was formed.

No. of C atoms in nitrile	2.	3.	4.	5.	6.
Methane, % .....	68.6	48.6	42.7	2.0	12.0
Ethane, % .....	None	None	None	70.5	50.0

The only variable in the different experiments was the length of the carbon chain. There is a definite "break" at the fifth carbon atom in the chemical reactions of these *n*-fatty nitriles. We assume that a stereochemical cause is responsible for this anomaly.

*Fusion of n-Fatty Nitriles with Potassamide.*—The nitriles were heated with potassamide in equimolecular quantity at  $350^{\circ}$ , the experiments being comparative. Again the only difference introduced was in the length of the chain.

No. of C atoms in nitrile.	2.	3.	4.	5.	6.
Gaseous products	$\text{CH}_4$	$\text{H}_2, \text{CH}_4$ $\text{C}_2\text{H}_6$	$\text{H}_2, \text{CH}_4$ $\text{C}_2\text{H}_6$ $\text{C}_3\text{H}_8$	$\text{CH}_4, \text{C}_3\text{H}_8$ , $\text{C}_4\text{H}_{10}$ ( $\text{C}_2\text{H}_6$ trace)	$\text{C}_2\text{H}_6, \text{C}_3\text{H}_8$ $\text{C}_4\text{H}_{10}$ ( $\text{CH}_4$ trace)

At  $\text{C}_5$  the yield of methane was a minimum with only a trace of ethane, whereas at  $\text{C}_6$  the ethane yield was good, with only a trace of methane. There is again a distinct anomaly at  $\text{C}_5$  in the reactions of these chemically similar nitriles. The mechanism of these reactions might be interpreted in different ways, and we lay less stress on these than on the electrolytic experiments. Nevertheless, there is some peculiarity which can be related to the number of carbon atoms in the chain.

Neither the ordinary plane formula of the organic chemist nor the plane zigzag of certain X-ray investigators accounts for this

chemical anomaly at the fifth carbon atom. The phenomenon is much more general than may have been supposed.

Our thanks are due to Professors E. C. Franklin and F. W. Bergstrom for their helpful suggestions during the course of this investigation.

### CXXXII.—*The Addition of Halogens to Unsaturated Acids and Esters. Part III. The Velocity of Bromine-addition.*

By NORMAN WILLIAM HANSON and DAVID MATTHEW WILLIAMS.

WILLIAMS and JAMES (J., 1928, 343) showed that addition of bromine to unsaturated acids and esters in the dark in non-hydroxylic solvents, such as carbon tetrachloride and chloroform, was an autocatalytic reaction, and adduced evidence that the catalyst was hydrogen bromide. Davis (*J. Amer. Chem. Soc.*, 1928, 50, 2769) suggested that bromine-addition in the dark to olefins in carbon tetrachloride proceeded mainly through the medium of a bromine hydrate because the reaction velocity increased as the temperature was lowered from 25° to 0°. Further, the same thermal reaction was studied by Meyer and Pukall (*Z. physikal. Chem.*, 1929, 145, 360) for the case of cinnamic acid in chloroform; here, again, the reaction was autocatalytic, and it was suggested that the catalyst was produced by the action of bromine on the solvent and that the rapidity of the photobromination was due to the rapid production of the catalyst under the influence of light rays.

The present communication is an attempt to investigate systematically the effect of constitutional differences on the velocity of bromine-addition to unsaturated acids and methyl esters. The latter were used chiefly in those cases in which the acids were insoluble in the two solvents, and where comparison was possible, the ester was found to react slightly less readily than the acid. The addition was invariably more rapid in chloroform than in carbon tetrachloride, and hence, where choice was possible, the former was used for the slow and the latter for the rapid reactions. Solutions of purified bromine in either of the purified solvents can be kept in the dark for long periods without any deterioration, so the explanation of Meyer and Pukall does not seem to apply to the dark reaction.

The rate of addition to both forms of *o*-methoxycinnamic acid is

several hundred times greater than to cinnamic acid, the velocity diminishing more rapidly than would be expected for a bimolecular reaction (Williams and James, *loc. cit.*). This work has now been extended to include the methyl esters of *m*- and *p*-methoxycinnamic acids, and the reaction velocities are all of the same order of magnitude. The attachment of the strongly activating methoxyl group to the nucleus greatly intensifies the rate of nuclear substitution, and hence it seems that the enhanced rate of reaction is due to the ease with which hydrogen bromide is produced. This suggestion is in accordance with the observations of Davies and Davies (J., 1928, 602) and of Reimer and Tobin (*J. Amer. Chem. Soc.*, 1930, 52, 341), that addition of bromine respectively to *m*-methoxycinnamic acid and to 2:4-dimethoxycinnamic acid always results in considerable substitution in the nucleus. It was anticipated that a nuclear deactivating group directly attached to the nucleus in cinnamic acid would have the converse effect, decreasing the rate of addition and causing a long inhibition period. This expectation has been realised, for the nitro-group in the methyl esters of *o*-, *m*-, and *p*-nitrocinnamic acids was found to have the anticipated effects on the velocity of addition of bromine. Further, the inhibition periods vanished when hydrogen bromide was added initially as a catalyst.

Halogen atoms attached to the carbon atoms of the double linkage show interesting contrasts, for an  $\alpha$ -halogen atom completely inhibits addition, even in the presence of hydrogen bromide, while a  $\beta$ -halogen atom does not noticeably affect the rate. Although no other substituents in these positions have yet been studied, it is clear that the character of the groups attached to the doubly linked carbon atoms is an important factor in determining the rate.

Comparison of rates of addition to a number of *cis*- and *trans*-isomerides has shown that in every case addition of bromine to the *cis*-form occurs more readily, but the difference in rate varies considerably from pair to pair. An important fact relating to this point was discovered by the study of methyl fumarate and methyl maleate. Neither of these esters reacts with bromine in the dark in carbon tetrachloride at 18°. The fumarate is perfectly stable towards bromine even if heated in sealed tubes at 100° for several days, but the maleate is not so inactive at high temperatures: being an oil at ordinary temperature, it is more difficult to purify, and probably its impurities, by producing traces of hydrogen bromide, cause it to react slowly with bromine. In the presence of hydrogen bromide, the fumarate reacts with bromine very slowly, but the maleate reacts very rapidly and an apparent equilibrium is attained, after which the reaction is exceedingly slow. This is probably due to

the fact that a proportion of the maleate is converted into the fumarate under the influence of hydrogen bromide, concurrently with the addition. This shows that a third factor influencing the rate of addition is the rate of conversion of the unstable or *cis*-form into the stable or *trans*-form, and this seems to point to the existence of the same intermediate form in the conversion and in the addition. The same conclusion was reached by Schmidt (*Z. physikal. Chem.*, 1928, *B*, 1, 205) as regards the photochemical action of bromine on methyl maleate and methyl fumarate.

#### EXPERIMENTAL.

Exactly the same methods of purification of bromine and solvents were adopted as in the previous work. The solid esters were repeatedly recrystallised, and the liquid esters were twice redistilled under reduced pressure. The methyl maleate on standing for a few weeks deposited crystals of the fumarate, and since the presence of the latter does not interfere with the bromination of the former, a saturated solution of the fumarate in the maleate at 13° was used. This solution, as shown by the melting-point curve of mixtures of the two esters (Schmidt, *loc. cit.*), contains 4% of fumarate.

The procedure for the velocity measurements was modified accordingly as the reaction was rapid or slow. Equal volumes of *M*/30-solutions of the substance and of bromine at 0° were mixed either in well-stoppered brown bottles or in tubes, and the latter were at once sealed in a very faint red light. The vessels were then kept at 0° in the dark for the required period, the reaction being stopped either by adding excess of potassium iodide solution or by breaking the bulb under the solution. A definite volume (excess) of standard sodium thiosulphate solution was then added, the whole shaken until colourless, and the excess thiosulphate titrated against *N*/50-iodine solution.

In studying the catalytic effect of hydrogen bromide, definite volumes of a solution of the carefully dried gas in the solvent were added to the reaction mixture, a separate bottle being used for each determination. The concentration of the hydrogen bromide solution was determined either by titration with baryta or by precipitation as silver bromide. The catalytic effect on the addition of bromine to methyl maleate was so great that the best results were obtained by mixing 100 c.c. of each reacting solution in a large brown bottle, adding a definite volume of hydrogen bromide solution, and withdrawing samples of 20 c.c. for analysis at definite intervals.

The velocity measurements are summarised in the following tables. Since in no case was the reaction bimolecular in the absence of added hydrogen bromide, no velocity coefficients are given. For a com-

parison of rates, the approximate inhibition period and the time for 25% change are given, time being in hours throughout.

Table I shows the influence on the rate of the nitro- and methoxy-groups attached to the nucleus. The position of the substituent in the ring is a secondary factor compared with its nature. It will be seen that both types of addition, (a) and (b), are considerably accelerated by hydrogen bromide.

TABLE I.

Isomeride.	Without initial HBr.		With initial HBr.	
	Inhibition period.	Time for 25% change.	[HBr]/[Br <sub>2</sub> ].	Time for 25% change.

Do not react to a measurable extent with bromine at 0° in either solvent, even under the influence of hydrogen bromide.			

The velocity measurements with methyl maleate and methyl fumarate were conducted in carbon tetrachloride in a thermostat at 18°. No addition took place to either of the esters unless hydrogen bromide was added, whereupon the two esters exhibited widely

different rates of reaction. In Table III are given the periods for 50% change with the maleate for different amounts of the catalyst, and also the position of equilibrium, which shows the percentage change into the fumarate.

TABLE III.

### CXXXIII.—*The Behaviour of Hydrogen Chloride in Different Solvents.*

By W. F. KENRICK WYNNE-JONES.

HYDROGEN chloride when dissolved in water behaves as a very strong electrolyte, so strong, indeed, that it is usual to regard it as a completely ionised acid, since its solutions conform quite closely to the equations of the Debye-Hückel theory. The anhydrous compound, on the other hand, is a non-electrolyte, and it is generally considered that the hydrogen and chlorine atoms are so intimately bound that it requires considerable energy to separate them as ions. These facts have led to the hypothesis that the dissociation of the acid is occasioned by its combination with the solvent and that, according to Brönsted's definition of an acid and a base (*Rec. trav. chim.*, 1923, **42**, 718), the acid will be ionised only in a basic solvent. Thus in water, ammonia, and methyl alcohol we have the reaction schemes  $\text{HCl} + \text{H}_2\text{O} \rightleftharpoons \text{H}_3\text{O}^+ + \text{Cl}'$ ;  $\text{HCl} + \text{NH}_3 \rightleftharpoons \text{NH}_4^+ + \text{Cl}'$ ;  $\text{HCl} + \text{CH}_3\text{OH} \rightleftharpoons \text{CH}_3\text{OH}_2^+ + \text{Cl}'$ .

This hypothesis makes a clear distinction between an electrolyte such as hydrochloric acid and other strong electrolytes such as salts, since, with the latter, dissociation is primarily determined by the dielectric constant, whereas with hydrochloric acid the chemical nature of the medium is the determining factor.

In order to test this hypothesis further, it was decided to examine the behaviour of hydrogen chloride in a solvent of no marked basic character but possessing a fairly high dielectric constant. For this purpose, nitrobenzene seemed admirably suited, since its dielectric constant is 34, and, from an acid-base standpoint, it might be expected to be inert; moreover its immiscibility with water made it possible to use the partition method for investigating the behaviour of hydrogen chloride.

This method has been employed by several investigators, and the work of Rothmund and Drucker (*Z. physikal. Chem.*, 1903, **46**, 827) and of Cavanagh (*Proc. Roy. Soc.*, 1924, *A*, **106**, 243), in particular, has proved the trustworthiness of the method for determining activities in one solvent when those in the other solvent are known. There has, however, been a certain amount of criticism of the method, owing partly to a misunderstanding of the nature of the results obtained by it, and partly to a misconception of its limitations. On the one hand, it is clear that the Nernst equation

$$K = C_1^n / C_2 \quad \dots \quad (1)$$

where  $C_1$  and  $C_2$  refer to the concentrations in the two solvents and  $n$  is the degree of association in solvent 2, is only an approximation

and certainly cannot hold for electrolytes. A more precise method of treating the results is to write for solutions in one solvent

$$\mu = RT/n \cdot \log cf + k \quad (2)$$

where  $\mu$  is the chemical potential of the solute,  $n$  the degree of association,  $f$  the activity coefficient of the associated molecules, and  $k$  a constant, the other symbols having the usual significance. If, for the other solvent, the values of  $\mu$  are known, then these values may be substituted in the above equation. In a case such as that studied here, we may write for aqueous solutions

$$\mu_1 = RT \log p + k_1 \quad (2a)$$

while for solutions in nitrobenzene we have

$$\mu_2 = RT/n \cdot \log cf + k_2 \quad (2b)$$

whence, for equilibrium,

$$K = p^n/cf \quad (3)$$

$p$  being the partial pressure.

The limitations of the method, on the other hand, must be clearly recognised. Evidently, the application of equation (2a) is only justifiable if the chemical potential of the solute is not markedly affected by the presence of the other solvent. Also the results for the second solvent will refer, not to the pure liquid, but to one saturated with the other solvent. The solubility of one solvent in the other, provided it remain constant, as at low concentration of the solute, will not invalidate the results; if, however, the solubility varies appreciably, then some uncertainty will be introduced dependent upon the manner in which the potential of the solute varies with the properties of the solvent.

#### EXPERIMENTAL.

In view of the fact that hydrogen chloride is much more soluble in water than in nitrobenzene, it was thought possible that errors might arise through traces of emulsification if the two liquids were brought into direct contact as is usual in partition measurements. In order to avoid this, an H form of apparatus was constructed and equilibrium between the two liquids was reached through the vapour phase; the attainment of equilibrium was accelerated by evacuating the apparatus through a tap on the connecting tube. Siphon tubes were introduced through rubber stoppers in the two upright tubes, and the apparatus was filled and emptied by means of these siphons. In most of the experiments the apparatus was left in a thermostat, electrically controlled at  $25.00^\circ \pm 0.01^\circ$ , for 2—5 days with occasional shaking; in a few of the later experiments a shaking apparatus was installed and equilibrium attained

in less than 24 hours. At the end of this time air was admitted to the apparatus, the ends of the siphons were broken, and suitable amounts of the two liquids run into flasks and weighed. Titrations were carried out with carbonate-free sodium hydroxide, bromocresol-purple being used as indicator. The ultimate standard was constant-boiling hydrochloric acid, prepared according to the directions of Foulk and Hollingsworth (*J. Amer. Chem. Soc.*, 1923, **45**, 1220).

In one experiment with nitrobenzene and all the experiments with benzene the two liquids were shaken together in stoppered bottles. The agreement of the nitrobenzene value thus obtained with the others is satisfactory evidence that either method can give correct results under proper conditions.

The solubility of hydrogen chloride in water and nitrobenzene was determined by passing the gas for several hours through the liquids contained in test tubes: the gas passed out through two guard tubes and was then absorbed in alkali. The hydrogen chloride was generated by dropping A.R. hydrochloric acid into concentrated sulphuric acid. As a check on this method, a few measurements were made with gas generated by the action of sulphuric acid on ammonium chloride, but no difference was detected.

The nitrobenzene was of "pure" quality. It was shaken with caustic soda and distilled twice under 20 mm. pressure, the second distillation being from phosphoric oxide. The final product was very pale yellow.

*Results.*—The results are summarised in Table I. In the first column are recorded the values ( $C_w$ ) of the concentration in the

aqueous layer expressed in mols. per 1000 g. of water; in the 2nd, the concentrations ( $C_n$ ) in the nitrobenzene similarly expressed; in the 3rd, the values of the activities in the aqueous layer calculated from the data of Randall and Young (*J. Amer. Chem. Soc.*, 1928, 50, 989) up to a concentration of 16 molal, and, for higher concentrations, from the vapour pressures given in the International Critical Tables, Vol. III, p. 301.

### *Discussion of Results.*

On comparing these results with those of Knight and Hinshelwood (*J.*, 1927, 470) for the distribution of hydrogen chloride between benzene and water, we find two marked differences. In the first place, there is a difference in the general form of the curves representing the variation of the concentration in the non-aqueous phase with the concentration in the water. For, whereas in this work the curve rises continuously and is always concave towards the axis of the concentration in the water, Knight and Hinshelwood's curve has a point of inflexion and flattens out very considerably at high concentrations, where a constant value is actually obtained for the ratio of the concentrations in the two layers. Such a result is quite inexplicable on theoretical grounds and, moreover, is in conflict with the vapour-pressure data of a number of authors. That it is probably due to some experimental error is further shown by the fact that the value given by Knight and Hinshelwood for the solubility of hydrogen chloride in water at 20° differs considerably from the standard value. Thus, Roscoe and Dittmar (*J.*, 1859, 12, 128) found that 1 g. of water at 20° dissolves 0.721 g. of hydrogen chloride, whereas Knight and Hinshelwood found that 1 litre of the saturated solution contains 718.8 g. of hydrogen chloride; combining this with the density of the solution, *viz.*, 1.22, we obtain a value of 1.44 g. of hydrogen chloride per g. of water.

TABLE II.

Knight and Hinshelwood's results at 20°.

$C_w$ , g./l.	$C_b$ , g./l.	$p_{HCl}$	$p_{HCl}/C_b$
165.9	0.100	0.0343	0.343
212.0	0.252	0.162	0.643
236.1	0.382	0.351	0.92
249.0	0.449	0.538	1.20
259.0	0.532	0.742	1.40
289.3	0.706	1.905	2.70
312.0	0.929	3.91	4.21

A further peculiarity about the results of these authors is that the concentrations in the benzene layer are not even approximately proportional to the partial pressures of the aqueous solutions. This is shown in Table II where a few of the data are tabulated.

The concentrations are expressed as g. of acid per litre of solution; the vapour pressures have been interpolated from the data in the International Critical Tables (*loc. cit.*) and are expressed in mm. of mercury.

In order to determine whether this deviation from normality had any real existence, it was decided to carry out a few experiments with benzene. The results are summarised in Table III, in which the concentrations are expressed as mols. per 1000 g. of solvent.

TABLE III.  
Results with benzene at 25°.

$C_w$	$C_b$	$p_{\text{HCl}}$	$p_{\text{HCl}}/C_b \times 10^3$
9.603	0.00213	2.95	1.39
10.215	0.00340	4.67	1.37
10.508	0.00423	5.72	1.35
11.43	0.00768	10.74	1.40
11.99	0.0110	15.6	1.42
12.93	0.0216	28.1	1.30

It is clear that the behaviour of hydrogen chloride in benzene is quite normal.

FIG. 1.

That hydrogen chloride is a normal solute in nitrobenzene also is shown most clearly in Fig. 1, where the logarithm of the activity is plotted against the logarithm of the concentration in the solvent; the straight line has been drawn with a slope of unity and it is

evident that over the whole range the activity is proportional to the concentration.

As previously mentioned, the activities were obtained by combining Randall and Young's results with the vapour-pressure data in the International Critical Tables. If Randall and Young's values of  $\log \gamma$  are plotted against  $\sqrt{M}$  (where  $M$  = molality) a linear relationship holds over the range 9–16*M*, but it is not possible to use this for extrapolation, since the values thus obtained diverge considerably from the values calculated from the vapour pressures by means of the equation

$$\log \gamma - 1.718 = \log \sqrt{p}/M.$$

That there is no serious error in the vapour pressures is shown by the fact that the interpolated value for the concentration of the saturated solution (under a pressure of 760 mm. of Hg) is 19.33*M*, in exact agreement with the figure obtained in this work. It is also quite justifiable to calculate activities from the vapour pressures, since Gray and Burt (J., 1909, 95, 1633) have shown that at 0° and a pressure of 1 atm. the deviation of hydrogen chloride vapour from the gas laws is less than 1%. Since there are no published values for the activity coefficients of hydrochloric acid at concentrations above 16*M*, Table IV has been compiled from the vapour-pressure data.

TABLE IV.

Activity coefficients of hydrochloric acid at 25°.

<i>M</i> (mols./1000 g.) ...	16	17	18	19	20
$\log \gamma$ .....	1.628	1.708	1.776	1.836	1.890
<i>p</i> (mm. Hg) .....	169.1	276	423	623	884

The value of  $\log \gamma$  at 16*M* is that given by Randall and Young and may be somewhat in error, but further investigation is required to decide this.

The results presented in this paper clearly support the theoretical considerations outlined in the introduction: in the three solvents water, nitrobenzene, and benzene, with dielectric constants 79, 34, and 2.2, respectively, the behaviour of hydrogen chloride is conditioned, not by the dielectric constant of the medium, but by its capacity to combine with it. That hydrogen chloride probably forms a compound with water has long been postulated, but it is interesting to note that vapour-pressure data lend considerable support to this view and also enable us, on the basis of a simple assumption, approximately to evaluate the extent of combination. Roscoe and Dittmar have measured the vapour pressures of hydrochloric acid solutions at 0° up to a pressure of 1300 mm.; in addition, Faraday (*Phil. Trans.*, 1845, 135, 155) determined the vapour

pressure of pure hydrogen chloride at the same temperature. These results are combined in Fig. 2, where the vapour pressure is plotted against the mol fraction of hydrogen chloride, which is calculated on the assumption that the molecular weights of hydrogen chloride and of water are normal. Although there is a large range for which no data are available, it is very striking that a linear extrapolation of Roscoe and Dittmar's results comes very close to Faraday's value for pure hydrogen chloride. The whole form of the curve strongly suggests that at mol fractions of less than 0.25 practically all the hydrogen chloride has combined with the water and exerts a negligible vapour pressure, whereas above that value any additional hydrogen chloride added to the solution is uncombined and is able

FIG. 2.

to exert its full vapour pressure. This can be simply explained if each molecule of hydrogen chloride is combined with 3 molecules of water.

If we now assume that the partial pressure of hydrochloric acid is always proportional to the mol fraction of the uncombined acid, it is possible to calculate its amount. Thus, the partial pressure of a molal solution at  $0^\circ$  is  $2 \times 10^{-8}$  atm., while the vapour pressure of pure hydrogen chloride is 26.2 atm.; hence the mol fraction of uncombined hydrochloric acid is  $2 \times 10^{-8}/26.2$ , and its molality is  $55 \times 2 \times 10^{-8}/26.2 = 4 \times 10^{-8}$ . On the assumption that all the combined hydrogen chloride is ionised, the dissociation constant of hydrochloric acid is  $K = 1/4 \times 10^{-8} = 2.5 \times 10^7$ . This value agrees well with the previous estimates of Schreiner (*Z. physikal.*

*Chem.*, 1924, **111**, 419) and of Ebert (*Naturwiss.*, 1925, **13**, 393), both based on quite different considerations.

*Summary.*

The partition of hydrogen chloride between nitrobenzene and water has been determined, and the results indicate that in nitrobenzene it behaves as a normal undissociated solute. A few measurements on the system benzene-water lead to a similar conclusion. These results support the view that the behaviour of an acid is primarily determined by the basic character, and not by the dielectric constant, of the solvent.

Consideration of the vapour-pressure data shows that a molecule of hydrogen chloride in aqueous solution is probably associated with 3 molecules of water, and it is estimated that the dissociation constant of hydrochloric acid is  $2.5 \times 10^7$ .

I wish to express my thanks for a grant from the Research Fund of the Chemical Society which has helped to defray the cost of this work.

# CXXXIV.—*Investigations in the Diphenyl Series. Part IX. Further Experiments with Sulphonamides.*

By FRANK BELL.

ALTHOUGH the acetyl derivatives of 2-amino- and 4-amino-diphenyl can be nitrated only to dinitro-compounds (Scarborough and Waters, J., 1927, 89), it appeared probable that by the use of sulphonyl derivatives trinitro-compounds and hence trinitroamines would be obtainable (Bell, J., 1928, 2772). To avoid complications during the vigorous nitration, *m*-nitrobenzenesulphonyl derivatives were employed and in this way both 2-amino- and 4-amino-diphenyl were easily converted into trinitro-compounds.

The reaction of outstanding interest in the substitution of derivatives of 2-amino- and 4-amino-diphenyl is the bromination of 4-acetamidodiphenyl (Scarborough and Waters, J., 1926, 507; Kenyon and Robinson, *ibid.*, p. 3050), for in marked contrast with every other simple monosubstitution reaction of aminodiphenyls and their derivatives there is produced a considerable yield of a heteronuclear-substituted product, 4'-bromo-4-acetamidodiphenyl.

Since the above experiments showed that the arylsulphonamides readily undergo substitution, the bromination of 2- and 4-*p*-toluenesulphonamidodiphenyls was investigated. The latter is brominated

exclusively in the 3-position and is then dibrominated in the 4'-position, whereas 2-*p*-toluenesulphonamidodiphenyl is brominated in the 5-position and is then resistant to further substitution under the conditions employed.

These results show very clearly the marked difference which exists in the processes of nitration and bromination. Both 2- and 4-*p*-toluenesulphonamidodiphenyls are dinitrated with the utmost ease in the 3 : 5-positions and although the failure to brominate 3-bromo-4-*p*-toluenesulphonamidodiphenyl in the 5-position may be attributed to the competitive action of the bromo- and the *p*-toluenesulphonamido-group acting in the same nucleus, this explanation can scarcely be valid for the monobromination of 4-acetamidodiphenyl.

The comparison of the processes of nitration and bromination was extended to include 4-methoxydiphenyl. This substance on bromination gave a mixture of 3-bromo- and 4'-bromo-4-methoxydiphenyls, the yields being about 60% and 30% respectively. Both these monobromo-derivatives on further bromination gave 3 : 4'-dibromo-4-methoxydiphenyl. In this case, therefore, there is much less contrast between bromination and nitration (Bell and Kenyon, J., 1926, 3047).

It was intended to include 2-dimethylaminodiphenyl in this study, but 2-aminodiphenyl on methylation under the same conditions which readily produced 4-dimethylaminodiphenyl (Bell, J., 1926, 2709) gave only 2-methylaminodiphenyl.

During the course of this work it was noticed that certain of these sulphonamides readily reacted with a further molecule of sulphonyl chloride to give disulphonamides, and it was thought of interest to examine this reaction in greater detail. The following results were obtained :

(a) 3 : 5-Dibromo-4-aminodiphenyl, 2-nitro-*p*-toluidine, and 6-nitro-*o*-toluidine reacted with the sulphonyl chloride (1 mol.) to give disulphonamides. The yield was not quantitative even when 2 mols. of sulphonyl chloride were employed, and therefore the velocity of disulphonamide formation must be high compared with that of monosulphonamide formation.

(b) *o*-Nitroaniline and 1 : 8-dinitro- $\beta$ -naphthylamine with the sulphonyl chloride (1 mol.) gave mixtures of monosulphonamide and disulphonamide (Bell, J., 1929, 2787).

(c) Other amines gave monosulphonamides which were converted into disulphonamides with very different velocities.

It would appear that the velocity of disulphonamide formation is determined by the tendency of the sulphonamide-hydrogen atom to undergo ionisation. For instance, the *m*-nitrobenzenesulphonyl derivatives of the nitroanilines (II) react readily with a molecule of a

sulphonyl chloride, whereas that of aniline (I) reacts very slowly. This accords with the electron-absorbing character of the nitro-group, which is most easily satisfied if the hydrogen of the amino-group

separates with a positive charge (gives up its electron and separates as a hydrogen ion). Similarly the mobility of this hydrogen atom is influenced by the substituents present in the benzenesulphonyl group. It would be expected that *p*-toluenesulphonamides (III) should be less reactive than *m*-nitrobenzenesulphonamides, and this is actually the case. For example, under the same experimental conditions, *m*-nitrobenzenesulphon-*m'*-nitroanilide reacts quantitatively with *p*-toluenesulphonyl chloride, whereas *p*-toluenesulphon-*m'*-nitroanilide gives only a 50% yield of the same compound when treated with *m*-nitrobenzenesulphonyl chloride.

Sulphonamides capable of giving rise to disulphonamides will also undergo acetylation. For instance, *p*-toluenesulphon-*m'*-nitroanilide is easily converted into *p*-toluenesulphon-*m'*-nitroacetanilide. On the other hand, the acetyl derivatives of *o*- and *m*-nitroanilines did not react with either *m*-nitrobenzenesulphonyl chloride or *p*-toluenesulphonyl chloride in pyridine solution. This is comparable with the well-known fact that secondary amines, such as methyl-aniline, are readily acetylated, whereas acetylated primary amines cannot be methylated by shaking with methyl sulphate.

The diminution in directing power which takes place when the sulphonamido- is converted into the disulphonamido-group (J., 1929, 2877) is further illustrated by the fact that 5-nitro-2-di-*m*-nitrobenzenesulphonamidodiphenyl can only be converted into a dinitro-derivative, whereas the sulphonamido-derivative is easily trinitrated. Also *m*-nitrobenzenesulphon-*m'*-nitroanilide is very vigorously attacked by fuming nitric acid, whereas di-*m*-nitrobenzenesulphon-*m*-nitroanilide can be recovered unchanged from this reagent.

#### EXPERIMENTAL.

Unless otherwise stated, sulphonamides and disulphonamides were prepared by interaction of the appropriate amine, or sulphonamide,

and sulphonyl chloride in pyridine solution and were recrystallised from acetic acid.

4-m-Nitrobenzenesulphonamidodiphenyl formed colourless needles, m. p.  $149^{\circ}$  (Found: C, 61.3; H, 4.0.  $C_{18}H_{14}O_4N_2S$  requires C, 61.0; H, 4.0%).

To this compound (15 g.) in acetic acid (150 c.c.) was added nitric acid ( $d$  1.5, 15 c.c.) in acetic acid (15 c.c.). The solution rapidly deposited crystals which, after recrystallisation from acetic acid, gave pure 3-nitro-4-m-nitrobenzenesulphonamidodiphenyl in yellow prisms, m. p.  $170^{\circ}$  (Found: C, 54.2; H, 3.3.  $C_{18}H_{13}O_6N_3S$  requires C, 54.1; H, 3.3%). This compound (5 g.) was added in small portions to nitric acid ( $d$  1.5, 12 c.c.) and after  $\frac{1}{4}$  hour the resultant solution was diluted with acetic acid; the 3:5:4'-trinitro-4-m-nitrobenzenesulphonamidodiphenyl thus precipitated, after crystallisation from acetic acid, formed needles, m. p.  $199^{\circ}$  (Found: C, 44.2; H, 2.3.  $C_{18}H_{11}O_{10}N_5S$  requires C, 44.2; H, 2.3%). 3 G. were dissolved in sulphuric acid (6 c.c.) and after  $\frac{1}{4}$  hour the solution was poured into water. The resulting precipitate after crystallisation from pyridine gave 3:5:4'-trinitro-4-aminodiphenyl as long yellow needles, m. p.  $282^{\circ}$  (Found: C, 46.9; H, 2.6.  $C_{12}H_8O_6N_4$  requires C, 47.4; H, 2.6%).

3-Nitro-4-di-m-nitrobenzenesulphonamidodiphenyl formed prisms, m. p.  $187^{\circ}$  (Found: C, 48.8; H, 2.8.  $C_{24}H_{16}O_{10}N_4S_2$  requires C, 49.3; H, 2.7%), and 2-m-nitrobenzenesulphonamidodiphenyl colourless needles, m. p.  $128^{\circ}$  (Found: C, 61.0; H, 4.1.  $C_{18}H_{14}O_4N_2S$  requires C, 61.0; H, 4.0%).

Nitration of 2-m-Nitrobenzenesulphonamidodiphenyl.—(a) 3 G. were warmed on a water-bath for 15 hours with a mixture of water (20 c.c.) and nitric acid (4 c.c.). The product, crystallised from alcohol, gave 5-nitro-2-m-nitrobenzenesulphonamidodiphenyl in platelets, m. p.  $150^{\circ}$  (Found: C, 54.3; H, 3.5.  $C_{18}H_{13}O_6N_3S$  requires C, 54.1; H, 3.3%).

(b) To 4 g., dissolved in acetic acid (40 c.c.) at  $70^{\circ}$ , was added nitric acid ( $d$  1.5; 3 c.c.) in acetic acid (3 c.c.) and the whole was maintained at  $70^{\circ}$  for  $\frac{1}{4}$  hour. On cooling, the liquid filled with pale yellow leaflets, m. p. *ca.*  $145^{\circ}$ , containing acetic acid of crystallisation. Recrystallised from alcohol, this product furnished pure 3:5-dinitro-2-m-nitrobenzenesulphonamidodiphenyl in needles, m. p.  $148^{\circ}$  (Found: C, 48.2; H, 2.9.  $C_{18}H_{12}O_8N_4S$  requires C, 48.7; H, 2.7%). This constitution was proved by hydrolysis: a solution of the compound (1 g.) in sulphuric acid (2 c.c.) was after  $\frac{1}{2}$  hour poured into water and neutralised with ammonia; the precipitated 3:5-dinitro-2-aminodiphenyl crystallised from alcohol in yellow plates, m. p.  $182^{\circ}$  (Bell, J., 1928, 2774).

(c) 3 : 5-Dinitro-2-*m*-nitrobenzenesulphonamidodiphenyl (2 g.) was added slowly to nitric acid (*d* 1.5; 6 c.c.), and the solution poured into water. The resulting gum was filtered off, dried, and crystallised from benzene. After benzene had been expelled by heating at 120° for several hours, impure 3 : 5 : 4'-*trinitro*-2-*m*-nitrobenzenesulphonamidodiphenyl was obtained as a pale yellow powder, m. p. 170—175° (Found : C, 44.9; H, 2.6.  $C_{18}H_{11}O_{10}N_3S$  requires C, 44.2; H, 2.3%). Hydrolysis of this gave 3 : 5 : 4'-*trinitro*-2-aminodiphenyl as prisms, m. p. 239° after recrystallisation from pyridine (Bell, J., 1928, 2775).

5-Nitro-2-*di-m*-nitrobenzenesulphonamidodiphenyl was obtained as a white powder, m. p. 222° (Found : C, 49.5; H, 2.9.  $C_{24}H_{16}O_{10}N_4S_2$  requires C, 49.3; H, 2.7%).

This compound (2 g.) was added to nitric acid (*d* 1.5; 5 c.c.); after  $\frac{1}{4}$  hour the solution was diluted with acetic acid, and the resulting precipitate collected and extracted with hot acetic acid; 5 : 4' (?) -*dinitro*-2-*di-m*-nitrobenzenesulphonamidodiphenyl, m. p. 240°, was left undissolved (Found : C, 45.4; H, 2.7.  $C_{24}H_{15}O_{12}N_5S_2$  requires C, 45.8; H, 2.4%). Attempts to hydrolyse this compound were unsuccessful.

*Bromination of 4-Methoxydiphenyl.*—To 4-methoxydiphenyl (8 g.) in chloroform (25 c.c.) was added bromine (7 g.) in chloroform (10 c.c.). The solution was evaporated, and the residue fractionally crystallised from petroleum; it then separated into 4'-*bromo*-4-methoxydiphenyl, plates, m. p. 144° (Found : C, 59.2; H, 4.0.  $C_{13}H_{11}OBr$  requires C, 59.3; H, 4.2%), and the more soluble 3-*bromo*-4-methoxydiphenyl, large prismatic needles, m. p. 79° (Found : C, 59.6; H, 4.4%). Both compounds were identified by comparison with the products obtained by the methylation of the corresponding bromo-4-hydroxydiphenyls.

3 : 4'-*Dibromo*-4-methoxydiphenyl.—(a) To a warm solution of 4'-*bromo*-4-methoxydiphenyl in chloroform was added bromine (1 mol.) in chloroform. The mixed solution was evaporated to small bulk and diluted with petroleum; 3 : 4'-*dibromo*-4-methoxydiphenyl, m. p. 134°, then separated.

(b) 3-Bromo-4-methoxydiphenyl treated as under (a) gave a product from which a 60% yield of purified 3 : 4'-*dibromo*-4-methoxydiphenyl was obtained (Found : C, 45.8; H, 2.9.  $C_{13}H_{10}OBr_2$  requires C, 45.5; H, 2.9%).

3 : 5-*Dibromo*-4-methoxydiphenyl, prepared by methylation of the corresponding phenol, crystallised from petroleum in needles, m. p. 87° (Found : C, 45.2; H, 2.7%).

3 : 5 : 4'-*Tribromo*-4-methoxydiphenyl, prepared by methylation of the corresponding phenol, crystallised from benzene in needles, m. p.

115° (Found: C, 36.7; H, 2.2.  $C_{13}H_{19}OBr_3$  requires C, 36.9; H, 2.1%).

*Dibromination of 4-p-Toluenesulphonamidodiphenyl.*—To 7 g. in warm chloroform (20 c.c.) was added bromine (7.5 g.) in chloroform (3 c.c.). The reaction was completed on the water-bath and after cooling the solution was filtered from the hydrobromide of 3:5:4'-tribromo-4-aminodiphenyl (free base, m. p. 149°; acetyl derivative, m. p. 256°). The filtrate on concentration deposited large prismatic needles containing chloroform of crystallisation (loss in weight on drying at 100° = 15.3%), which on recrystallisation from alcohol furnished pure 3:4'-dibromo-4-p-toluenesulphonamidodiphenyl in prisms, m. p. 130° (Found: C, 47.1; H, 3.1.  $C_{19}H_{13}O_2NBr_2S$  requires C, 47.4; H, 3.1%).

*Bromination of 4'-Bromo-4-p-toluenesulphonamidodiphenyl.*—To 5 g. in warm chloroform (20 c.c.) was added bromine (2 g.) in chloroform (3 c.c.). Treated as above, this gave a small amount of 3:5:4'-tribromo-4-aminodiphenyl hydrobromide, the remainder being almost pure 3:4'-dibromo-4-p-toluenesulphonamidodiphenyl.

3:4'-Dibromo-4-di-p-toluenesulphonamidodiphenyl formed needles, m. p. 238° (Found: C, 49.1; H, 3.3.  $C_{26}H_{21}O_4NBr_2S_2$  requires C, 49.1; H, 3.3%).

3:5-Dibromo-4-di-p-toluenesulphonamidodiphenyl, the only product which could be isolated from the interaction of 3:5-dibromo-4-p-toluenesulphonamidodiphenyl and p-toluenesulphonyl chloride (1 mol.) in pyridine solution, crystallised from pyridine in needles, m. p. 291° (Found: C, 49.5; H, 3.3%).

*Bromination of 2-p-Toluenesulphonamidodiphenyl.*—To 10 g. in chloroform (30 c.c.) was added bromine (5 g.) in chloroform (5 c.c.). After completion of the reaction the solution was evaporated to small bulk and diluted with light petroleum; 5-bromo-2-p-toluenesulphonamidodiphenyl then separated in almost theoretical yield. It was recrystallised from alcohol, forming stout needles, m. p. 115° (Found: C, 56.9; H, 4.0.  $C_{19}H_{16}O_2NBrS$  requires C, 56.7; H, 4.0%), and was identical with the compound obtained by the interaction of 5-bromo-2-aminodiphenyl (Scarborough and Waters, J., 1927, 94) and p-toluenesulphonyl chloride in pyridine solution.

Attempts to dibrominate 2-p-toluenesulphonamidodiphenyl resulted in the production of gummy masses containing 3:5-dibromo-2-aminodiphenyl (compare Scarborough and Waters, *loc. cit.*, p. 95).

*Methylation of 2-Aminodiphenyl.*—2-Aminodiphenyl was shaken with a considerable excess of methyl sulphate and sodium hydroxide, and the resultant oil extracted with ether. The ethereal extract was dried with sodium sulphate, evaporated, and the residue distilled in a vacuum. The distillate, b. p. 155°/10 mm., appeared to be a mixture

of substances, as it would not set solid. It was therefore dissolved in dilute hydrochloric acid and treated with a slight excess of sodium nitrite. The liquid was extracted with ether, the extract dried and evaporated, and the residue crystallised from alcohol. It gave stout prismatic needles of 2-nitrosomethylaminodiphenyl, m. p.  $70^{\circ}$  (Found: C, 73.7; H, 5.8.  $C_{13}H_{12}ON_2$  requires C, 73.6; H, 5.7%). From the aqueous layer left after the ether extraction, no substance corresponding in properties with a nitroso-tertiary base could be isolated.

*Acetylation of p-Toluenesulphon-m'-nitroanilide.*—This substance was dissolved in warm acetic anhydride and two drops of sulphuric acid were added. On cooling, p-toluenesulphon-m'-nitroacetanilide separated; it formed a white powder, m. p.  $165^{\circ}$ , after recrystallisation from acetic acid (Found: C, 54.2; H, 4.3.  $C_{15}H_{14}O_5N_2S$  requires C, 53.9; H, 4.2%).

By the same method m-nitrobenzenesulphon-p'-nitroanilide was converted into m-nitrobenzenesulphon-p'-nitroacetanilide, m. p.  $214^{\circ}$  (Found: C, 45.8; H, 3.4.  $C_{14}H_{11}O_7N_3S$  requires C, 46.0; H, 3.0%).

m-Nitrobenzenesulphon-m'-nitroanilide, prisms, m. p.  $151^{\circ}$  (Found: C, 44.9; H, 2.9.  $C_{12}H_9O_6N_3S$  requires C, 44.6; H, 2.8%), underwent vigorous nitration on dissolving in fuming nitric acid to give a mixture of polynitro-compounds.

Di-m-nitrobenzenesulphon-m'-nitroanilide, white powder, m. p.  $235^{\circ}$  (Found: C, 42.2; H, 2.6.  $C_{18}H_{12}O_{10}N_4S_2$  requires C, 42.5; H, 2.4%), was recovered unchanged after solution in fuming nitric acid.

m-Nitrobenzenesulphon-p-toluenesulphon-m'-nitroanilide, prepared by interaction of m-nitrobenzenesulphonyl chloride and p-toluenesulphon-m'-nitroanilide or of p-toluenesulphonyl chloride with m-nitrobenzenesulphon-m'-nitroanilide, formed small needles, m. p.  $207^{\circ}$  (Found: C, 47.4; H, 3.4.  $C_{19}H_{15}O_8N_3S_2$  requires C, 47.8; H, 3.1%).

Di-p-toluenesulphon-m'-nitroanilide, plates, m. p.  $180^{\circ}$  (Found: C, 54.1; H, 4.1.  $C_{20}H_{18}O_6N_2S_2$  requires C, 53.9; H, 4.0%).

m-Nitrobenzenesulphon-p'-nitro-o'-toluidide, prisms, m. p.  $189^{\circ}$  (Found: C, 46.0; H, 3.6.  $C_{13}H_{11}O_6N_3S$  requires C, 46.3; H, 3.3%).

Di-m-nitrobenzenesulphon-p'-nitro-o'-toluidide, m. p.  $201^{\circ}$  (Found: C, 43.2; H, 2.7.  $C_{19}H_{14}O_{10}N_4S_2$  requires C, 43.7; H, 2.7%).

Di-m-nitrobenzenesulphon-o'-nitro-p'-toluidide, prisms, m. p.  $215^{\circ}$  (Found: C, 43.8; H, 2.7%).

Di-m-nitrobenzenesulphon-o'-nitro-o'-toluidide, pale yellow needles, m. p.  $193^{\circ}$  (Found: C, 43.4; H, 2.6%).

Di-p-toluenesulphonanilide, large prismatic needles, m. p.  $183^{\circ}$  (Found: C, 59.7; H, 4.6.  $C_{20}H_{19}O_4NS_2$  requires C, 59.8; H, 4.7%).

CXXXV.—*Oxidation of p-Aminophenyltrimethylammonium Methosulphate and Some Quaternary Ammonium Derivatives.*

By AHMAD ZAKI.

It was proposed to compare the meta-directing power of the nitro- and the quaternary ammonium radical in one and the same nucleus by nitrating *p*-nitrophenyltrimethylammonium salts. It was, however, found impossible to synthesise the *p*-nitrophenyltrimethyl ammonium salt, a fact in itself not without significance. Methyl sulphate, very carefully purified, and *p*-nitrodimethylaniline interacted neither in benzene solution nor when heated under pressure. With methyl iodide, there was no reaction at 120° and carbonisation took place at 165°. *p*-Aminophenyltrimethylammonium chloride was then submitted to the oxidising action of Caro's salt, in the hope that the expected nitroso-derivative could be oxidised to the required nitro-compound. The product, however, proved to be the corresponding azoxy-compound:

When this was nitrated, a nitro-group entered each nucleus in the ortho-position with respect to the azoxy-group.

Although comparison between the nitro- and the quaternary ammonium group could not be undertaken in the direct manner proposed, yet the superiority of the latter group over the former in its characteristic effects is plainly indicated by the failure to obtain the quaternary nitroso-compound required as compared with the fact that *p*-nitroaniline when similarly oxidised gives about an 80% yield of *p*-nitrosonitrobenzene. The first stage in the oxidation of an aniline by Caro's salt gives the corresponding phenylhydroxylamine (Bamberger and Tschirner, *Ber.*, 1899, 32, 1675). A meta-directing group in the para-position would draw more or less heavily for electrons on the nuclear carbon atom carrying the hydroxylamino-radical, thereby increasing the conjugation of the tertiary nitrogen with the nucleus, at the same time decreasing its capacity for oxidation. The stronger the meta-directing group the less is the inclination of the hydroxylamino-nitrogen towards oxidation, and therefore the lower the state of oxidation of the final product. As an azoxy-compound represents a lower stage of oxidation than a nitroso-compound, the quaternary ammonium group must be more strongly meta-orienting than the nitro-group. A circumstance that gives strength to the ammonium radical in the present oxidation is that the reaction is carried out in aqueous solution and the salt is

therefore almost completely ionised. Oxidation could not be carried out in other solvents.

The same effect underlies the unreactivity of *p*-nitrodimethylaniline towards methyl sulphate and methyl iodide. If this is the true explanation, one would expect less resistance in the ortho-compound and still less in the meta-compound. Accordingly experiments were carried out on *o*- and *m*-nitrodimethylaniline as well as on dimethylaniline itself. The last compound reacted vigorously with methyl sulphate in the cold in benzene solution, with the *m*-compound boiling was necessary, and no reaction occurred with the *o*-compound. The resistance of the *o*-compound to this addition is, however, limited, as it reacts with methyl iodide on heating under pressure (Friedländer and Dinesmann, *Monatsh.*, 1898, 19, 636). The same order obtains for the solubility of these anilines in acids.

*p*-Dimethylaminobenzaldehyde, *p*-aldehydophenyltrimethylammonium methosulphate, and nitrosodimethylaniline condensed readily with diketohydrindene and with *p*-aminophenyltrimethylammonium chloride.

#### EXPERIMENTAL.

*Action of Methyl Sulphate on Nitrosodimethylaniline.*—The two substances reacted very slowly in benzene. In molecular proportion, without a solvent or in ethereal solution, they reacted vigorously. The dark red oily product was washed with ether and benzene and left in a vacuum over sulphuric acid for many weeks; it thickened considerably but failed to crystallise (Found: N, 9.9.  $C_{10}H_{16}O_5N_2S$  requires N, 10.2%). In aqueous solution it gave barium sulphate on treatment with barium chloride, but no precipitate with perchloric or picric acid. Boiling alkali liberated a volatile base having the odour of dimethylamine. The compound would therefore appear to be the  $\psi$ -methosulphate corresponding to the  $\psi$ -methiodide prepared by Knorr (*Ber.*, 1897, 30, 934).

*p*-Acetamidophenyltrimethylammonium Methosulphate.—To a boiling benzene solution of *p*-acetamidodimethylaniline (1 mol.) was added a benzene solution of methyl sulphate (1.5 mols.), with shaking. After 10 minutes' boiling, the mixture was cooled and the colourless crystals were collected, washed with benzene (yield, practically theoretical) and recrystallised from alcohol; the methosulphate then melted at 165° (Found: C, 47.2; H, 6.5.  $C_{12}H_{20}O_5N_2S$  requires C, 47.4; H, 6.6%).

*p*-Aminophenyltrimethylammonium Methosulphate.—The preceding compound (1 g.) was heated on the water-bath with 10 c.c. of concentrated hydrochloric acid for 2½ hours: titration with

standard sodium nitrite then showed that the hydrolysis was complete. Heating with concentrated sulphuric acid (2 c.c.) and water (3 c.c.) for 5 hours caused almost complete hydrolysis, but the use of smaller concentrations of the acid or heating for a shorter time resulted in incomplete hydrolysis.

*p*-Acetamidophenyltrimethylammonium methosulphate (3 g.) was hydrolysed with hydrochloric acid and then diazotised with sodium nitrite (0.68 g.) at 0°. The cold solution was neutralised with sodium carbonate and mixed with  $\alpha$ -naphthol (1.44 g.) dissolved in an equivalent of aqueous sodium carbonate. After a few hours, addition of perchloric acid to the crimson solution precipitated *p*- $\alpha$ -naphtholazophenyltrimethylammonium perchlorate, which crystallised from 90% alcohol in red needles, m. p. 247° (decomp.) (Found: N, 10.3.  $C_{19}H_{20}O_5N_3Cl$  requires N, 10.3%).

The perchlorate of the  $\beta$ -naphthol compound, similarly prepared, had m. p. 267° (decomp.) (Found: N, 10.1%).

A similarly diazotised solution was treated with  $\alpha$ -naphthylamine in dilute hydrochloric acid. *p*- $\alpha$ -Aminonaphthaleneazophenyltrimethylammonium chloride, which was slowly precipitated, crystallised from alcohol-dilute hydrochloric acid in long reddish-violet needles, m. p. 196° (decomp.) (Found: N, 14.5.  $C_{19}H_{21}N_4Cl.HCl$  requires N, 14.8%).

*p*-Dimethylaminobenzeneazophenyltrimethylammonium Perchlorate.—Molecular quantities of nitrosodimethylaniline and *p*-aminophenyltrimethylammonium chloride were boiled together in hydrochloric acid solution and perchloric acid was then added. The long brown needles of the perchlorate that had formed after 24 hours were recrystallised from dilute perchloric acid solution. They charred above 280° (Found: N, 11.4.  $C_{17}H_{23}O_4N_4Cl.HClO_4$  requires N, 11.6%).

*p*-Dimethylaminobenzylidene - *p*-aminophenyltrimethylammonium Perchlorate.—When *p*-dimethylaminobenzaldehyde (1 mol.) and *p*-aminophenyltrimethylammonium chloride (1 mol.), each in hydrochloric acid solution, were mixed, a greenish-yellow colour developed at once, indicating that the condensation in this case takes place at the ordinary temperature. The mixture was boiled to complete the reaction, concentrated, and perchloric acid added. The copious precipitate obtained crystallised from dilute perchloric acid solution in orange-red needles, m. p. 253° (decomp.) (Found: N, 8.6.  $C_{18}H_{24}O_4N_3Cl.HClO_4$  requires N, 8.7%).

*Oxidation of p*-Aminophenyltrimethylammonium Chloride.—The solution in hydrochloric acid obtained by hydrolysis of the acetyl compound (see p. 1079) was neutralised with aqueous sodium hydroxide, cooled with ice, and treated with the equivalent amount

of ammonium persulphate made into Caro's salt by Willstätter's method (*Ber.*, 1909, **42**, 1842). The deep brownish-red solution of azoxybenzene-*pp'*-bistrimethylammonium chloride produced was kept for several hours and the following three salts were then prepared from it.

(1) The *perchlorate*,  $\text{ON}_2(\text{C}_6\text{H}_4\cdot\text{NMe}_3\cdot\text{ClO}_4)_2$ , precipitated by the addition of perchloric acid to the neutral or slightly alkaline solution, crystallised from a mixture of dilute aqueous perchloric acid and alcohol in needles which varied in colour from yellow to brown and red. It melted and decomposed at  $268^\circ$ , sometimes with violent explosion (this property made the estimation of carbon and hydrogen impossible) (Found: N, 10.7, 10.6, 10.8; Cl, 13.7.  $\text{C}_{18}\text{H}_{26}\text{O}_9\text{N}_4\text{Cl}_2$  requires N, 10.9; Cl, 13.8%), and was identical with the synthetic perchlorate described on p. 1084.

(2) The *picrate*, precipitated from the neutral solution of the salt with aqueous picric acid, crystallised from much acetone and water (10:8) after several hours in needles; m. p.  $244^\circ$  (decomp.). It was analysed after several crystallisations. Notwithstanding its explosiveness, determinations of carbon and hydrogen were successful twice, a large excess of copper oxide and a very long copper spiral being used (Found: C, 46.9, 46.7; H, 4.2, 4.2; N, 18.0.  $\text{C}_{30}\text{H}_{30}\text{O}_{15}\text{N}_{10}$  requires C, 46.7; H, 4.2; N, 18.2%).

(3) The ferricyanide was obtained by the addition of a solution of potassium ferricyanide. This salt is a very sparingly soluble, uncrystallisable, greenish-yellow substance. When it is boiled with a slight excess of copper sulphate solution, and the filtered liquid is freed from copper and sulphate ions by baryta, and then from barium by passage of carbon dioxide, the final filtrate contains the quaternary carbonate, from which other salts can be obtained by neutralising the solution with the requisite acid.

The chloride was obtained by boiling the picrate with a large excess of concentrated hydrochloric acid. After cooling, the picric acid was removed by filtration and by repeated extraction with ether, and the filtrate evaporated to dryness on the water-bath. The deep red, glassy residue, which was extremely deliquescent, was crystallised from much absolute alcohol and dried in a vacuum desiccator. The straw-coloured needles of the chloride quickly reddened in the air. The highest melting point observed was  $252^\circ$  (decomp., preceded by considerable shrinkage).

The iodide was precipitated when solutions of the chloride and of sodium iodide in alcohol were mixed and was recrystallised from much methyl alcohol and dried in a vacuum desiccator; the orange plates obtained melted at  $198^\circ$  (decomp.). In the air the iodide absorbed moisture and turned brown.

*Volumetric Analysis of Azoxybenzene-pp'-bistrimethylammonium Perchlorate.*—This application of Knecht and Hibbert's titanous chloride method ("New Reduction Methods in Volumetric Analysis," 1925) to the estimation of the azoxy-group is novel. Through a mixture of 0.0300 g. of the perchlorate, 100 c.c. of water, and 10 c.c. of concentrated hydrochloric acid, carbon dioxide was passed for 10 minutes. The solution was then warmed to 60–70° and titrated with standard titanous chloride until the yellow colour was destroyed. Towards the end of the titration, at least 3 minutes were allowed after the addition of every 0.5 c.c. of the chloride, as the reduction was then by no means instantaneous. The end-point was not very sharp (Titres found : 26.2, 26.4, 26.0, 27.2 c.c. Calc. : 25.8 c.c.). The presence of the perchlorate ion has no effect on the titanous chloride at the dilution used, as was proved by blank experiments on potassium chlorate solutions. The indirect method (excess of titanous chloride and back-titration) was useless.

*Nitration of Azoxybenzene-pp'-bistrimethylammonium Salts.*—Nitric acid alone had no nitrating action on the azoxy-chloride; when the solution was evaporated to dryness, the *nitrate* remained. This crystallised from anhydrous methyl alcohol in small, light orange, needle-like prisms, m. p. 220–222° (decomp.). It was hygroscopic, but was practically insoluble in absolute alcohol and acetone (Found : N, 18.8.  $C_{18}H_{26}O_7N_6$  requires N, 19.2%).

When the nitrate (1.5 g.) was added to concentrated nitric acid (10 c.c.; *d* 1.42), followed by concentrated sulphuric acid (15 c.c.), a vigorous action took place with evolution of oxides of nitrogen in the cold. The solution was boiled for 1.5 hours, the resulting clear yellow liquid diluted and neutralised with sodium carbonate, and perchloric acid added. The *dinitroazoxybenzene-pp'-bistrimethylammonium perchlorate* obtained crystallised from aqueous alcohol in deep brown crystals, m. p. 265° (decomp.) {Found : N, 13.9.  $ON_2[C_6H_3(NO_2) \cdot NMe_3 \cdot ClO_4]_2$  requires N, 14.0%}. The corresponding *chloride*, obtained from the picrate by treatment with concentrated hydrochloric acid as previously described, crystallised from dilute hydrochloric acid in thin, reddish-brown, rectangular plates which melted with decomposition (Found : N, 17.3.  $C_{18}H_{24}O_5N_6Cl_2$  requires N, 17.7%).

The diamine produced by complete reduction of the nitro-compound with zinc and hydrochloric acid was an *o*-diamine, for it gave a deep wine colour with ferric chloride and condensed instantly with phenanthraquinone on the addition of a drop of alkali, giving a dark green precipitate.

*Diketohydrindene Condensations.*—These were undertaken with the object of comparing the reactivities of the nitroso- and the

aldehydo-group and of studying the effect on the reactivity of a quaternary ammonium group in the para-position.

*With nitrosodimethylaniline.* Molecular quantities of diketohydrindene and nitrosodimethylaniline were boiled together in absolute alcohol for 3 minutes. At once, a deep blood-red colour developed and a crystalline compound separated; this, after being washed with absolute alcohol and dried, melted at  $210^{\circ}$  (decomp.) (Found: N, 9.8.  $C_{17}H_{14}O_2N_2$  requires N, 10.1%).

*With p-dimethylaminobenzaldehyde.* The condensation was carried out as in the last experiment and took place just as quickly. The product separated from alcohol in crystals with a blue lustre, m. p.  $99-100^{\circ}$  (compare Noelting and Blum, *Ber.*, 1901, 34, 2467).

*With p-aldehydophenyltrimethylammonium methosulphate.* Equimolecular quantities of the methosulphate (see below) and diketohydrindene were boiled in absolute alcohol. The colour changed from yellow to orange and the reaction was complete in less than 5 minutes. Water was then added and the solution was extracted with benzene to remove any excess of diketohydrindene and boiled. On standing, the product separated in deep orange needles, which were washed with a little alcohol and dried; m. p.  $243^{\circ}$  (decomp.) (Found: N, 3.5.  $C_{20}H_{21}O_6NS$  requires N, 3.5%).

*With the azoxy-quaternary salts.* These were recovered unaltered when a similar condensation was tried with them.

*p-Aldehydophenyltrimethylammonium Methosulphate.*—Pure dry methyl sulphate was mixed in slight excess with *p*-dimethylaminobenzaldehyde and warmed very gently to start the reaction, which proceeded rather violently. The voluminous frothy product, on cooling, changed to a small, dark red, glassy mass which became crystalline in a few hours. The methosulphate, recrystallised from hot methyl alcohol, formed long yellow needles, which were washed with ether dried over sodium. They were extremely soluble in water and melted at  $138-139^{\circ}$  (Found: N, 5.2; OMe, nil.  $C_{11}H_{17}O_5NS$  requires N, 5.1%).

The perchlorate was precipitated from a solution of the methosulphate as an oil which slowly solidified. It crystallised from dilute perchloric acid solution after some time in yellow plates, m. p.  $140-141^{\circ}$  after being washed with absolute alcohol and dried. It was appreciably soluble in water and puffed strongly when heated in a flame (Found: N, 5.4.  $C_{10}H_{14}O_5NCl$  requires N, 5.3%).

*Benzylideneaniline - pp'-bistrimethylammonium Perchlorate.*—*p*-Aminophenyltrimethylammonium chloride in hydrochloric acid solution was boiled with an equivalent quantity of *p*-aldehydophenyltrimethylammonium methosulphate and perchloric acid was then added; after 2 days, long, thin, slightly yellow needles

had formed. These when dry became deep red at 240° and charred at about 260°. Heated in a flame, the compound exploded (Found: N, 8.2.  $C_{19}H_{27}O_8N_3Cl_2$  requires N, 8.4%).

*Addition of Methyl Sulphate to pp'-Tetramethyldiaminoazoxybenzene.*—Methyl sulphate ( $1\frac{1}{2}$  mols.) was added to the base (1 mol.), and enough benzene to ensure its solution on boiling, which was continued under reflux for an hour. The benzene was then decanted, the product washed with ether, and the coffee-brown crystalline residue dissolved in water. Addition of perchloric acid precipitated a perchlorate which, after being crystallised from alcohol-dilute perchloric acid solution and dried, melted, alone or mixed with the azoxy-perchlorate described on p. 1081, at 268° (decomp.). The two picrates also were identical.

*m-Nitrophenyltrimethylammonium Methosulphate.*—A mixture of *m*-nitrodimethylaniline (28 g.; 1 mol.); methyl sulphate (30 g.; 1.5 mols.), and benzene (25 c.c.) was heated in a water-bath for 1 hour. The heavy oil produced solidified on cooling, and after decantation of the benzene and washing with ether the residue crystallised from slightly aqueous alcohol in thin needle-like plates, m. p. 220°, which were very soluble in water (Found: N, 9.5.  $C_{10}H_{16}O_6N_2S$  requires N, 9.6%).

The *picrate* crystallised from water in yellow prismatic plates, m. p. 150° (decomp.) (Found: N, 17.1.  $C_{15}H_{15}O_9N_5$  requires N, 17.1%), and the *perchlorate* from dilute perchloric acid solution in white feathery needles, m. p. 230–232° (decomp.) (Found: N, 9.9.  $C_9H_{13}O_6N_2Cl$  requires N, 10.0%).

The *iodide*, obtained by adding a concentrated solution of sodium iodide to a solution of the methosulphate, crystallised from water in large white needles, m. p. 202° (Found: N, 8.9.  $C_9H_{13}O_6N_2I$  requires N, 9.1%).

*Phenyltrimethylammonium Methosulphate.*—When a solution of dimethylaniline (30 g.; 1 mol.) in benzene (20 c.c.) was treated with methyl-sulphate (30 g.; 1 mol.), it soon got hot and the benzene boiled away even through a reflux condenser. The oily product quickly solidified and then crystallised from acetone in colourless needles. The *perchlorate*, precipitated with perchloric acid from a solution of the methosulphate, crystallised from dilute perchloric acid solution in colourless needles (Found: N, 5.8.  $C_9H_{14}O_4NCl$  requires N, 5.9%).

CXXXVI.—*The Action of Fuming Nitric Acid on the 4-Halogeno-2 : 6-dibromo-phenols and -anisoles. Anomalous Behaviour of Fluorine Derivatives.*

By HERBERT HENRY HODGSON and JOSEPH NIXON.

KOHN and ROSENFELD (*Monatsh.*, 1925, **46**, 101) prepared 4-chloro-2 : 6-dibromo-3-nitro- and -3 : 5-dinitro-anisoles by the nitration of 4-chloro-2 : 6-dibromoanisole and of the mononitrated product. In an attempt to repeat their reaction with 4-fluoro-2 : 6-dibromoanisole, the product obtained was 2 : 6-dibromo-*p*-benzoquinone and consequently it appeared of interest to submit each of the 4-halogeno-2 : 6-dibromo-phenols and -anisoles to the action of fuming nitric acid in order to ascertain the rôle of the 4-halogen. All the phenols except the 4-iodo-compound (which was destroyed) gave 2 : 6-dibromo-*p*-benzoquinone, Kohn and Rosenfeld's results with 4-chloro-2 : 6-dibromoanisole (*loc. cit.*) were confirmed, and 2 : 4 : 6-tribromoanisole behaved similarly, *i.e.*, was mono- and di-nitrated. 4-Iodo-2 : 6-dibromoanisole, however, reacted anomalously to form 2 : 6-dibromo-4-nitroanisole.

The mechanism of reaction in the case of 4-fluoro-2 : 6-dibromoanisole can be regarded as a three-stage operation, *viz.*, the combined general effect (Allan, Oxford, Robinson, and Smith, J., 1926, 401) of the three halogens rendering the methyl group sufficiently mobile (positive) for detachment and oxidation (I); rearrangement of the residue to the quinonoid form (II), facilitated by the same general effect; and subsequent attack by oxygen (III) with separation of ionic fluorine (IV). The same mechanism will also apply to the phenols.

In the 4-chloro- and 4-bromo-2 : 6-dibromoanisoles, the combined general effect of the halogens is inadequate to produce the necessary reactivity (positivity) of the methyl group, and so normal nitration occurs. The above general effect is still further reduced in 4-iodo-

2 : 6-dibromoanisole, and consequently the methyl group remains intact, but the electron-donating power of the iodine is now sufficient to enable kationoid attack by the nitric acid to take place at the 4-carbon atom with nitration and elimination of iodine.

That fluorine exerts a far greater general effect than the other halogens is shown by the relatively much greater solubility of *p*-fluorophenol in water (indicating considerable ionisation) than is exhibited by the other *p*-halogenophenols, the order being  $F > Cl > Br > I$ , in accord with the order of general effects.

#### EXPERIMENTAL.

*Preparation of p-Fluorophenol.*—*p*-Fluoronitrobenzene, obtained in 25% yield by the authors' method for *m*-fluoronitrobenzene (J., 1928, 1879), was reduced by means of tin and hydrochloric acid to *p*-fluoroaniline, which was converted into *p*-fluorophenol by the standard procedure (Hodgson, E.P. 200,714).

4-Fluoro-2 : 6-dibromophenol was obtained when a solution of *p*-fluorophenol (11.2 g.) in water (250 c.c.) was treated gradually and shaken vigorously with a solution of bromine (10 c.c.; 2 mols.) in water (80 c.c.) containing potassium bromide (27 g.). The voluminous white precipitate produced was filtered off and washed with water; it crystallised from dilute alcohol in colourless needles, m. p. 48° (Found : Br, 59.2.  $C_6H_3OFBr_2$  requires Br, 59.3%).

4-Fluoro-2 : 6-dibromoanisole.—Methylation of the above phenol was best carried out by Haworth and Lapworth's procedure in xylene solution with methyl sulphate and potassium carbonate (J., 1923, 123, 2986), the direct method with methyl sulphate and caustic alkali giving poor yields. The product crystallised from light petroleum in small colourless needles, m. p. 55° (Found : Br, 56.5.  $C_7H_5OFBr_2$  requires Br, 56.3%).

*Action of Fuming Nitric Acid on the 4-Halogeno-2 : 6-dibromophenols and -anisoles.*—*General procedure.* The substance (5 g.) was dissolved in ice-cold nitric acid (50 c.c.;  $d$  1.5), the mixture poured after 15 minutes on ice, and the resulting precipitate crystallised from alcohol.

*Results.* (1) 4-Fluoro-2 : 6-dibromo-phenol and -anisole each gave 2 : 6-dibromo-*p*-benzoquinone, m. p. and mixed m. p. 130—131° (Found : Br, 59.9, 60.2. Calc. : Br, 60.1%).

(2) 4-Chloro-2 : 6-dibromophenol gave 2 : 6-dibromo-*p*-benzoquinone, whereas 4-chloro-2 : 6-dibromoanisole gave 4-chloro-2 : 6-dibromo-3-nitroanisole, m. p. 58°, and this on further nitration with a mixture of fuming nitric and concentrated sulphuric acids gave 4-chloro-2 : 6-dibromo-3 : 5-dinitroanisole, m. p. 146° (compare Kohn and Rosenfeld, *loc. cit.*)

(3) 2:4:6-Tribromophenol gave 2:6-dibromo-*p*-benzoquinone, and 2:4:6-tribromoanisole gave 2:4:6-tribromo-3-nitroanisole, which crystallised in small colourless plates, m. p. 82° (Found: N, 3.9; Br, 61.8.  $C_7H_4O_3NBr_3$  requires N, 3.6; Br, 61.5%), and gave 2:4:6-tribromo-3:5-dinitroanisole, which crystallised from alcohol in colourless needles, m. p. 148° (Found: N, 6.6; Br, 55.5.  $C_7H_3O_5N_2Br_3$  requires N, 6.4; Br, 55.2%), on further nitration as above.

(4) 4-Iodo-2:6-dibromophenol (m. p. 105°; prepared by direct dibromination of *p*-iodophenol in glacial acetic acid; compare King and McCombie, J., 1913, 103, 222) was completely destroyed by ice-cold fuming nitric acid.

2:6-Dibromo-4-iodoanisole, prepared from the above phenol by Haworth and Lapworth's method (*loc. cit.*), crystallised from light petroleum in colourless needles, m. p. 78° (0.1310 g. gave 0.2040 g. of mixed silver halides. Calc.: 0.2036 g.). On nitration with fuming nitric acid as above, 2:6-dibromo-4-nitroanisole was obtained, which crystallised in long colourless needles; the m. p. and mixed m. p. with an authentic specimen, prepared by dibromination of *p*-nitrophenol and subsequent methylation, was 122° (Found: N, 4.8; Br, 51.7. Calc.: N, 4.5; Br, 51.5%).

The authors desire to thank the British Dyestuffs Corporation for gifts of chemicals.

TECHNICAL COLLEGE, HUDDERSFIELD.

## CXXXVII.—*Polycyclic Aromatic Hydrocarbons. Part I.*

### 1- and 2-Phenylanthracenes and Derivatives of 1:2-Benzanthracene.

By JAMES WILFRED COOK.

THE substance responsible for the cancer-producing properties of tars and mineral oils is probably a polycyclic aromatic hydrocarbon of very high boiling point, and the hydrocarbons to be described in this and subsequent communications have been prepared in the course of a search for an active carcinogenic substance of known structure. The correlated experiments on animals are being conducted by E. L. Kennaway and the fluorescence spectra of the pure hydrocarbons have been examined by I. Hieger for comparison with the characteristic banded spectrum of tars and other cancer-producing mixtures (for example, the products of the action of

aluminium chloride upon 1:2:3:4-tetrahydronaphthalene). The results of Kennaway and Hieger are published elsewhere (*Biochem. J.*, in the press).

Of the three possible structural isomerides of monophenylanthracene only the *meso*-compound has hitherto been described. 1- and 2-Phenylanthracenes have now been prepared, the former by pyrolysis of 2-*o*-toluoyldiphenyl (I; R = Ph) obtained from magnesium 2-diphenyl iodide and *o*-toluoyl chloride, and the latter by reduction of 2-phenyl-9-anthrone :

1-Phenylanthracene resembles 1-methylanthracene in its ready solubility and fusibility, whereas 2-phenylanthracene, like the 2-methyl compound, is sparingly soluble and high-melting. When *di-o*-tolyl ketone (I; R = CH<sub>3</sub>), prepared from magnesium *o*-tolyl bromide and *o*-toluoyl chloride, was boiled for a long time, it underwent the condensation of an *o*-methyl benzophenone derivative to an anthracene derivative discovered by Elbs (*Ber.*, 1884, **17**, 2848; 1886, **19**, 408; *J. pr. Chem.*, 1886, **33**, 185; 1887, **35**, 471; 1890, **41**, 1) and recently extended by Morgan and Coulson (*J.*, 1929, 2203, 2551) and by Clar and his co-workers (*Ber.*, 1929, **62**, 351, 940, 951, 1574, 3021). The product was not 1-methylanthracene, however, but anthracene itself, one methyl group being eliminated from the ketone. This observation emphasises the need for confirmation of structures assigned to  $\alpha$ -alkylanthracenes obtained by pyrogenic means. For instance, H. Meyer and Bernhauer (*Monatsh.*, 1929, **53** and **54**, 731) obtained an anthracene hydrocarbon, m. p. 199°, by distillation of benzyl-*o*-xylene, but were in error in regarding their product as 1-methylanthracene, which has been shown by several investigators to melt at 86° (*e.g.*, von Braun and Bayer, *Ber.*, 1926, **59**, 916). The formation of 1:3-dimethylanthracene by pyrolysis of benzylmesitylene (Louise, *Ann. Chim.*, 1885, **6**, 185) shows that this loss of  $\alpha$ -methyl groups is not universal. 2-Methylanthracene and its derivatives have frequently been obtained by pyrogenic methods (*e.g.*, *Eng. Pats.* 251,270; 253,911; Elbs, *loc. cit.*; Morgan and Coulson, *loc. cit.*), but no case of loss of a  $\beta$ -methyl group appears to have been recorded.

6-Phenyl-1:2-benzanthracene (III) was formed by pyrolysis of 1-*p*-phenylbenzoyl-2-methylnaphthalene (II), obtained from 2-methylnaphthalene and *p*-phenylbenzoyl chloride :

Reduction of 3-methyl-1:2-benzanthraquinone (Scholl and Tritsch, *Monatsh.*, 1911, **32**, 997) with zinc dust and potassium hydroxide, although slow and incomplete, led to 3-methyl-1:2-benzanthracene. 1:2-Benzanthraquinone reacted normally with magnesium phenyl bromide to give 9:10-diphenyl-9:10-dihydro-1:2-benzanthraquinol, which was reduced by zinc dust in boiling acetic acid to 9:10-diphenyl-1:2-benzanthracene. Subsequent to this preparation these two compounds were described by Clar (*Ber.*, 1930, **63**, 118).

1:2-Benz-10-anthrone (IV), formed by dehydration of 1-naphthylphenylmethane-2'-carboxylic acid, was converted by benzoic anhydride in pyridine solution into 1:2-benzanthranyl 10-benzoate, m. p. 171°, whereas reduction of 1:2-benzanthraquinone with aluminium powder and concentrated sulphuric acid led to an anthrone (V), which gave the isomeric 1:2-benzanthranyl 9-benzoate, m. p. 202—203°. These two benzoates were obtained by Barnett and Matthews (*Chem. News*, 1925, **130**, 339) from the mixture of anthrones obtained by reduction of benzanthaquinone with tin and hydrochloric acid and the methods of preparation now given require transposition of the orientations suggested by these authors.

1:2-Benz-10-anthrone reacted normally with magnesium benzyl chloride. The resulting 10-hydroxy-10-benzyl-9:10-dihydro-1:2-benzanthracene was dehydrated to 10-benzyl-1:2-benzanthracene, and the same hydrocarbon was also formed in small yield when 1:2-benzanthracene was heated with benzyl chloride and zinc dust in carbon disulphide solution (compare Lippmann and Fritsch, *Monatsh.*, 1904, **25**, 793). Treatment of 1:2-benz-10-anthrone with magnesium methyl iodide yielded only resinous products, and the same remark applies to the action of magnesium benzyl chloride on 1:2-benz-9-anthrone.

With the object of obtaining intermediate compounds from which 9:10-dibenzyl-1:2-benzanthracene might be prepared by a method analogous to that previously used for dibenzyl-

anthracene (Barnett and Cook, J., 1928, 567), 1:2-benz-9-anthrone and 1:2-benz-10-anthrone were heated with benzyl chloride and potassium hydroxide solution. Both anthrones yielded only resinous products. When 1:2-benzanthraquinone was heated with benzyl chloride and alkali in presence of sodium hydrosulphite, similar resinous products were formed, together with a small amount of a substance which had the composition and properties of a *benzyloxybenzanthracene*. Such a compound might conceivably be formed by monobenylation and reduction of 1:2-benzanthraquinol. The anticipated benzyhydroxybenzanthrone was not isolated.

3-Acenaphthylphenylmethane-2'-carboxylic acid was completely sulphonated in 2 hours by concentrated sulphuric acid at room temperature, but was dehydrated by zinc chloride to acenaphthanthrone (VI), not obtained pure but characterised as the acetate of its enol. This anthrone was reduced by zinc dust and sodium hydroxide to *acenaphthanthracene* (VII) and was converted by magnesium benzyl chloride into an unstable dihydroanthranol which passed into *benzylacenaphthanthracene* (VIII):

An attempt to condense acenaphthylene with phthalic anhydride was unsuccessful, the acenaphthylene being polymerised by aluminium chloride to the polyacenaphthylene, m. p.  $345\text{--}350^\circ$ , described by Dziewoński and Leyko (*Ber.*, 1914, 47, 1685).

Experiments are in progress which have as their object the preparation of derivatives of chrysene and other condensed 4-ring hydrocarbons together with more highly condensed compounds. It is probable that 3:4-benzphenanthrene has not yet been prepared, since the compound so described by Weitzenböck and Lieb (*Monatsh.*, 1912, 33, 564) may equally well be 1:2-benzanthracene, which has more recently been shown to have the same m. p. as their hydrocarbon.

## EXPERIMENTAL.

### *Phenylanthracenes.*

*o*-Iododiphenyl.—This compound was mentioned by Bachmann and Clarke (*J. Amer. Chem. Soc.*, 1927, 49, 2049), who gave no description of its preparation. It was readily obtained in 70% yield by the addition of a concentrated aqueous solution of potassium

iodide to a diazotised solution of *o*-aminodiphenyl\* in dilute sulphuric acid. The crude *iodo*-compound was twice distilled in a vacuum and then formed a colourless viscous oil, b. p.  $140^{\circ}/3-4$  mm. (Found: C, 53.2; H, 3.5.  $C_{12}H_9I$  requires C, 51.4; H, 3.2%). The high figure obtained for carbon was probably due to the presence of diphenyl, but the substance was sufficiently pure for the subsequent experiments.

*2-o-Toluoyldiphenyl* (I; R = Ph).—A Grignard solution prepared from *o*-iododiphenyl (20 g.), magnesium turnings (1.7 g.), and ether (45 c.c.) was added slowly, with agitation, to *o*-toluoyl chloride (10 c.c.) diluted with ether (30 c.c.) and cooled to  $-10^{\circ}$ . After  $\frac{1}{2}$  hour at  $-10^{\circ}$ , the solution was allowed to warm slowly and then boiled for an hour. The product was decomposed with ice and hydrochloric acid, and the crude ketone freed from unchanged acid chloride by passing steam into its alkaline suspension for  $\frac{1}{2}$  hour. It was then dried in ethereal solution with sodium sulphate and distilled in a vacuum. The chief fraction was collected at  $190-192^{\circ}/3-4$  mm. The distillate, a yellowish syrup, was obtained in 55% yield as a colourless crystalline powder, m. p.  $66-67^{\circ}$ , by crystallisation from light petroleum (Found: C, 88.3; H, 5.95.  $C_{20}H_{16}O$  requires C, 88.2; H, 5.9%). This *ketone* gave a yellow solution in concentrated sulphuric acid.

*1-Phenylantracene*.—The aforesaid ketone (5 g.) was boiled gently for  $7\frac{1}{2}$  hours, and the product distilled. The red wax-like distillate was triturated with acetic acid and the solid in suspension was collected after 2 days and recrystallised from alcohol. The product (0.85 g.) was obtained pure by recrystallisation from ligroin and then twice from alcohol. It formed small, pale yellow prisms, m. p.  $110-112^{\circ}$ , readily soluble in the usual media (Found: C, 94.1; H, 5.6.  $C_{20}H_{14}$  requires C, 94.5; H, 5.5%).

*2-Phenylantracene*.—2-Phenyl-9-anthrone (5 g.) (Scholl and Neovius, *Ber.*, 1911, **44**, 1078) was reduced with zinc dust (15 g.) activated with copper, and 2*N*-sodium hydroxide solution (100 c.c.). The product, after extraction of the zinc with hydrochloric acid, was recrystallised from methyl ethyl ketone and then from ethyl acetate. 2-Phenylantracene formed small, pale yellow leaflets, m. p.  $207-207.5^{\circ}$ , sparingly soluble in most media (Found: C, 94.2; H, 5.4%).

#### *Di-o-tolyl Ketone.*

A Grignard solution prepared from *o*-bromotoluene (36.5 g.), magnesium turnings (5.1 g.), and ether (100 c.c.) was added slowly, with agitation, to *o*-toluoyl chloride (30 c.c.) diluted with ether (100

\* The author is indebted to Professor G. T. Morgan, F.R.S., for a gift of the *o*-aminodiphenyl used in this experiment.

c.c.) at  $-10^{\circ}$ . After  $\frac{1}{2}$  hour the solution was allowed to warm and then boiled for an hour. The product was decomposed with ice and hydrochloric acid, and the crude *ketone* freed from unchanged *o*-toluoyl chloride and distilled (b. p.  $307-308^{\circ}$ ). The solid distillate was recrystallised from methyl alcohol (yield, 25 g.) and then formed colourless needles, m. p.  $64-67^{\circ}$  (Found: C, 85.6; H, 6.5.  $C_{15}H_{14}O$  requires C, 85.7; H, 6.7%).

*Pyrolysis.* Di-*o*-tolyl ketone (5 g.) was boiled gently for 24 hours, and the product distilled. The distillate was diluted with alcohol and the resulting crystals were collected and recrystallised from ethyl acetate, forming colourless plates, shown by the method of mixed melting points to consist of pure anthracene. After removal of the solvents from the mother-liquor, oxidation of the residue with chromic acid in glacial acetic acid yielded anthraquinone but no anthraquinonecarboxylic acid.

#### *Derivatives of 1:2-Benzanthracene.*

6-*Phenyl-1:2-benzanthracene*.—(i) Anhydrous aluminium chloride (11.5 g.) was slowly added to 9.4 g. of *p*-phenylbenzoyl chloride\* (Scholl and Seer, *Annalen*, 1912, 394, 148; Wieland and others, *ibid.*, 1927, 452, 7) and 2-methylnaphthalene (6.5 g.) in carbon disulphide (50 c.c.). After 3 hours, the reaction was completed by  $\frac{1}{2}$  hours' heating on the water-bath. The product was decomposed with ice and hydrochloric acid, the carbon disulphide distilled off, and the steam-volatile by-products removed. The residue was dried and distilled in a vacuum (b. p.  $265^{\circ}/4-5$  mm.). The distillate, an amber-coloured resin, was dissolved in hot ligroin, and the solution cooled. The resulting crystalline solid was obtained analytically pure by two recrystallisations from methyl alcohol. 1-*p*-Phenylbenzoyl-2-methylnaphthalene (II) formed colourless needles, m. p.  $109-110^{\circ}$  (Found: C, 89.4; H, 5.6.  $C_{24}H_{18}O$  requires C, 89.4; H, 5.6%). The solution in sulphuric acid was cherry-red.

(ii) 1-*p*-Phenylbenzoyl-2-methylnaphthalene (4 g.) was boiled gently for  $\frac{1}{2}$  hour, and the dark-coloured residue distilled. The distillate was recrystallised from benzene (yield, 0.3 g.) and then from ethyl acetate. 6-*Phenyl-1:2-benzanthracene* (III) formed pale yellow leaflets, m. p.  $240-241^{\circ}$  (Found: C, 94.4; H, 5.3.  $C_{24}H_{16}$  requires C, 94.7; H, 5.3%). This compound gave a crimson solution with a yellowish-green fluorescence in concentrated sulphuric acid. On gentle warming, the colour became purple and then

\* *p*-Phenylbenzoic acid was obtained in good yield by oxidation of 4-acetyldiphenyl (Adam, *Ann. Chim.*, 1888, 15, 255) with boiling alkaline potassium permanganate.

intensely blue. This colour reaction is shown by 1:2-benzanthracene itself and also by all its hydrocarbon derivatives so far examined with the exception of the 9:10-diphenyl derivative.

**3-Methyl-1:2-benzanthracene.**—3-Methyl-1:2-benzanthraquinone (5 g.), mixed with zinc dust (15 g.), was heated on the water-bath with concentrated aqueous ammonia (50 c.c.) diluted with water (25 c.c.). After 3 hours, the initial blood-red colour had faded to pale yellow but was restored by the addition of 50% potassium hydroxide solution (25 c.c.). After boiling for 20 hours, the solution was treated with a further 5 g. of zinc dust and then boiled for 50 hours. Reduction was still incomplete, but the product was collected and zinc removed by hydrochloric acid and unchanged quinone by boiling alkaline sodium hydrosulphite solution. The residue was recrystallised from pyridine and alcohol, glacial acetic acid, and benzene-light petroleum. 3-Methyl-1:2-benzanthracene formed almost colourless plates, m. p. 153–154° (Found: C, 94.1; H, 5.8.  $C_{19}H_{14}$  requires C, 94.2; H, 5.8%).

**1:2-Benz-10-anthrone (IV).**—Twenty g. of 1-naphthylphenylmethane-2'-carboxylic acid (Scholl, Seer, and Zinke, *Monatsh.*, 1920, 41, 601) were intimately mixed with anhydrous zinc chloride (60 g.) and heated at 180° for 20 minutes. The molten mass was cooled and extracted with water and then with dilute sodium carbonate solution, the latter treatment removing a small amount of unchanged acid. Purification of the crude anthrone (16 g.) was not feasible on account of its instability. This method of preparation gave much better results than dehydration of the acid with concentrated sulphuric acid, which led to considerable oxidation and sulphonation.

**1:2-Benzanthranlyl 10-benzoate** was formed when the anthrone was treated with benzoic anhydride and pyridine at 100°. It melted at 171–172°, in agreement with the figure given by Barnett and Matthews (*loc. cit.*) for the compound which they suggested was the 9-benzoate.

**1:2-Benzanthranlyl 10-acetate** was obtained when the above anthrone (3 g.) was treated at 100° for an hour with acetic anhydride (5 c.c.) and pyridine (20 c.c.). It formed straw-coloured needles, from benzene and alcohol, which melted at 156° to a cloudy liquid, becoming clear at 163° (Found: C, 83.7; H, 4.85.  $C_{20}H_{14}O_2$  requires C, 83.9; H, 4.9%).

**10-Hydroxy-10-benzyl-9:10-dihydro-1:2-benzanthracene.**—To a Grignard solution prepared from benzyl chloride (6 c.c.) and magnesium powder (1.5 g.), cooled in a freezing mixture, was added finely powdered 1:2-benz-10-anthrone (IV; 5 g.). After 2 hours, the product was allowed to warm to room temperature, kept over-

night, and decomposed with ice and ammonium chloride. The washed ethereal solution was evaporated, and the residual oil mixed with 2 volumes of hot alcohol. The crystalline solid obtained by cooling was recrystallised from benzene–light petroleum (Found : C, 89.2; H, 5.9.  $C_{25}H_{20}O$  requires C, 89.3; H, 5.95%). This *dihydroanthranol* formed a colourless crystalline powder, m. p. 153–153.5°. Treatment of its solution in boiling alcohol with a few drops of hydrochloric acid resulted in separation of a thick meal of crystals of 10-*benzyl*-1 : 2-*benzanthracene*, yellowish leaflets (from benzene), m. p. 195–196°, intensely fluorescent in solution (Found : C, 94.1; H, 5.6.  $C_{25}H_{18}$  requires C, 94.3; H, 5.7%). The same compound was also obtained in small yield when 1 : 2-*benzanthracene* (6.4 g.), benzyl chloride (6.75 c.c.), and zinc dust (0.5 g.) were heated together in carbon disulphide (50 c.c.) for 16 hours. After removal of the solvent from the filtered solution a viscous oil remained. Its ethereal solution slowly deposited the 10-*benzyl*-1 : 2-*benzanthracene*.

1 : 2-*Benz-9-anthrone* (V).—This was obtained when aluminium powder (12.5 g.) was slowly added with occasional cooling to a solution of 1 : 2-*benzanthraquinone* (50 g.) in concentrated sulphuric acid (500 c.c.). After 3 hours, the orange-yellow solution was poured into ice and water, and the precipitate collected and dried in a vacuum desiccator. The resulting brown powder was recrystallised from chloroform, in which it was extremely easily soluble. It could not be obtained analytically pure on account of its instability, but was converted by benzoic anhydride in pyridine into the benzoate, m. p. 201–202°, described by Barnett and Matthews (*loc. cit.*). This benzoate, which depressed the m. p. of the 10-benzoate, is clearly 1 : 2-*benzanthranyl* 9-benzoate.

*Benzylation of Benzanthraquinol*.—A boiling suspension of 1 : 2-*benzanthraquinone* (5.2 g.) in 10% potassium hydroxide solution (100 c.c.) was treated with excess of sodium hydrosulphite and then with benzyl chloride (4.6 c.c.). After 2 hours' boiling, addition of more potassium hydroxide solution (20 c.c.) and benzyl chloride (1 c.c.) resulted in rapid fading of the red colour of the solution. Steam-volatile products were removed and the residual resin was dissolved in hot alcohol. The solution yielded, on cooling, a small amount of crystalline material, which was recrystallised from benzene and alcohol. The substance, probably 10-*benzyloxy*-1 : 2-*benzanthracene*, formed colourless needles, m. p. 178–179°. Its solutions in benzene and in sulphuric acid were fluorescent, and alcoholic alkali produced no "anthranol colour" (Found : C, 90.1; H, 5.6.  $C_{25}H_{18}O$  requires C, 89.8; H, 5.4%).

*Acenaphthanthrone* (VI).—3-Acenaphthylphenylmethane-2'-carboxylic acid (12 g.), prepared by reduction of the corresponding keto-

acid with zinc and sodium hydroxide (compare Lorriman, *J. Amer. Chem. Soc.*, 1925, 47, 215), was dehydrated with zinc chloride (36 g.) in the manner described for the preparation of 1 : 2-benz-10-anthrone. The acenaphthanthrone, obtained in good yield, had little power of crystallisation and was characterised as the *acenaphthanthranyl acetate*, obtained with acetic anhydride and pyridine at 100° and recrystallised from xylene. This acetate formed straw-coloured needles, m. p. 229–230° (Found : C, 84.5; H, 5.15.  $C_{22}H_{16}O_2$  requires C, 84.6; H, 5.1%).

*Acenaphthanthracene* (VII).—The aforesaid anthrone (from 12 g. of acid) was reduced by boiling for 16 hours with zinc dust (35 g.) and 2*N*-sodium hydroxide solution (200 c.c.). The product, after extraction of zinc with hydrochloric acid, was crystallised from acetic acid (yield, 4 g.) and obtained analytically pure by recrystallising it twice from xylene and twice from benzene. This *hydrocarbon* formed yellow plates, m. p. 192°, and gave the usual benzanthracene colour reaction with sulphuric acid (Found : C, 94.5; H, 5.5.  $C_{20}H_{14}$  requires C, 94.5; H, 5.5%).

10-*Benzylacenaphthanthracene* (VIII).—Acenaphthanthrone (VI; 1 mol.) was treated with magnesium benzyl chloride (3 mols.) as described in the case of 1 : 2-benz-10-anthrone. The intermediate dihydroanthranol was unstable and partly dehydrated to the hydrocarbon even by boiling alcohol. Conversion was completed by crystallisation from glacial acetic acid and the product was finally recrystallised twice from ethyl acetate. 10-*Benzylacenaphthanthracene* formed pale yellow needles, m. p. 199–200° (Found : C, 93.9; H, 5.8.  $C_{27}H_{20}$  requires C, 94.2; H, 5.8%).

The author desires to express his thanks to Mr. F. Goulden for valuable assistance in the preparation of material.

## CXXXVIII.—*The Dismutation of Some Disulphides.*

By ERNEST WILSON McCLELLAND and LEONARD ARTHUR WARREN.

FURTHER investigation of 2 : 2'-*oo'*-dithiodiphenyl-4 : 5-dihydroglyoxaline (I) (McClelland and Warren, *J.*, 1929, 2623) shows that this disulphide exhibits anomalous properties in solution. Molecular-weight determinations of the material in alcohol and benzene by the ebullioscopic method give low values which diminish with

dilution (Table I). The low values obtained cannot be ascribed to reaction of solvent and solute, since the latter when recovered is identical with the original and gives values in agreement with those obtained in the initial experiment. Moreover, the apparent molecular weight of the disulphide at a given concentration is constant even on prolonged boiling; it is thus evident that the anomalous results are not due to decomposition but accord with a reversible dissociation of the disulphide.

Solutions of the disulphide are thermochromic, the intensity of the colour increasing with rise of temperature and decreasing on cooling again. This property has previously been observed by Lecher (*Ber.*, 1915, 48, 524) in certain disulphides and has been attributed to a weakening of the S-S link. The dihydroglyoxaline disulphide, unlike the disulphides investigated by Lecher, shows a marked divergence from Beer's law (Table III).

These unusual properties of the disulphide might be accounted for by dissociation in solution to free radicals (A), or by a reversible change of the type (B) which may be termed reversible dismutation.

It is evident that process (A) may be regarded as the preliminary stage in the formation of the products (II) and (III) and thus any proof of dismutation (B) does not exclude the formation of free radicals as the initial stage of the dismutation. It is noteworthy that tetra-arylhydrazines (Wieland, *Annalen*, 1911, 381, 200; Wieland and Lecher, *ibid.*, 1912, 392, 156) and hexaphenylethanes (Schmidlin and García-Banús, *Ber.*, 1912, 45, 1344) undergo irreversible dismutation which appears to be dependent on the formation of free radicals from these substances.

Since solutions of the dihydroglyoxaline disulphide do not react with oxygen, and no evidence of abnormal reactivity could be obtained, the production of free radicals with anything more than a transitory existence appears to be excluded; indeed their formation although possible is not necessary to an explanation of the phenomena. Evidence proving the formation of the products of dis-

mutation (II and III) is forthcoming from the following independent sources.

The apparent molecular weight of the disulphide (I) in alcohol to which the free thiol (III) has been added is higher than that in the pure solvent and increases with increasing concentration of the thiol (Table II); this result accords with reversible dismutation of the disulphide to thiol (III) and the tricyclic compound (II). Moreover, the disulphide is formed by treatment of an equimolecular mixture of the tricyclic hydrobromide and the thiol with one equivalent of alkali; the yield of disulphide excludes the possibility of its formation by decomposition of the tricyclic compound and leads to the conclusion that the thiol and the free tricyclic compound react to give the disulphide in equilibrium with these; direct proof of this cannot be obtained, as the tricyclic compound itself has not been isolated.

Further evidence of the dismutation process (B) is obtained from the action of methyl iodide on the disulphide, which gave the hydriodide of the *S*-methyl ether of the thiol (III) together with the hydriodide of the tricyclic compound (II); the formation of these products is readily accounted for by dismutation of the disulphide to thiol and tricyclic compound, the hydrogen iodide liberated in the methylation of the thiol forming salts of the *S*-methyl ether and of the tricyclic compound, thus permitting the isolation of the latter salt.

Substitution of the imino-hydrogen of the dihydroglyoxaline disulphide (I) should inhibit dismutation, since cyclisation would be prevented. Unfortunately, attempts to prepare the requisite derivatives have been unsuccessful.

The behaviour of 2:2'-mm'- and 2:2'-pp'-dithiodiphenyl-4:5-dihydroglyoxalines has been studied in comparison with that of the ortho-compound. These disulphides have now been synthesised from the amides of mm'- and pp'-dithiobenzoic acids. The nitriles, obtained from these, on treatment with ethylenediamine in presence of hydrogen sulphide were readily converted into the dihydroglyoxaline disulphides and thiols; the *S*-methyl ethers of the latter have also been prepared. Normal values for the molecular weight of these disulphides were obtained. Owing to the improbability that the tricyclic system could be formed from the *m*- and *p*-disulphides, it was not anticipated that they would show dismutation in solution, but it was considered that a variation in the stability of the S-S link might exist. The *p*-disulphide, like the *o*-compound, is readily reduced by hydrogen sulphide, but the *m*-compound is not reduced to the thiol. This variation in stability indicates that the dihydroglyoxaline nucleus tends to weaken the S-S link when

in the *o*- or *p*-position to it but not in the *m*-, and the effect is probably an electronic one. The instability of the S-N link when in the *o*-position to the  $\text{-C=N-}$  group (McClelland and Warren, *loc. cit.*, p. 2624) appears to be of a similar character.

The authors are not aware of any previously recorded example of reversible dismutation. Irreversible dismutation has been observed in the thiodiazoline series (Busch, *Ber.*, 1895, 28, 2635); *e.g.*, disulphides of the type (IV,  $\text{R} = \text{H}_2$ ) when kept in chloroform yield the corresponding thiols and the endocyclic compounds.

The presence of the  $\text{N}=\text{C}_n\text{-S}$  complex in these compounds ( $n = 1$ ) and in the *o*-dihydroglyoxaline disulphide (I,  $n = 3$ ) is significant and suggests that such a complex in a disulphide tends to weaken the S-S link; the reaction of the thioketothiodiazoline disulphides (IV,  $\text{R} = \text{S}$ ) with methyl iodide (Busch and Lingenbrink, *J. pr. Chem.*, 1900, 61, 330) or ammonia (Busch, *Ber.*, 1896, 29, 2127) to give *S*-methyl ethers or sulphamines confirms this view.

Further evidence is forthcoming from the relative ease of formation of mercaptides from disulphides, which may be taken as an indication of the stability of the S-S link. Many disulphides do not react with mercury (compare Konek, *Ber.*, 1920, 53, 1666) or do so only under intense conditions (Lecher, *ibid.*, p. 589). On the other hand, the thioketothiodiazoline disulphide (IV,  $\text{R} = \text{S}$ ) and disulphides of the types (V and VI,  $\text{R} = \text{Cl}, \text{OH}$ ) which contain the  $\text{N}=\text{C}_n\text{-S}$  complex readily give mercaptides with this metal (Söderbäck, *Annalen*, 1928, 465, 184). The formation of mercaptides from antipyrine and homoantipyrine disulphides (Konek, *loc. cit.*) suggests that the  $\text{O}=\text{C}_n\text{-S}$  complex may have a similar influence; the effect of such groups on the stability of disulphides is being investigated.

Reversible dismutation affords a convenient explanation of many reactions of disulphides. The condensation of 2:2'-dithiobenzoic acid with aromatic hydrocarbons (Prescott and Smiles, *J.*, 1911, 99, 640) to give thioxanthenes, in which the intermediate formation of a sulphenic acid has been postulated, may be regarded as the reaction of the dismutation product (VII) with the hydrocarbon and is thus analogous to the formation of anthraquinones from phthalic anhydride (Baeyer and Caro, *Ber.*, 1874, 7, 968), and the formation of 3-hydroxy-1-thionaphthen and its 2-derivatives

(Hutchinson and Smiles, J., 1912, **101**, 570) may be interpreted on the same basis.

The oxidation of substituted 2:2'-dithiobenzamides (VIII) (McClelland, Warren, and Jackson, J., 1929, 1584) to the *N*-substituted saccharins instead of to the disulphoxides may be ascribed to the dismutation of the amides into ketobenzisothiazoles (IX), which have previously been shown to be readily oxidised to the saccharins (McClelland and Gait, J., 1926, 921). The production of thiazoles by the oxidation of thioanilides and thiourethanes (Jacobson, *Ber.*, 1886, **19**, 1067) may be attributed to the dismutation of an intermediate disulphide (X, R = Ph, OEt) containing the N=(C)<sub>n</sub>-S complex.

#### EXPERIMENTAL.

The molecular weight of 2:2'-*oo'*-dithiodiphenyl-4:5-dihydroglyoxaline (I) (J., 1929, 2626) was determined by the Menzies-Wright method (*J. Amer. Chem. Soc.*, 1921, **43**, 2314). Values typical of those obtained are recorded below. Those given under (a) and (b) refer to different specimens, and under (c) the value obtained with material recovered after one of these experiments is given.

TABLE I.

Solvent: ethyl alcohol. <i>M</i> , calc., 354.									
	(a)		(b)						(c)
Conc. (g./l.) ...	3.19	7.05	0.669	1.58	2.40	3.67	5.15	6.47	4.095
Apparent <i>M</i> ...	232	264	168	177	227	236	247	251	243
Solvent: benzene.	Conc. (g./l.)		0.649		1.60				
	Apparent <i>M</i>		303		307				

*The Effect of the Presence of the Thiol (III) on the Apparent Molecular Weight of the Disulphide (I).*—The elevation of the boiling point of ethyl alcohol (31.8 c.c.) produced by the disulphide (0.1028 g.) was determined in the usual way; successive quantities of the thiol were added, and the resulting elevations noted. From these values the elevation due to the thiol alone, calculated from the experimental value 185.5, was deducted, whence the apparent

molecular weight of the disulphide in presence of the thiol was calculated.

TABLE II.

Apparent <i>M</i> of disulphide .....	243	304	336	360
Weight (g.) of thiol added .....	—	0.0694	0.1243	0.1800

*The Divergence from Beer's Law of Alcoholic Solutions of the Disulphide (I).*—Solutions of the disulphide of different concentrations were matched against a given length of a standard solution of the disulphide in a colorimeter. Three determinations (a, b, c) with different lengths of the standard column were made. Under (C) are given the lengths of columns of a solution of the disulphide of concentration *C* which matched the standard; under  $\frac{1}{2}C$  and  $\frac{1}{4}C$  are given the corresponding lengths for solutions of a half and a quarter of the concentration *C*. The theoretical values (Beer's law) are given in parentheses.

TABLE III.

	Lengths (cm.) of standard.	C.	$\frac{1}{2}C$ .	$\frac{1}{4}C$ .
(a)	2.0	3.2	4.8 (6.4)	5.8 (12.8)
(b)	4.0	5.9	8.5 (11.8)	13.2 (23.6)
(c)	6.0	9.8	13.9 (19.6)	16.1 (39.2)

*Methylation of the Disulphide (I).*—A solution of the disulphide (4 g.) in ethyl alcohol (200 c.c.) and methyl iodide (5 c.c.) was heated on the water-bath till almost colourless (about 10 minutes). Alcohol (100 c.c.) was distilled off; the hydriodide (1.7 g.) which crystallised on cooling was dissolved in hot water and treated with silver nitrate, and the precipitated iodide filtered off. Excess of potassium bromide was added to the filtrate; the hydrobromide which crystallised on cooling, after purification from alcohol, had m. p. 257°, alone or mixed with an authentic specimen of the hydrobromide of the tricyclic compound (II) (J., 1929, 2627). The alcoholic mother-liquor after removal of the hydriodide was diluted with water and concentrated; the material (3.2 g.) which crystallised was purified from water (charcoal). It had m. p. 206—208°, alone or mixed with the hydriodide of 2-*o*-methylthiolphenyl-4 : 5-dihydroglyoxaline (J., 1929, 2626), and on treatment with alkali gave a base, m. p. 98—100° alone or mixed with 2-*o*-methylthiolphenyl-4 : 5-dihydroglyoxaline (picrate, yellow needles, m. p. 207°).

*Reaction of 2-*o*-Thiolphenyl-4 : 5-dihydroglyoxaline (III) and the Tricyclic Compound (II).*—A mixture of the tricyclic hydrobromide (1 mol., from 0.45 g. of disulphide I) and the thiol (III) (1 mol.) in boiling alcohol was treated with aqueous potassium hydroxide (1 mol.), and the alcohol removed; the disulphide (I) (0.6 g.) was obtained from the residue.

**3 : 3'-Dithiobenzamide.**—3 : 3'-Dithiobenzoic acid (8 g.) (J., 1921, 119, 1792) was refluxed for  $\frac{1}{4}$  hour with an excess of thionyl chloride and a trace of ferric chloride. After removal of the thionyl chloride, the product was poured on ice and treated with aqueous ammonia ( $d$  0.880); the resulting solid was washed with hydrochloric acid and crystallised from acetic acid (charcoal), giving colourless plates (6.0 g.), m. p.  $243^{\circ}$  (Found : N, 9.3.  $C_{14}H_{12}O_2N_2S_2$  requires 9.2%).

**3 : 3'-Dithiobenzonitrile.**—3 : 3'-Dithiobenzamide (5 g.) was refluxed in xylene (300 c.c.) with phosphoric oxide (5 g.) for 4 hours; the solution was filtered and the xylene removed in steam. The residual material (3.5 g.), purified from alcohol, had m. p.  $102-103^{\circ}$  (Found : S, 23.6.  $C_{14}H_8N_2S_2$  requires S, 23.9%).

**2-m-Thiolphenyl-4 : 5-dihydroglyoxaline.**—A solution of 3 : 3'-dithiobenzonitrile (6 g.) and ethylenediamine (6 c.c.) in alcohol (100 c.c.) was saturated with hydrogen sulphide at  $-10^{\circ}$ . The mixture was heated under pressure for  $1\frac{1}{4}$  hours at  $90-100^{\circ}$ , and the alcohol distilled off. The residual oil was extracted with hydrochloric acid (2*N*) and the extract was treated with charcoal, filtered, and concentrated. The hydrochlorides which separated were treated with excess of sodium hydroxide, the undissolved material (disulphide) was filtered off, and the filtrate treated with carbon dioxide. The precipitated thiol was purified from water, giving yellow needles, m. p.  $225-228^{\circ}$  after previous softening (Found : S, 17.8; *M*, 190.  $C_9H_{10}N_2S$  requires S, 18.0%; *M*, 178). 2-m-Thiolphenyl-4 : 5-dihydroglyoxaline is sparingly soluble in alcohol and readily soluble in acids and alkalis; it gives a transient red colour with ferric chloride.

**2 : 2'-mm'-Dithiodiphenyl-4 : 5-dihydroglyoxaline**, obtained by oxidation of an alkaline solution of the thiol with potassium ferricyanide, crystallised from alcohol (90% aqueous) in pale yellow, hexagonal plates, m. p.  $193^{\circ}$  (Found : S, 17.9.  $C_{18}H_{18}N_4S_2$  requires S, 18.1%). A series of molecular-weight determinations in alcohol at different concentrations gave values from 359 to 370 ( $C_{18}H_{18}N_4S_2$  requires *M*, 354), no regular variation in molecular weight with diminishing concentration was observed, and in no case was the observed value less than 354.

**2-m-Methylthiolphenyl-4 : 5-dihydroglyoxaline.**—2-m-Thiolphenyl-4 : 5-dihydroglyoxaline (0.46 g.) and methyl iodide (3 c.c.) in alcohol (30 c.c.) were heated on the water-bath till colourless. The hydriodide which separated crystallised from aqueous alcohol (charcoal) in pale brown needles, m. p.  $262-264^{\circ}$  (decomp.) (Found : I, 39.7.  $C_{10}H_{12}N_2S.HI$  requires I, 39.7%). The base, obtained in the usual way, crystallised from water in fine colourless needles, m. p.  $94-96^{\circ}$ .

The following *p*-compounds were prepared in a similar way to the *m*-compounds :

4 : 4'-*Dithiobenzamide* from 4 : 4'-dithiobenzoic acid (J., 1922, 121, 2024), m. p. 278° (with previous softening) (Found : S, 21.0.  $C_{14}H_{12}O_2N_2S_2$  requires S, 21.1%).

4 : 4'-*Dithiobenzonitrile*, pale yellow needles, m. p. 172—173° (Found : S, 23.9.  $C_{14}H_8N_2S_2$  requires S, 23.9%).

2-*p*-*Thiolphenyl*-4 : 5-*dihydroglyoxaline*.—4 : 4'-Dithiobenzonitrile (3 g.) and ethylenediamine (4 c.c.) in alcohol (100 c.c.) were saturated with hydrogen sulphide at -15° and heated under pressure at 100° for 1½ hours. The product, treated as in the preparation of the *m*-compound, gave the disulphide (0.6 g.) and the required material (0.98 g.), which separated from water in pale yellow needles, m. p. 290° (decomp.) (Found : S, 18.1.  $C_9H_{10}N_2S$  requires S, 18.0%). The *thiol* gives a green colour with ferric chloride.

2 : 2'-*pp'*-*Dithiodiphenyl*-4 : 5-*dihydroglyoxaline*, obtained in the previous experiment and by oxidation of the *thiol* in alkaline solution by potassium ferricyanide, separated from alcohol in very small, colourless crystals, m. p. 213° (Found : S, 18.4.  $C_{18}H_{18}N_4S_2$  requires S, 18.1%). Molecular-weight determinations in alcohol at different concentrations gave values from 367 to 381 ( $C_{18}H_{18}N_4S_2$  requires *M*, 354), no regular variation in molecular weight with varying concentration was observed, and in no case was the observed value less than 354.

2-*p*-*Methylthiolphenyl*-4 : 5-*dihydroglyoxaline* hydriodide, m. p. 237°, gave the base, which separated from water in colourless plates, m. p. 155—156°.

*Action of Hydrogen Sulphide on the Dithiodiphenyl-4 : 5-dihydroglyoxalines*.—Hydrogen sulphide was bubbled through a solution of 2 : 2'-*pp'*-dithiodiphenyl-4 : 5-dihydroglyoxaline (0.5 g.) in warm alcohol (50 c.c.) for 2 hours. The precipitated material was extracted with sulphuric acid (2*N*), and the filtered extract made alkaline; after removal of some unchanged disulphide (0.06 g.) which was precipitated at this stage, the solution was saturated with carbon dioxide; 2-*p*-thiolphenyl-4 : 5-dihydroglyoxaline (0.27 g.) was then obtained, m. p. 290° alone or mixed with an authentic specimen.

2 : 2'-*oo'*-Dithiodiphenyl-4 : 5-dihydroglyoxaline on similar treatment yielded 2-*o*-thiolphenyl-4 : 5-dihydroglyoxaline (0.35 g.), m. p. 242° alone or mixed with an authentic specimen. 2-*m*-Thiolphenyl-4 : 5-dihydroglyoxaline was not obtained when the *m*-disulphide was treated in a similar way with hydrogen sulphide.

CXXXIX.—*The Production of Fog in the Neutralisation of Alkali with Hydrogen Halides. Part II. The Significance of the Presence of Ammonia.*

By RICHARD WALTER ALDIS and JAMES CHARLES PHILIP.

THE earlier communication (Askew, J., 1927, 966) described an experimental study of the acid fogs obtained by passing a stream of air charged with hydrogen chloride or bromide through a solution of sodium hydroxide or other non-volatile alkali. Among the points investigated were the concentration of acid in the fog droplets, the dimensions of the latter, and the relation of the amount of fog formed to the concentration of the alkali solution. Further information on various aspects of the phenomenon was required, however, before the mode of production and the stability of the fogs could be adequately interpreted.

In the fresh work which was undertaken attention was first directed to the reproducibility of the results. Various minor modifications of the earlier apparatus and procedure failed to secure the desired degree of reproducibility, and it was only a fortunate circumstance which led to the discovery of the source of the difficulty. In two parallel series of experiments, designed to correlate the amount of fog produced with the concentration of the caustic soda solution, it was found that the quantities of fog obtained in the one series were throughout about twice as great as in the other. This serious discrepancy led to the recognition that the caustic soda solutions employed in the two series had been made up with distilled water from separate sources, and examination of the two waters showed that they differed appreciably in their content of ammonia, as proved by Nessler tests. This clue was followed up, and definite evidence was obtained that the production of fog under the given conditions was determined by the presence of traces of ammonia in the caustic soda solution. The quantitative results which support this view are set out below, but it may be stated that when ammonia is rigorously excluded or removed from the caustic soda solution the amount of fog produced is negligible.

EXPERIMENTAL.

*Apparatus and Procedure.*—The apparatus was in general the same as already described (Askew, *loc. cit.*), and it is necessary to refer only to a few modifications which have been introduced. It was thought desirable to improve the temperature control, and accordingly the vessel containing concentrated hydrochloric acid, in which the air current was saturated with hydrogen chloride, was

kept in a bath at 25°, and the dried mixture of gases was then passed through the fog production chamber, containing the alkali solution. This vessel, as well as the fog absorption tube, was immersed in the same thermostat as the hydrogen chloride saturator. Provision was made for renewing the acid in the saturator after each experiment.

The U-tube employed for collecting the fog was charged with asbestos wool and calcium chloride, so that the figures given below for "weight of fog" (in mg.) generally include the water vapour which accompanied the fog droplets. In some cases, where the composition of the fog itself was to be ascertained, the collecting tube was charged with asbestos wool only.

In the majority of the experiments the air-hydrogen chloride mixture was passed at a rate of about 200 c.c. per minute for 8—10 minutes, and this may be regarded as a standard run. The conditions were, of course, maintained constant in any one series of comparable experiments.

*Measurements and Observations.*—Following the discovery of the significance of traces of ammonia for the production of acid fogs under the conditions described above, the further investigation of the character and stability of the fogs was made with alkali solutions to which known quantities of ammonium chloride had been added initially. A series of experiments with increasing concentration of caustic soda, but the same initial concentration of ammonia in each case, showed that the amount of fog obtained in a standard run first increased, reached a maximum, and subsequently decreased. The results obtained in three such series are set out in Table I and represented graphically in Fig. 1.

TABLE I.

(a) $\text{NH}_3 = 0.00005\%$ .		(b) $\text{NH}_3 = 0.0005\%$ .		(c) $\text{NH}_3 = 0.002\%$ .	
Normality of NaOH.	Weight of fog (mg.).	Normality of NaOH.	Weight of fog (mg.).	Normality of NaOH.	Weight of fog (mg.).
0.1	10	0.1	102	0.1	158
0.5	50	0.4	170	0.48	250
1.2	65	0.85	192	0.55	264
2.4	50	2.0	155	0.88	250
4.8	5	3.5	78	2.0	198
				3.5	105

The figures in Table I indicate that the amount of fog increases as the ammonia concentration rises, but series of experiments carried out at constant caustic soda concentrations and with a much wider range of ammonia values show that the amount of fog tends to become steady. The results obtained in one such series, in which the sodium hydroxide was 0.84*N*, were as follows:

$\text{NH}_3$ , % .....	0.0001	0.00025	0.001	0.003	0.005	0.007
Weight of fog (mg.)	125	160	224	260	267	270

As already indicated, a number of experiments were made in which the fog, after being collected and weighed, was analysed for hydrochloric acid (by titration) and for ammonia (by Nessler tests). The strongly acid character of the fogs is proved by the figures in

FIG. 1.

Table II, which show also that during each experiment a fair proportion of the ammonia was transferred from the caustic soda solution to the fog droplets.

TABLE II.

Normality of NaOH.	NH <sub>3</sub> initially, g.	Weight of fog (mg.).	Found in the fog.	
			NH <sub>3</sub> , g.	HCl, %.
0.39	0.00002	25	0.00001	5.9
0.39	0.00005	40	0.00002	5.9
0.39	0.0001	72	0.00005	5.8
0.39	0.0005	173	0.0003	5.8
0.39	0.001	246	0.0007	5.8
1.00	0.001	244	0.0005	6.4
3.90	0.001	106	0.0006	8.9

In some cases the passage of the acid-laden air stream was continued until fog formation practically ceased, and this was found to occur when the ammonia originally in the caustic soda had been transferred to the fog. Thus, for example, in one experiment the stream was bubbled through 100 c.c. of a 2.0*N*-caustic soda solution containing 0.002 g. of ammonia. When fog formation had practically ceased, after the passage of 12 litres of the gas mixture, the caustic soda solution was run out and found to be

1.75*N*, and to be free from ammonia. The fog formed during this experiment had been collected in a tube containing asbestos wool (previously shown to be free from ammonia). The wool was washed and the washings were made up to 200 c.c., aliquot portions being then tested with Nessler's solution. The total ammonia found in this way was equal to that originally present in the caustic soda solution.

In the earlier investigation it was observed that the amount of fog produced was markedly increased when small quantities of certain substances, such as gelatin and methylene-blue, were added to the alkali solution. These observations have been confirmed, and proof has been obtained that the substances in question owe their influence to the small quantities of ammonia liberated from them in caustic soda solution. It is noteworthy also that the ability to promote fog formation when an air-hydrogen chloride stream is passed through caustic soda is possessed, not only by ammonia, but by other volatile bases, such as methylamine and diethylamine.

The size of the droplets forming the fogs was estimated in the usual way by observing the rate of settling of the cloud. The value so obtained for the radius of the droplets varied somewhat according to the conditions under which the fog was produced, but was of the same order, *viz.*,  $10^{-4}$ — $10^{-5}$  cm., as that already recorded by Askew (*loc. cit.*). Definite evidence was obtained that the size of the droplets diminishes with increasing concentration of the caustic soda from which the fog was obtained.

Variation in the size of the droplets and the density of the fog, according to the vapour pressure of the surrounding medium, was further demonstrated by experiments in which thin fogs were passed through water. Thus, for example, a faint fog was obtained by bubbling the usual acid-air mixture through a concentrated (6*N*) caustic soda solution containing 0.002% of ammonia. This fog when bubbled through water became quite dense, but showed no change when bubbled through very concentrated solutions of potassium iodide or calcium chloride.

Further, when a fairly dense fog from the caustic soda solution was bubbled through concentrated sulphuric acid, it disappeared, but the inference that the fog had been absorbed was proved to be erroneous by subsequently passing the air stream through water, whereupon the fog reappeared, although in somewhat diminished intensity. The fact that concentrated sulphuric acid may render a fog invisible without absorbing it has been observed for ozone fogs (Rothmund, *Monatsh.*, 1918, **39**, 571), and for moist sulphur trioxide fogs (Remy, *Z. Elektrochem.*, 1922, **28**, 467).

Experiments carried out with the object of detecting any definite electrical charge on the fog droplets gave negative results. This is

in harmony with Askew's observations (*loc. cit.*, p. 978), as also with earlier investigations on the electrical condition of other chemical fogs (de Broglie and Brizard, *Compt. rend.*, 1909, **149**, 923; Rothmund, *loc. cit.*; Remy and Koch, *Z. anorg. Chem.*, 1924, **139**, 69).

#### Discussion.

The novel feature of the fogs described in this and the earlier communication is that they are strongly acid, although produced in an alkaline medium. Remy and his collaborators (*Z. angew. Chem.*, 1926, **39**, 147; *Z. anorg. Chem.*, 1927, **159**, 241), it is true, have shown that moist sulphur trioxide fogs can be bubbled through caustic potash solutions with only partial absorption, but these fogs were already formed before they came in contact with the alkaline medium.

Another important characteristic of the acid fogs described in the present paper is that their formation is conditional on the presence of ammonia (or other volatile alkali) in amounts which are very small compared with the quantity of acid contained in the droplets. The measurements and observations recorded above establish beyond doubt the significance of ammonia for the whole phenomenon, and warrant the view that the formation of ammonium chloride particles within the gas bubbles is the first and necessary stage in the production of the fog.

Such ammonium chloride particles, under the conditions prevailing, act as condensation nuclei, and droplets of solution are formed. These droplets then dissolve some of the hydrogen chloride in the gas bubble, and their vapour pressure is correspondingly lowered. This involves an increase in size by further condensation of water, the extent to which this takes place being determined mainly by the vapour pressure of the caustic soda solution surrounding the gas bubble.

Another consideration which is of significance in determining the stability of fogs such as those described above is the fact that the vapour pressure of a minute droplet of a liquid is greater than that at a plane surface. The bearing of this—as expressed by the Kelvin equation—on the stability of chemical fogs has been discussed by a number of earlier workers (Townsend, *Proc. Camb. Phil. Soc.*, 1899, **10**, 52; Rothmund, *loc. cit.*; Remy, *Chem. Zeit.*, 1928, **52**, 677). The vapour pressures for water droplets of radius  $10^{-4}$  and  $10^{-5}$  cm. are respectively about 0.1% and 1% greater than at a plane water surface at the same temperature. Hence, in an atmosphere saturated with water vapour in the ordinary way, such droplets would tend to disappear. They will be stabilised, however, even in such an atmosphere, if a compensating reduction of vapour pressure is effected by the presence of dissolved substances in the

droplets. Townsend (*loc. cit.*) has calculated that droplets of  $5 \times 10^{-5}$  cm. radius containing approximately 0.004 g. of sulphuric acid per g. of water would be stable in an atmosphere saturated with water vapour. It is assumed in the calculation that the sulphuric acid is completely ionised.

The fog droplets with which the present communication is concerned contain a much larger proportion of dissolved substance. Where the total amount of fog collected is small, the estimation of the acid which it contains is probably subject to a considerable error, but some of the figures recorded in Table II provide a basis for calculating the concentration of dissolved substance. The data of the experiment, for example, in which fog, weighing 246 mg., was produced from 0.39*N*-sodium hydroxide indicate that the droplets were approximately 1.5*N* as regards hydrochloric acid and 0.15*N* as regards ammonium chloride. Again, the solution constituting the droplets of the last experiment of Table II was approximately 2.5*N* as regards hydrochloric acid and 0.35*N* as regards ammonium chloride.

The fog droplets, of course, consist mainly of water, and the extent to which their concentration is altered by condensation or evaporation should be determined by the vapour pressure of water in the surrounding air. The measurements made so far and recorded above are not such as to permit the quantitative study of this adjustment, but attention is directed to one or two observations which are significant in this connexion. Thus, consideration of the last three experiments in Table II shows that, with increasing caustic soda concentration, the amount of acid in the droplets increases relatively to the water, and this means a lowering of the vapour pressure of the droplets. Again, an investigation of the size of the droplets obtained from caustic soda solutions of different concentrations showed a regular falling off with increasing alkali concentration.

It appears, however, that owing to the operation of certain factors, there are limits to the growth or shrinkage of droplets constituting a stable fog. If much water condenses on a droplet of radius  $10^{-4}$ – $10^{-5}$  cm., which is the stable range, it becomes so large as to settle very rapidly. If, on the other hand, a droplet within the stable range loses much water, the enhanced vapour pressure associated with high curvature may become the determining factor, with the result that the droplet becomes unstable and dries up. It is clear that further measurements are necessary in order to elucidate the relation between the vapour pressure of the droplets and that of the surrounding air.

The fact that the droplets, once formed inside the gas bubble, do not find their way to the surface of the bubble and get absorbed,

is probably due to their comparatively low mobility. The significance of this characteristic for the stability of chemical fogs has been discussed at length by A. Smith ("Text-book of Inorganic Chemistry," 1927, p. 482) and by Remy (*loc. cit.*, 1926 and 1927).

The character of the curves in Fig. 1 invites comment. The occurrence of a maximum is no doubt due to opposition between factors tending to increase the amount of fog and those which tend to diminish it. The vapour pressure of the ammonia in the caustic soda solution increases with increasing concentration of the latter, and this would lead to a larger number of nuclei and a greater weight of fog for a given run. Again, as the concentration of the caustic soda increases, it becomes more viscous, the air-acid mixture will form larger bubbles, and hence there is a greater chance of the droplets escaping in the air stream. The main factor operating in the reverse direction is the steady fall of water vapour pressure as the concentration of the caustic soda increases.

The observations recorded in this paper present one or two points of interest for the analytical chemist. The production of fog when an air-acid stream is passed through a solution of caustic soda is a sensitive test for small quantities of ammonia (or other volatile alkali) in the soda solution: the delicacy of the test approaches that of Nessler's solution. Further, it appears that the removal of hydrogen chloride from an air stream by passage through caustic soda solution is incomplete if the latter contains even small quantities of ammonia. In many of the experiments recorded above, as much as 10–15% of the hydrogen chloride escaped absorption in the caustic soda solution.

Under the conditions of the present work, where the factor of supersaturation is absent, the significance of hygroscopic nuclei for the production of fogs has been clearly demonstrated. In this connexion, it is interesting to note the view, now widely held by meteorologists, that atmospheric condensation does not normally commence on ordinary dust particles or on ions, but on hygroscopic substances. In view of the results of the present investigation, it seems possible that the small quantities of ammonia in the air may play a more important part in the production of atmospheric fogs than has been generally supposed.

One of the authors (R. W. A.) desires to express his thanks to the Department of Scientific and Industrial Research for a maintenance grant during the progress of the work described in the present communication.

CXL.—*The Constitution of Santonin. Part II.*  
*The Synthesis of Racemic desmotropoSantonin.*

By GEORGE ROGER CLEMO, ROBERT DOWNS HAWORTH, and ERIC WALTON.

IN Part I (J., 1929, 2368) a constitution (I) was suggested for santonin and the  $\beta$ -position of the propionic acid side-chain was established by a synthesis of *dl*-santonous acid, and as a result, two formulæ (III and IV) can be suggested for the lactone desmotropo-santonin, which is prepared by the action of mineral acids on santonin (Andreocci, *Gazzetta*, 1893, **23**, ii, 469; *Ber.*, 1898, **31**, 3131). Structure (III) appears to have been generally accepted,

(I.)

(II.)

although hitherto there has been no evidence to enable a decision to be made between the two formulæ and older publications (compare Gucci and Grassi-Cristaldi, *Gazzetta*, 1892, **22**, i, 1) employ structure (IV).

(III.)

(IV.)

The present communication describes the synthesis of a lactone possessing the structure (IV), which is identical in all respects with racemic *desmotropo*santonin (Andreocci, *loc. cit.*). This synthesis establishes the  $\alpha$ -position of the lactonic oxygen atom and provides a further illustration of the preference shown in biosynthesis for the angular fusion of ring systems. At the same time, this necessitates a corresponding modification of the structure (I) which has been suggested for santonin and the structure (II), now adopted, is in agreement with the chemical behaviour of this substance.

The starting point in these synthetical experiments was ethyl  $\delta$ -4-methoxy-2:5-dimethylbenzoylbutane- $\beta\beta\gamma$ -tricarboxylate (XVI; R = Me in Part I), and an improved method is described for its conversion into  $\alpha$ -( $\beta$ -4-methoxy-2:5-dimethylphenylethyl)- $\alpha'$ -

methylsuccinic acid (VI). The tricarboxylate was hydrolysed with aqueous-alcoholic sodium hydroxide and the mixed racemates

of 8-4-methoxy-2:5-dimethylbenzoylbutane- $\beta\gamma$ -dicarboxylic acid (XVII; R = Me in Part I, compare p. 2385) were converted into the anhydride (V) by heating at 180°. One form only of this anhydride has been isolated, and when this was reduced by Clemmensen's method, the succinic acid derivative (VI) was obtained. Two racemic modifications of this acid were described in Part I (p. 2386), but the lower-melting isomeric only is obtained by reducing the anhydride (V).

The succinic acid derivative (VI) was refluxed with hydriodic acid and converted into  $\alpha$ -( $\beta$ -4-hydroxy-2:5-dimethylphenylethyl)- $\alpha'$ -methylsuccinic acid, which was not isolated in the crystalline state, but converted into the lactone (VII) of the enolic form of  $\alpha$ -7-hydroxy-1-keto-5:8-dimethyl-1:2:3:4-tetrahydronaphthyl-2-propionic acid by the action of warm concentrated sulphuric acid.

This lactone (VII) was not reduced by palladium and hydrogen in acetic acid solution, but with sodium amalgam in alcoholic solution, the lactone (IV) of  $\alpha$ -1:7-dihydroxy-5:8-dimethyl-1:2:3:4-tetrahydronaphthyl-2-propionic acid was obtained. This was identical with a specimen of racemic *desmotroposantonin*, prepared from santonin by the method outlined by Andreocci (*loc. cit.*), supplementary details of which will be found in the experimental section of this communication, and further the identity of the natural and the synthetic product has been confirmed by a comparison of their *acetyl* derivatives.

In Part I (p. 2374), the structure of ethyl 8-4-methoxy-2:5-dimethylbenzoylbutane- $\beta\gamma$ -tricarboxylate was discussed and an interesting result has now been obtained in an attempt to confirm the suggested structure. *Ethyl*  $\beta$ -bromo- $\beta$ -4-methoxy-2:5-dimethyl-

*benzoylpropionate* (VIII), prepared by bromination of *ethyl β-4-methoxy-2 : 5-dimethylbenzoylpropionate* (compare Part I, p. 2382), was condensed with ethyl sodiomethylmalonate. A tricarboxylate was obtained which, after hydrolysis and heating, gave the anhydride (V). This indicates that hydrogen bromide is eliminated in one or both of the methods for preparing the anhydride (V), and that the ethyl sodiomethylmalonate condenses with the acrylic ester derivative by a Michael reaction. These observations, however, do not demand any alteration in our views with regard to the structure of ethyl *δ-4-methoxy-2 : 5-dimethylbenzoylbutane-βγ-tricarboxylate*.

#### EXPERIMENTAL.

*Methyl and Ethyl β-4-Methoxy-2 : 5-dimethylbenzoylpropionates*.—*β-4-Methoxy-2 : 5-dimethylbenzoylpropionic acid* (5 g.) in methyl alcohol (30 c.c.) was saturated with dry hydrogen chloride with cooling in an ice-bath. After some hours, the mixture was refluxed for 2 hours on the water-bath, the bulk of the alcohol then removed, water added, followed by a slight excess of sodium hydroxide, the solid collected and dried (4.8 g.). Crystallisation from light petroleum (b. p. 80—100°) gave large colourless prisms (4.4 g.), m. p. 94—95° (Found: C, 67.1; H, 7.2.  $C_{14}H_{18}O_4$  requires C, 67.2; H, 7.2%). The *ethyl ester*, prepared similarly, formed stout colourless prisms, m. p. 49—50° (Found: C, 68.3; H, 7.3.  $C_{15}H_{20}O_4$  requires C, 68.2; H, 7.5%).

*Methyl and Ethyl β-Bromo-β-4-methoxy-2 : 5-dimethylbenzoylpropionates* (VIII).—A solution of bromine (3.5 g.) in light petroleum (b. p. 60—80°; 33 c.c.) was added to a solution of methyl *β-4-methoxy-2 : 5-dimethylbenzoylpropionate* (5 g.) in light petroleum (b. p. 60—80°; 40 c.c.); the bromine was rapidly decolorised and hydrogen bromide was evolved. The solvent was removed under reduced pressure; the residual oil crystallised from light petroleum (b. p. 40—60°) in large colourless prisms, m. p. 96° (Found: C, 51.3; H, 5.3; Br, 24.4.  $C_{14}H_{17}O_4Br$  requires C, 51.1; H, 5.1; Br, 24.3%). The *ethyl ester*, prepared similarly, separated from light petroleum (b. p. 40—60°) in large colourless prisms, m. p. 98—100°, which gave a considerable depression in m. p. when mixed with ethyl *α-bromo-β-4-methoxy-2 : 5-dimethylbenzoylpropionate* (compare Part I, p. 2382) (Found: C, 52.6; H, 5.6; Br, 23.1.  $C_{15}H_{19}O_4Br$  requires C, 52.5; H, 5.5; Br, 23.3%).

The ethyl ester was condensed with ethyl sodiomethylmalonate in benzene solution and the product after hydrolysis and heating yielded the anhydride, m. p. 171°, described below.

*δ-4-Methoxy-2 : 5-dimethylbenzoylbutane-βγ-dicarboxylic Anhydride* (V).—Ethyl *δ-4-methoxy-2 : 5-dimethylbenzoylbutane-βγ-tricarboxylate*.

oxylate (12 g.) was dissolved in ethyl alcohol (24 c.c.), sodium hydroxide (24 c.c. of 2*N*) added, and the mixture refluxed for 2 hours on the water-bath and then evaporated to a small bulk under reduced pressure. Water (30 c.c.) was added, and after standing, the precipitated 4-methoxy-2 : 5-dimethylacetophenone (0.5 g.) was filtered off. The filtrate was acidified with a mixture of concentrated hydrochloric acid (30 c.c.) and water (30 c.c.), the resulting milky emulsion rapidly extracted with ether, and the extract allowed partly to evaporate spontaneously over-night. The colourless 8.4-methoxy-2 : 5-dimethylbenzoylbutane- $\beta\gamma$ -dicarboxylic acid (5.3 g.) was collected and washed with a little ether and the ethereal filtrates were combined (A). The residue was heated in two portions for 1 hour in a metal-bath at 180°. After a brisk effervescence, a viscid, pale yellow gum resulted, which was stirred with ether while still warm and the colourless solid collected (2.85 g.). The ethereal filtrate on evaporation and reheating in the metal-bath gave 0.1 g. more of ether-insoluble solid. This solid was moderately easily soluble in boiling benzene, and separated in stout rhombic prisms, m. p. 171° (Found : C, 66.4; H, 6.2.  $C_{16}H_{18}O_5$  requires C, 66.2; H, 6.2%). The *anhydride* is insoluble in cold sodium hydroxide solution, and sparingly soluble in ethyl alcohol, from which it separates in jagged prisms. On evaporation of filtrate (A), a yellow viscid oily acid resulted, from which no solid could be obtained by solution in sodium hydroxide and reprecipitation with acid; but on being heated in a metal-bath as above, it gave 1.65 g. of the crude anhydride, together with a further 0.1 g. when the ethereal extract was again heated.

*Methyl 8.4-methoxy-2 : 5-dimethylbenzoylbutane- $\beta\gamma$ -dicarboxylate* was obtained on esterifying the anhydride with methyl alcohol and hydrogen chloride, and after distillation crystallised from light petroleum (b. p. 40—60°) in colourless prisms, m. p. 73—74° (Found : C, 64.3; H, 7.1.  $C_{18}H_{24}O_6$  requires C, 64.3; H, 7.1%).

$\alpha$ -( $\beta$ -4-Methoxy-2 : 5-dimethylphenylethyl)- $\alpha'$ -methylsuccinic Acid (m. p. 131—132°; compare Part I, p. 2386).—The anhydride (V) (1 g.), amalgamated zinc (5 g.), and concentrated hydrochloric acid (7 c.c.) were refluxed for 24 hours. The oil produced was decanted from the zinc residues, which were extracted with a small amount of ethyl alcohol, diluted with water and left over-night, and the colourless solid was collected and dried on porous plate (0.95 g.). The compound dissolved completely in hot benzene (4—5 c.c.) and on dilution with light petroleum (12 c.c.) gave colourless prisms, m. p. 131—132° (Found : C, 65.2; H, 7.8. Calc. : C, 65.3; H, 7.5%).

*Lactone of  $\alpha$ -7-Hydroxy-1-keto-5 : 8-dimethyl-1 : 2 : 3 : 4-tetrahydronaphthyl-2-propionic Acid (VII).*— $\alpha$ -( $\beta$ -4-Methoxy-2 : 5-dimethylphenylethyl)- $\alpha'$ -methylsuccinic acid (2.5 g.) was refluxed for 1 hour

with hydriodic acid (7.5 c.c.;  $d$  1.7), water (7.5 c.c.) added, the mixture extracted with ether, the extract freed from iodine by shaking three times with saturated sodium bisulphite solution and dried over sodium sulphate, and the ether removed.  $\alpha$ -( $\beta$ -4-Hydroxy-2:5-dimethylphenylethyl)- $\alpha'$ -methylsuccinic acid remained as a gum, which was stirred for 2 minutes in the water-bath with concentrated sulphuric acid (7.5 c.c.), the resulting dark brown solution cooled, and ice added; a straw-coloured gum was then obtained. After 1 hour, the dilute acid solution was decanted, the residue stirred with a cold saturated solution of sodium bicarbonate, and the colourless solid collected, washed with water, and dried on the water-bath. The material from three such experiments was dissolved in boiling acetic acid (80 c.c.) and water (10 c.c.), charcoal added to remove a faint purple coloration, and the filtrate diluted with boiling water (35 c.c.). On cooling, colourless, stout, rhombic prisms (3.1 g.), m. p. 250—253° (decomp.), separated (Found: C, 73.8; H, 6.8.  $C_{15}H_{16}O_3$  requires C, 73.8; H, 6.5%). The lactone is hydrolysed by warming for 15 minutes with methyl-alcoholic potassium hydroxide to give  $\alpha$ -7-hydroxy-1-keto-5:8-dimethyl-1:2:3:4-tetrahydronaphthyl-2-propionic acid, which dissolves in two-thirds strength acetic acid to give a persistent intense green solution, but crystallises from methyl alcohol in colourless prisms, m. p. 191° (Found: C, 68.4; H, 6.8.  $C_{15}H_{18}O_4$  requires C, 68.7; H, 6.9%).

*Synthetic Racemic desmotropoSantonin* (IV).—The above lactone (1 g.) was dissolved in ethyl alcohol (50 c.c.), washed sodium amalgam (80 g. of 4%) added, and the mixture refluxed for 15 hours on the water-bath. The solution was decanted from the mercury and filtered from a trace of sediment and the alcohol was removed under reduced pressure. The residue was dissolved in a small volume of water, acidified with hydrochloric acid, and extracted three times with ether and the extract was dried with sodium sulphate and evaporated to about 2 c.c. After 12 hours, 0.2 g. of a crystalline solid separated, m. p. 178—184°, raised to 194—196° after four recrystallisations from alcohol. When the above dried ethereal extract was evaporated, however, and the residue again refluxed over-night with alcohol (10 c.c.) and washed amalgam (40 g. of 4%), then, after removal of the alcohol and solution in water, acidification yielded a solid which was collected and crystallised once from alcohol, giving colourless prisms (0.3 g.), m. p. 199°, raised to 200—201° by one recrystallisation (Found: C, 73.4; H, 7.4.  $C_{15}H_{18}O_3$  requires C, 73.2; H, 7.3%). The compound is sparingly soluble in ethyl alcohol, readily in ethyl acetate, and almost insoluble in ether, and its m. p. is not depressed by admixture with racemic

*desmotroposantonin* prepared from *santonin* as described below. Synthetic *acetyl desmotroposantonin*, obtained by treatment with acetic anhydride and sodium acetate, separated in colourless prisms, m. p.  $146^{\circ}$ , again not depressed by mixture with *acetyl desmotroposantonin* prepared from *santonin* (Found: C, 71.1; H, 7.2.  $C_{17}H_{20}O_4$  requires C, 70.8; H, 7.0%).

*Racemic desmotropoSantonin from Santonin.*—*d-desmotropoSantonin* was prepared as follows: *Santonin* (10 g.) and fuming hydrochloric acid (60 c.c.) were heated in a sealed tube at  $35^{\circ}$  for 36 hours. The product was diluted with water, and the solid collected, dissolved in dilute sodium hydroxide solution, and filtered. The filtrate was acidified and warmed and the *d-desmotroposantonin* (8.5 g.) was collected; it crystallised from ethyl alcohol in fine prisms, m. p.  $260^{\circ}$  (compare Andreocci, *Gazzetta*, 1893, **23**, ii, 469). *isodesmotropoSantonin* was prepared from the *d*-form according to the method of Andreocci (*loc. cit.*), the reaction being complete in about  $1\frac{1}{2}$  hours. *isodesmotropoSantonin* melts at  $194^{\circ}$  [Andreocci gives  $187-188^{\circ}$  (decomp.)] and its acetyl derivative melts at  $154^{\circ}$ . *l-desmotropoSantonin* (the enantiomorph of *isodesmotroposantonin*) and racemic *desmotroposantonin* were prepared as described by Andreocci (*Ber.*, 1898, **31**, 3131).

Our thanks are due to the Chemical Society for a grant which has partly defrayed the cost of this investigation.

## CXLI.—The Scission of Diaryl Ethers and Related Compounds by Means of Piperidine. Part IV. Elimination of Halogen Atoms and Scission Reactions during Substitution Processes.

By DOROTHY LILIAN FOX and EUSTACE EBENEZER TURNER.

IN earlier investigations in the present series, a number of halogenated diphenyl ethers have been nitrated, with results that can be explained by current theories of aromatic substitution. We have now encountered some cases in which nitration is not of the simple type hitherto met with, but is accompanied by elimination of halogen atoms or disruption of the molecule.

The 2:2'-nitration of 4:4'-dichloro- and 4:4'-dibromodiphenyl ether proceeds without difficulty (J., 1927, 1168), and the mononitro-derivatives obtained by controlling the conditions of

nitration are readily convertible into the dinitro-compounds. We have now found that under the conditions which favour the formation of these dinitro-derivatives, both the 2- and the 2'-nitro-derivative of 4-chloro-4'-bromodiphenyl ether undergo partial elimination of chlorine, and that when the nitration is performed at 100°, complete elimination of chlorine occurs, with the formation of 4-bromo-2 : 2' : 4' -trinitrodiphenyl ether :

The same product is formed when the more drastic nitration conditions are applied to 4-chloro-4'-bromo-2 : 2' -dinitrodiphenyl ether. The latter compound may be obtained by nitrating either of the corresponding mononitro-compounds under definite conditions. Prolonged nitration of the bromotrinitro-ether causes very slow removal of the bromine atom. On the other hand, when 4-bromo-2-nitrodiphenyl ether is nitrated, the bromine atom is eliminated more readily, and with prolonged nitration pure 2 : 4 : 2' : 4' -tetranitrodiphenyl ether is produced :

Elimination of chlorine occurs during the prolonged nitration of 4 : 4' -dichloro-2 : 2' -dinitrodiphenyl ether, but, in view of the above facts, it is surprisingly slow, and we have not succeeded in obtaining a pure specimen of the tetranitro-ether by this process. In short, the product of one replacement of chlorine by a nitro-group, namely, 4-chloro-2 : 2' : 4' -trinitrodiphenyl ether (compare the stability of the analogous bromo-compound) is relatively resistant. It is produced by the nitration of 4-chloro-2'-nitrodiphenyl ether, and, together with 4 : 4' -dichloro-2 : 2' -dinitrodiphenyl ether, by the hot nitration of 4 : 4' -dichloro-2-nitrodiphenyl ether.

There would appear to be three main factors determining such replacements of halogen by a nitro-group: (a) The factor that determines the course of ordinary aromatic substitution. In the present examples halogen and not hydrogen is eliminated. (b) The tendency of a co-valently attached halogen atom to become an ion. (c) The tendency of a halogen atom to remain in co-valent attachment to a carbon atom.

An excellent survey of the literature of atom or group elimination during substitution processes is given by de Lange (*Rec. trav. chim.*,

1926, 45, 19), and it is only necessary for present purposes to refer to a few general conclusions. It has usually been found that bromine is more readily eliminated than chlorine during nitration. Thus, for example, Ling (J., 1889, 55, 589) found that 2-chloro-4-bromo-6-nitrophenol was nitrated to give 2-chloro-4 : 6-dinitrophenol, and that 4-chloro-2-bromo-6-nitrophenol lost bromine in the *o*-position rather than chlorine in the *p*-, to give 4-chloro-2 : 6-dinitrophenol. That factor (*a*) is of greater importance than the nature of the halogen atom (factors *b* and *c*) would appear to be shown by the results of Hewitt and Mitchell (J., 1906, 89, 1167), who found that when diazotised *p*-nitroaniline was added to an alkaline solution of 1-chloro-, 1-bromo-, or 1-iodo- $\beta$ -naphthol, the product in each case was 1-benzeneazo- $\beta$ -naphthol. Again, it has already been shown (Parts II and III) that 2 : 4-dichloro- and 2 : 4-dibromo-2' : 4'-dinitrodiphenyl ethers readily undergo 5-nitration :

This occurs in the cold, but we have now submitted the two resulting trinitro-ethers to the action of fuming nitric acid at 100°. Although in both cases slight elimination of halogen occurs, almost the whole of the original substances may be recovered in the pure condition. It therefore seems probable that factor (*a*) is most important in these cases. In 4-chloro-4'-bromo-2- and -2'-nitrodiphenyl ether, the para-orienting effect of oxygen is the most powerful influence at work, whereas in 2 : 4-dichloro- and 2 : 4-dibromo-2' : 4'-dinitrodiphenyl ether this effect is more than counter-balanced by the 5-directing influence of the two halogen atoms, so that elimination of halogen does not occur. Again factor (*a*) takes control. The preferential elimination of chlorine from the chloro-bromo-ethers may be attributed to factor (*b*).

To some extent elimination reactions of the type under consideration are governed by mere mass effects in addition. For instance, bromination of 4-chloro-2 : 6-dinitrophenol under certain conditions causes replacement of a nitro-group by bromine, 4-chloro-2-bromo-6-nitrophenol being produced (Gordon, *Chem. News*, 1891, 63, 222), whilst picric acid, when gently warmed with bromine and water, gives 2-bromo-4 : 6-dinitrophenol (Armstrong, *Ber.*, 1873, 6, 650), and it is a common experience that in the chlorination of nitro-compounds at moderately high temperatures, nitrous fumes are occasionally given off, no doubt because partial elimination of the nitro-group has taken place.

A second type of elimination reaction has been observed in which a chlorine atom is replaced by the sulphonic acid group. Thus, when 4-chloro-2-nitro-4'-methyldiphenyl ether is dissolved in cold concentrated sulphuric acid, hydrogen chloride is at once evolved, and 2-nitro-4'-methyldiphenyl ether 4-sulphonic acid is formed :

This result is unexpected, for no halogen hydride is produced by the action of cold concentrated sulphuric acid on the isomeric 4-chloro-2'-nitro-4'-methyldiphenyl ether, or on 2:4:4'-trichloro-, 2:4-dichloro-2':4'-dinitro-, or 2:4-dibromo-2':4'-dinitro-diphenyl ether.

A third type of reaction which has to be recorded is that of scission during nitration. By mild nitration, 4-chloro-2-nitro-4'-methyldiphenyl ether may be converted into 4-chloro-2:2'-dinitro-4'-methyldiphenyl ether, but, when it is dissolved in cold fuming nitric acid, the main product is 4-chloro-2:6-dinitrophenol. This phenol is also the main product formed by similarly nitrating 4-chloro-2'-nitro-4'-methyldiphenyl ether. Yet, although it is difficult to avoid concluding that in both nitrations the initial product is 4-chloro-2:2'-dinitro-4'-methyldiphenyl ether, the latter substance does not undergo scission when heated with fuming nitric acid, but suffers partial replacement of chlorine by a nitro-group.

The apparent destruction of a tolyl group during the above nitrations is interesting in view of the fact (Pauly, Gilmour, and Will, *Annalen*, 1914, 403, 119) that 3-nitro-*p*-cresol is converted by fuming sulphuric acid into  $\beta$ -methyl- $\gamma$ -crotonolactone- $\gamma$ -acetic acid. Incidentally, Reilly, Drumm, and Barrett (J., 1927, 67) have found that di-*p*-tolyl ether also undergoes considerable scission when nitrated.

A fourth set of results concerns the scission of certain ethers by piperidine. Although 4-chloro-2'-nitro-4'-methyldiphenyl ether readily undergoes scission by piperidine, 4-chloro-2-nitro-4'-methyldiphenyl ether is somewhat resistant to this reagent. Since, in general, 2- or 4-nitrodiphenyl ethers permit of facile piperidine scission, it would appear that the chlorine atom in 4-chloro-2-nitro-4'-methyldiphenyl ether acts in opposition to the nitro-group. A similar effect may be produced by a bromine atom; *e.g.*, *o*-bromonitrobenzene readily reacts with potassium phenoxide to give 2-nitrodiphenyl ether; but 2:5-dibromonitrobenzene reacts very indifferently.

The nitration of 2-chloro-2'-nitrodiphenyl ether has been found to proceed according to the following scheme :

The constitution of the chlorodinitro-ether follows from the fact that the ether is not identical with 2-chloro-2':4'-dinitrodiphenyl ether. 2-Bromo-2'-nitrodiphenyl ether is nitrated similarly.

Bromination of 4-bromo-2-nitrodiphenyl ether takes place in the 4'-position, for the product is identical with that obtained by the mononitration of 4:4'-dibromodiphenyl ether.

#### EXPERIMENTAL.

*Preparation of Diphenyl Ethers.*—The general procedure was as follows: Potassium hydroxide (1 mol.) was treated with so much water that a clear melt was obtained on heating to about 250° (about 1/10 to 1/15 mol.). The melt was then allowed to cool until incipient crystallisation began, and at once the phenolic substance (1 mol.) was rapidly added, with shaking. Subsequent procedure depended on the nature of the halogenonitro-compound to be used: (a) Halogenomononitro-compounds such as *o*-chloronitrobenzene, 2:5-dibromonitrobenzene, etc. In such cases, the halogenonitro-compound (1 mol.) was added in one portion to the still hot phenoxide melt, the whole was well shaken, and then heated under a short air-condenser in a metal bath at 160–180° for 3–4 hours. (b) Halogenodinitro-compounds, such as 1-chloro-2:4-dinitrobenzene. The halogenodinitro-compound (1 mol.) was added gradually with vigorous shaking during about 5 minutes. As a rule, potassium halide began to separate almost immediately, and the reaction was rendered complete by an hour's heating at 100°. In all cases, the reaction product was shaken with hot dilute alkali, and the cooled mixture filtered or extracted with ether, according to the nature of the final product.

It has not been found advisable to use copper-bronze as a catalyst in any of the condensations.

4-Chloro-4'-bromo-2'-nitrodiphenyl ether, prepared from *p*-chlorophenol and 2:5-dibromonitrobenzene, was crystallised from glacial acetic acid; it then melted at 100–101°. Raiford and Colbert (*J. Amer. Chem. Soc.*, 1926, **48**, 2652) gave m. p. 100.5°.

4-Chloro-4'-bromo-2-nitrodiphenyl ether, from *p*-bromophenol and 2:5-dichloronitrobenzene, had m. p. 95°. Raiford and Colbert (*loc. cit.*) gave m. p. 93–94°.

*4-Chloro-4'-bromo-2:2'-dinitrodiphenyl Ether.*—4-Chloro-4'-bromo-2'-nitrodiphenyl ether (3 g.) was added to a cold mixture of 15 g. of nitric acid ( $d$  1.5) and glacial acetic acid (15 g.). The solution was gently warmed until the solid had dissolved, and then poured into water. The precipitated solid crystallised from glacial acetic acid in very pale yellow, silky needles, m. p.  $165^{\circ}$  (0.1482 g. gave 0.1350 g.  $\text{AgCl} + \text{AgBr}$ .  $\text{C}_{12}\text{H}_6\text{O}_5\text{N}_2\text{ClBr}$  requires  $\text{AgCl} + \text{AgBr}$ , 0.1316 g.).

Similar nitration of 4-chloro-4'-bromo-2-nitrodiphenyl ether gave a product which alone or mixed with the above compound melted at  $165^{\circ}$ .

*4-Bromo-2:2':4'-trinitrodiphenyl Ether.*—(1) 4-Chloro-4'-bromo-2-nitrodiphenyl ether was added to 10 parts of nitric acid ( $d$  1.5) and the resulting solution was heated at  $100^{\circ}$  for 2 hours and then cooled and poured into water. The precipitated solid crystallised from glacial acetic acid in pale yellow, prismatic needles, m. p.  $154^{\circ}$  (Found: Br, 20.1. Calc.: Br, 20.8%). Raiford and Colbert (*loc. cit.*) gave m. p.  $148.5^{\circ}$ . We have found that a specimen kept for some months melts at  $148$ – $149^{\circ}$ . (2) Similar nitration of 4-chloro-4'-bromo-2'-nitrodiphenyl ether gave an identical product.

*4:4'-Dichloro-2:2'-dinitrodiphenyl Ether.*—A solution of 4:4'-dichloro-2-nitrodiphenyl ether in 10 parts of nitric acid ( $d$  1.5) was warmed gently for 10 minutes. The cooled solution was poured into water, and the precipitate crystallised from glacial acetic acid. The dinitro-compound melted at  $154^{\circ}$  (compare Le Fèvre, Saunders, and Turner, J., 1927, 1168).

*4-Chloro-2:2':4'-trinitrodiphenyl Ether.*—(a) 4:4'-Dichloro-2-nitrodiphenyl ether was added to 10 parts of nitric acid ( $d$  1.5), and the solution heated at  $100^{\circ}$  for 2 hours. The whole was cooled and poured into water, and the solid obtained crystallised from glacial acetic acid. It formed yellow prismatic needles, m. p.  $155^{\circ}$ . Raiford and Colbert (*loc. cit.*) describe the compound as forming yellowish plates, m. p.  $154^{\circ}$  (Found: Cl, 10.8. Calc.: Cl, 10.5%).

(b) 4-Chloro-2:2':4'-trinitrodiphenyl ether was also prepared by condensing *p*-chlorophenol with 1-chloro-2:4-dinitrobenzene, the product being treated with cold fuming nitric acid. The solution was gently warmed and poured into water. The precipitate, after recrystallisation, had m. p.  $155^{\circ}$  alone or when mixed with the product from (a).

(c) 4-Chloro-2'-nitrodiphenyl ether, when nitrated in a similar manner, gave a product identical with those from (a) and (b).

*Prolonged Action of Nitric Acid on 2:4-Dichloro- and 2:4-Dibromo-5:2':4'-trinitrodiphenyl Ether.*—The dichloro-ether was heated with 10 parts of nitric acid ( $d$  1.5) for 2 hours at  $100^{\circ}$ . A little hydrogen chloride was slowly evolved. The solution was poured into water,

and the precipitate washed and dried. It had 90% of the weight of the original ether, and melted at 128°, alone or when mixed with the pure trinitro-ether. Similar treatment of the dibromo-ether gave 92% of unchanged ether, m. p. 139—140° alone or mixed with pure ether.

2-Chloro-2'-nitrodiphenyl ether had b. p. 345°, m. p. 47—48°. Roberts and Turner (J., 1925, 127, 1008) gave m. p. 48° (Found : Cl, 14.3. Calc. : Cl, 14.2%).

2-Chloro-2' : 4'-dinitrodiphenyl ether, prepared from *o*-chlorophenol and 1-chloro-2 : 4-dinitrobenzene, crystallised from glacial acetic acid-alcohol in cream-coloured prisms, m. p. 75—76° (Found : Cl, 12.0.  $C_{12}H_7O_5N_2Cl$  requires Cl, 12.05%).

2-Chloro-4 : 2'-dinitrodiphenyl Ether.—2-Chloro-2'-nitrodiphenyl ether was dissolved in 10 parts of nitric acid (*d* 1.4) with warming. The solution was poured into water; the precipitate obtained, after crystallising from glacial acetic acid, had m. p. 126—127° (Found : Cl, 12.0.  $C_{12}H_7O_5N_2Cl$  requires Cl, 12.05%).

2-Chloro-4 : 2' : 4'-trinitrodiphenyl Ether.—A solution of the 4 : 2'-dinitro-ether in 10 parts of nitric acid (*d* 1.5) was heated for 20 minutes at 100° and then poured into water. The resulting precipitate separated from glacial acetic acid in yellow rhombohedra, m. p. 135—136° (Found : Cl, 9.8.  $C_{12}H_6O_7N_3Cl$  requires Cl, 10.5%).

4-Bromo-2-nitrodiphenyl Ether.—A mixture of 6 g. of potassium hydroxide, 0.2 c.c. of water, 9 g. of phenol, and 28 g. of 2 : 5-dibromonitrobenzene was allowed to react for 6 hours under the usual conditions. Although potassium bromide separated, only 14 g. of 4-bromo-2-nitrodiphenyl ether were obtained, as a dark oil, b. p. 228—230°/21 mm. It was found impossible to remove a small quantity of unchanged dibromonitrobenzene (Found : Br, 28.7.  $C_{12}H_8O_3NBr$  requires Br, 27.2%).

Bromination of 4-Bromo-2-nitrodiphenyl Ether.—A solution of 29 g. of this ether and 14.8 c.c. of bromine in 135 c.c. of glacial acetic acid was heated under reflux at 100° until hydrogen bromide was no longer evolved. The solution was poured into water, and the precipitate filtered off. It melted at 94° after crystallisation from glacial acetic acid, and was identical with a specimen of 4 : 4'-dibromo-2-nitrodiphenyl ether obtained by the mononitration of 4 : 4'-dibromodiphenyl ether (Le Fèvre, Saunders, and Turner, *loc. cit.*).

Prolonged Nitration of 4-Bromo-2-nitrodiphenyl Ether.—The ether was dissolved in 10 parts of nitric acid (*d* 1.5), and a clear solution obtained by warming. On pouring the solution into water, and crystallising the precipitate from glacial acetic acid, a product was obtained, m. p. 180—182°. A second similar nitration raised the m. p.

to 191—192°, a third to 195—196°, and a fourth to 196°. The final product did not depress the m. p. of 2 : 4 : 2' : 4'-tetranitrodiphenyl ether. In another experiment, 5 g. of 4-bromo-2-nitrodiphenyl ether were heated with 25 g. of nitric acid (*d* 1.5) for 2 hours at 100°. The gases evolved were absorbed in alkali, and the alkaline solution analysed. It was found that 80% of the bromine originally present had been given off. Pure tetranitrodiphenyl ether was obtained from the nitric acid solution.

*Bromination of 2-Nitrodiphenyl Ether.*—A solution of 20 g. of the ether and 16 g. of bromine in 40 g. of glacial acetic acid was heated under reflux at 100° until the colour of the bromine had disappeared. The solution was poured into alcohol. The solid that separated on standing was crystallised from glacial acetic acid, and then had m. p. 72°. Raiford and Colbert (*loc. cit.*) obtained 4-bromo-2'-nitrodiphenyl ether by a condensation process, and gave m. p. 71°.

*2-Bromo-2' : 4'-dinitrodiphenyl ether*, from *o*-bromophenol and 1-chloro-2 : 4-dinitrobenzene, separated from glacial acetic acid in pale yellow leaflets, m. p. 88—89° (Found : Br, 23.4.  $C_{12}H_7O_5N_2Br$  requires Br, 23.6%).

*Mononitration of 2-Bromo-2' : 4'-dinitrodiphenyl Ether.*—The ether was added to a mixture of 5 parts of glacial acetic acid and 5 parts of nitric acid (*d* 1.5). A clear solution was produced by warming, and after 20 minutes it was poured into water, and the precipitate collected. The 2-bromo-4 : 2' : 4'-trinitrodiphenyl ether crystallised from glacial acetic acid in small yellow needles, m. p. 127—128° (Found : Br, 21.6.  $C_{12}H_6O_7N_3Br$  requires Br, 20.8%).

*2-Bromo-2'-nitrodiphenyl ether*, from *o*-bromophenol and *o*-chloro-nitrobenzene, had b. p. 251°/27 mm. It crystallised from glacial acetic acid-alcohol in yellow prisms, m. p. 49—50° (Found : Br, 27.6.  $C_{12}H_8O_3NBr$  requires Br, 27.2%).

*2-Bromo-4 : 2'-dinitrodiphenyl Ether.*—2-Bromo-2'-nitrodiphenyl ether (3 g.) was added to a mixture of 15 g. of glacial acetic acid and 15 g. of nitric acid (*d* 1.5). The whole was warmed until solution was complete, left for 20 minutes, and poured into water. The product separated from glacial acetic acid in rectangular crystals, m. p. 128° (Found : Br, 24.1.  $C_{12}H_7O_5N_2Br$  requires Br, 23.6%).

*Nitration of 4-Bromo-2' : 4'-dinitrodiphenyl Ether.*—A solution of the ether in 10 parts of nitric acid (*d* 1.5) was warmed for a few minutes and poured into water, and the precipitate crystallised from glacial acetic acid; 4-bromo-2 : 2' : 4'-trinitrodiphenyl ether was then obtained, m. p. 154°.

*4-Chloro-2-nitro-4'-methyldiphenyl ether*, prepared from *p*-cresol and 2 : 5-dichloronitrobenzene, crystallised from alcohol in pale brownish plates, m. p. 99° (Found : Cl, 13.8.  $C_{13}H_{10}O_3NCl$  requires Cl, 13.6%).

An attempt was made to nitrate the ether with concentrated sulphuric acid and potassium nitrate. When the ether was dissolved in the acid, hydrogen chloride was evolved, and on warming at  $100^{\circ}$  a clear solution was obtained, which on cooling and dilution gave white silky needles of 2-nitro-4'-methyldiphenyl ether 4-sulphonic acid, m. p.  $129-130^{\circ}$ . Crystallisation from light petroleum did not affect this m. p. (Found: S, 11.0.  $C_{13}H_{11}O_6NS$  requires S, 10.4%).

*Action of Piperidine on 4-Chloro-2-nitro-4'-methyldiphenyl Ether.*—The ether was heated for an hour at  $100^{\circ}$  with its own weight of piperidine. When the solution was made alkaline, a mixture of 4-chloro-2-nitrophenylpiperidine and unchanged ether was precipitated. The mixture was extracted with 50% sulphuric acid; from the acid extract, on treatment with alkali, the pure chloro-nitrophenylpiperidine was precipitated. In a second experiment, a solution of the ether in excess of piperidine was boiled for several hours, the bulk of the piperidine distilled off, and alkali added; the chloronitrophenylpiperidine which then separated was removed. The filtrate was extracted with benzene until it was colourless, traces of benzene were removed by boiling, and *p*-toluenesulphonyl chloride was added to the heated alkaline solution. After some time, *p*-tolyl *p*-toluenesulphonate separated; after crystallisation from acetic acid-alcohol, it had m. p.  $68^{\circ}$ , alone or when mixed with an authentic specimen.

*4-Chloro-2 : 2'-dinitro-4'-methyldiphenyl Ether.*—4-Chloro-2-nitro-4'-methyldiphenyl ether was dissolved in an ice-cold mixture of 5 parts of glacial acetic acid and 5 parts of nitric acid (*d* 1.5). The solution was heated at  $100^{\circ}$  for an hour, cooled, and poured into water. The precipitate crystallised from acetic acid and alcohol in very pale yellow plates, m. p.  $115^{\circ}$  (Found: Cl, 12.1.  $C_{13}H_9O_5N_2Cl$  requires Cl, 11.5%).

When a solution of the dinitro-ether in nitric acid (*d* 1.5) was heated at  $100^{\circ}$  for an hour, hydrogen chloride was slowly evolved. When the solution was poured into water, a solid was obtained, m. p.  $146-149^{\circ}$ . This could not be separated into definite fractions, but was probably a mixture of unchanged material with 2 : 4 : 2'-trinitro-4'-methyldiphenyl ether.

*4-Chloro-2'-nitro-4'-methyldiphenyl ether*, prepared from 4-chloro-3-nitrotoluene and *p*-chlorophenol, crystallised from alcohol in very pale yellow, irregular, rectangular plates, m. p.  $52^{\circ}$  (Found: Cl, 13.6.  $C_{13}H_{10}O_3NCl$  requires Cl, 13.6%).

When a solution of the ether in 5 parts of glacial acetic acid and 5 parts of nitric acid (*d* 1.5) was heated for an hour at  $100^{\circ}$ , 4-chloro-2 : 2'-dinitro-4'-methyldiphenyl ether was obtained, identical with the product of nitrating the isomeric 2-nitro-ether.

*Action of Piperidine on 4-Chloro-2'-nitro-4'-methyldiphenyl Ether.*—A solution of the ether in its own weight of piperidine was heated for an hour at 100°. When excess of alkali was added to the cooled solution, 2-nitro-4-methylphenylpiperidine separated, m. p. 69°.

*Nitrative Scission of 4-Chloro-2-nitro-4'-methyl- and of 4-Chloro-2'-nitro-4'-methyl-diphenyl Ether.*—The ethers were dissolved in 10 parts of nitric acid (*d* 1.5) at 0°. After 20 minutes, the solutions were poured into water, and the yellow precipitates collected. After crystallisation they both melted at 74–75°, and were pure specimens of 4-chloro-2:6-dinitrophenol.

All the m. p.'s given are corrected.

## CXLII.—10-Chloro-5:10-dihydrophenarsazine and its Derivatives. Part XII. Further Experiments in the Investigation of the 1- and 3-Methyl Derivatives.

By CHARLES STANLEY GIBSON and JOHN DOBNEY ANDREW JOHNSON.

It was shown in Part VII (J., 1929, 767) that an apparently homogeneous product, which can be either 10-chloro-1-methyl-5:10-dihydrophenarsazine (II) or 10-chloro-3-methyl-5:10-dihydrophenarsazine (III), can be obtained from 3-methyldiphenylamine-6'-arsinic acid (I) either by direct reduction or by conversion first into the homogeneous 1(or 3)-methylphenarsazinic acid hydrochloride (IV) and subsequent reduction of the latter compound. Further, in Part X (J., 1929, 1473), it was proved that the same compound (II) or (III) was the homogeneous condensation product of phenyl-*m*-tolylamine and arsenious chloride.

In order to determine the constitution of the cyclic reduction product obtained from compound (I), substances having the constitutions (II) and (III) were synthesised by methods which should leave no doubt as to their structural formulæ (Part VII, *loc. cit.*). The two substances thus synthesised were, however, indistinguishable and two explanations of this are possible: (1) the two substances may form solid solutions in each other, and (2) one of the rationally synthesised products may be transformed into the other by a rupture of the medial cyclic system, followed by cyclisation in the only other possible way (*loc. cit.*, p. 775).

The synthesis of substances (II) and (III) was attempted by the following series of reactions, which afford as little opportunity as possible of transformation of one into the other; the first stage in each case is analogous to that employed in the first synthesis of 10-chloro-5:10-dihydrophenarsazine (Burton and Gibson, J., 1926, 452):

The advantage of this method of synthesis appeared to be that the final cyclisation process did not involve the arsenic atom, and if the explanation (2, above) of the apparent or real identity of substances (II) and (III) is the rupture of the heterocyclic nucleus, followed by cyclisation in a different way—both of which processes involve the arsenic atom—there was a reasonable hope that the syntheses would be accomplished without intramolecular change.

The series of reactions (b) was readily accomplished, the intermediate substances, 2'-bromo-2-nitro-4-methyldiphenylarsinic acid (VIII) and 2'-bromo-2-amino-4-methyldiphenylarsinic acid (IX) being highly crystalline substances of undoubted purity. The 10-chloro-3-methyl-5:10-dihydrophenarsazine thus rationally synthesised was indistinguishable from either of the previously rationally synthesised products and from the homogeneous products obtained by the methods mentioned above.

Unfortunately, the proposed synthesis of 10-chloro-1-methyl-5:10-dihydrophenarsazine by the series of reactions (a) could not be accomplished. 2'-Bromo-2-nitro-6-methyldiphenylarsinic acid (V) was prepared, but the reduction product could not be purified and an attempt to convert this crude material into (II) was unsuccessful.

Although the immediate object of this part of these investigations has not been accomplished, it may be that 10-chloro-3-methyl-5:10-dihydrophenarsazine has now been definitely synthesised. Before, however, the constitution of the 10-chloro-1(or 3)-methyl-5:10-dihydrophenarsazine obtained in the above-mentioned reactions can be definitely stated, 10-chloro-1-methyl-5:10-dihydrophenarsazine must be synthesised in an unequivocal manner: the balance of evidence, however, appears to be in favour of its being the 3-methyl compound.

The present work indicates that possibly false conclusions may be drawn as to the constitution of the product of a reaction which may give rise to one of two substances when this proves to be identical with one synthesised product and is not compared with the other synthesised isomeric substance. This problem is being investigated in different directions.

#### EXPERIMENTAL.

*o*-Bromophenylarsenious oxide is most conveniently prepared by passing carbon dioxide into a solution of pure *o*-bromophenyldichloroarsine (Burton and Gibson, J., 1926, 457; Kalb, *Annalen*, 1921, 423, 39) in dilute aqueous sodium hydroxide, warmed if necessary. The colourless oxide is filtered off, washed with water, and dried over potassium hydroxide under reduced pressure; it is thus obtained as a fine colourless powder readily soluble in alkali hydroxide solutions.

2'-Bromo-2-nitro-4-methyldiphenylarsinic Acid (VIII).—Finely powdered and sieved 3-nitro-*p*-toluidine (7.6 g.) in hydrochloric acid (40 c.c.) and water (125 c.c.) was diazotised with sodium nitrite (3.8 g.) in water (9 c.c.) below 0°. A solution of *o*-bromophenylarsenious oxide (13.6 g.) in 5*N*-sodium hydroxide (87 c.c.) and water (163 c.c.) to which had been added ammoniacal cupric sulphate

(10% cupric sulphate solution treated with excess of ammonia; 5 c.c.) was then treated slowly at 20° with the diazo-solution without external cooling, the mixture being mechanically stirred. After one hour, the liquid was heated to boiling, treated with decolorising charcoal, and filtered. The filtrate was saturated with carbon dioxide to precipitate unchanged *o*-bromophenylarsenious oxide and, after filtration, carefully acidified with concentrated hydrochloric acid. The amorphous yellow acid which was precipitated could not be crystallised directly and was converted into its sodium salt by dissolving it in warm 20% aqueous sodium hydroxide and cooling the solution. The buff-yellow sodium salt was filtered off, washed with 20% aqueous sodium hydroxide and dissolved in water, and the solution acidified with hydrochloric acid. The almost colourless acid was recrystallised from slightly diluted acetic acid (charcoal) and obtained in colourless needles (4.33 g.), m. p. 252—254° (decomp. after slight softening) (Found: As, 19.2.  $C_{13}H_{11}O_4NBrAs$  requires As, 18.7%). The ammonium salt crystallises from solution in concentrated aqueous ammonia in characteristic, colourless, rhomb-shaped plates.

*2'-Bromo-2-amino-4-methyldiphenylarsinic Acid (IX).*—A hot solution of the preceding acid (5.95 g.) in sodium hydroxide solution (1.5 g. in 30 c.c.) was added to a boiling suspension of ferrous hydroxide [ferrous sulphate crystals (25 g.), water (75 c.c.), and sodium hydroxide solution (25%, 30 c.c.)], and the mixture boiled for 15 minutes and filtered. The filtrate was carefully acidified with concentrated hydrochloric acid; the precipitated acid, recrystallised from slightly diluted acetic acid (charcoal), was obtained in colourless needles (3.9 g.), decomposing vigorously at 264—265° after previous darkening from about 240° (Found: As, 20.7.  $C_{13}H_{13}O_2NBrAs$  requires As, 20.3%). This acid in contradistinction to the nitro-acid is soluble in cold concentrated hydrochloric acid.

*Cyclisation of 2'-bromo-2-amino-4-methyldiphenylarsinic acid.* A mixture of the preceding acid (3.08 g.), potassium carbonate (1.22 g.), amyl alcohol (22 c.c.), and a trace of copper powder was boiled for 15 hours, volatile substances then being removed by steam distillation, the aqueous solution filtered, and the filtrate acidified. The liquid filtered very slowly from the precipitated gelatinous discoloured acid. After being washed with water and dried as far as possible on the filter, the acid was dissolved in a mixture of alcohol and concentrated hydrochloric acid, to which a trace of iodine was added, and the solution was saturated with sulphur dioxide. The discoloured yellow solid was filtered off, dried over potassium hydroxide under reduced pressure, and crystallised from benzene (charcoal). After one crystallisation it had m. p. 215—216° after previous

softening from about  $211^{\circ}$ , and a further crystallisation gave 10-chloro-3-methyl-5:10-dihydrophenarsazine, m. p.  $215-216.5^{\circ}$ ; the yield was small (Found: Cl, 12.3. Calc.: Cl, 12.2%).

*2'-Bromo-2-nitro-6-methyldiphenylarsinic Acid* (V).—This was prepared in a similar manner to that employed for the isomeric acid (VIII), 3-nitro-*o*-toluidine being used instead of 3-nitro-*p*-toluidine. The crude acid was purified by direct crystallisation from slightly diluted acetic acid, from which it separated in almost colourless, small plates. When recrystallised from the same medium, it was obtained in pale yellow plates, softening at  $226^{\circ}$ , darkening and finally decomposing at  $237-239^{\circ}$ ; yield 29% (Found: As, 19.0.  $C_{13}H_{11}O_4NBrAs$  requires As, 18.7%). The sodium salt separates from a solution of the acid in warm 20% aqueous sodium hydroxide in colourless small plates.

### CXLIH.—*ortho*- and meta-Derivatives of Simple Alkyl Phenyl Ketones.

By LESLIE ALDERMAN ELSON, CHARLES STANLEY GIBSON,  
and JOHN DOBNEY ANDREW JOHNSON.

IN connexion with a part of an extended investigation of certain types of organic arsenical compound it has been necessary to review our knowledge of derivatives of aceto-, propio-, and *n*-butyrophenones required as starting materials. In certain cases, the published methods of preparation were not suitable for our purpose and, in others, the compounds as described were apparently not pure. This preliminary investigation was, of necessity, somewhat prolonged and entailed the preparation of derivatives not hitherto described.

The first compounds required were the *o*- and *m*-amino-derivatives of the above ketones and their preparation was carried out in the same way in all cases. Each of these ketones, on nitration, yields a mixture of the *o*- and *m*-nitro-compounds, from which the *m*-compound is easily separated and obtained pure, leaving an uncrystallisable oil (crude *o*-nitro-ketone) which is chiefly the *o*-compound containing some of the *m*-isomeride. The pure *m*-nitro-ketone is reduced to the corresponding amino-compound, which can be easily obtained in a state of purity. The crude *o*-nitro-ketone on reduction yields a mixture of the *o*- and the *m*-amino-ketone. From this mixture, the *o*-amino-ketone is

separated by steam distillation; in every case, the *m*-isomeride is much less volatile in steam than the *o*-compound, which can thus be readily obtained pure.

*o*-Aminoacetophenone has now been obtained as a pale yellow, crystalline solid, m. p. 20°. *m*-Bromoacetophenone has m. p. 7—8°; it yields 3 :  $\omega$ -dibromoacetophenone on direct bromination and 5-bromo-2-nitroacetophenone on nitration.

*m*-Aminopropiophenone does not yield a semicarbazone under the same conditions as the *o*-compound. The reaction between *o*-aminopropiophenone and semicarbazide hydrochloride, under the conditions described in the experimental portion, besides giving the semicarbazone, yields another product which is mentioned below. *o*-Bromopropiophenone, when brominated in acetic acid solution, yields 2 :  $\alpha$ -dibromopropiophenone.

*n*-Butyrophenone (*n*-propyl phenyl ketone), prepared from *n*-butyryl chloride by the Friedel-Crafts reaction, has m. p. 13° (compare Morgan and Hickinbottom, J., 1921, **119**, 1882). *o*-Bromobutyrophenone on bromination yields first 2 :  $\alpha$ -dibromobutyrophenone and then 2 :  $\alpha$  :  $\alpha$ -tribromobutyrophenone. Analysis of the latter compound and of 4 :  $\alpha$ -dibromobutyrophenone—prepared from bromobenzene and  $\alpha$ -bromobutyryl chloride by the Friedel-Crafts reaction—indicated the great tendency of these compounds to lose hydrogen bromide. 4-Chloro- $\alpha$ -bromobutyrophenone was, however, isolated in the crystalline state from chlorobenzene and  $\alpha$ -bromobutyryl chloride by the Friedel-Crafts reaction. Like *m*-aminopropiophenone, *m*-aminobutyrophenone does not yield a semicarbazone under the usual conditions. The reaction between *o*-aminobutyrophenone and semicarbazide hydrochloride is discussed below.

With the exceptions noted above, there is little difficulty in isolating the semicarbazones of many of the compounds described and these may prove useful for identification purposes. The reactions, however, between *o*-aminopropiophenone and semicarbazide and between the latter compound and *o*-amino-*n*-butyrophenone need special comment. In isolating the semicarbazone of *o*-aminopropiophenone, it was noticed that the crude substance was contaminated with a bright yellow substance the quantity of which was increased when the reaction was prolonged and especially when the mixture was heated. A yellow substance only was obtained when *o*-amino-*n*-butyrophenone was treated with semicarbazide hydrochloride under the usual conditions, and the yield, again, of this product was increased when the reaction mixture was heated. The two yellow substances resembled each other very closely, both crystallising in yellow needles; that obtained from *o*-amino-

propio-phenone had m. p. 130° and that from *o*-amino-*n*-butyro-phenone had m. p. 135°, this being obtained the more easily. The latter compound had the empirical formula  $C_{10}H_{13}N_2$  and the molecular weight determination by the method of Rast indicated that this was half the molecular formula. It soon became evident that the two compounds were ketazines, that from *o*-aminopropio-phenone being *ethyl-o-aminophenylketazine* (I) and that from *o*-amino-*n*-butyrophenone being *n-propyl-o-aminophenylketazine* (II).

The ease of formation of these substances seems unusual, ketazines being generally formed either by the action of hydrazine on ketones or by heating the semicarbazones to a moderately high temperature (Scholtz, *Ber.*, 1896, **29**, 610; Borsche, *Ber.*, 1901, **34**, 4301; Bruining, *Rec. trav. chim.*, 1922, **41**, [ii], 655), ammonia and hydrazodicarbonimide being formed during the decomposition. An attempt to prepare substance (I) by heating *o*-aminopropio-phenonesemicarbazone above its melting point was unsuccessful, although the formation of a yellow material and evolution of ammonia were noticed. An attempt to prepare methyl-*o*-aminophenylketazine by the action of semicarbazide hydrochloride on *o*-aminoacetophenone in a similar manner to that described above led only to the isolation of the semicarbazone.

#### EXPERIMENTAL.

The nitration of acetophenone has been extensively studied by Morgan and Moss (*J. Soc. Chem. Ind.*, 1923, 461T). For the present work, acetophenone in lots of 30 c.c. was run slowly into stirred nitric acid (*d* 1.50), 140 c.c. being used each time and the temperature kept below 0°. After  $\frac{1}{2}$  hour, the product was poured on ice, and the crystalline *m*-nitroacetophenone separated by filtration. From the filtrate, made alkaline with sodium carbonate and hydroxide, the crude *o*-nitroacetophenone (containing some of the *m*-isomeride) was extracted with ether, the extract was washed with water and dried with calcium chloride, and the ether evaporated. To this crude *o*-nitroacetophenone was added the oily residue resulting from the evaporation of the alcoholic mother-liquor from the recrystallisation of the *m*-nitroacetophenone.

The pure *m*-nitroacetophenone was reduced under substantially the same conditions as described by Morgan and Moss. After recrystallisation from alcohol, *m*-aminoacetophenone was obtained in pale yellow plates, m. p. 98—99° (Morgan and Moss give 92—93°).

*m*-Aminoacetophenonesemicarbazone crystallises from water in

colourless prisms, m. p.  $196^{\circ}$  (decomp.) (Found : N, 29.3.  $C_9H_{12}ON_4$  requires N, 29.2%), and *m*-*p*-toluenesulphonamidoacetophenone from alcohol in colourless needles, m. p.  $130^{\circ}$  (Found : N, 4.9.  $C_{15}H_{15}O_3NS$  requires N, 4.85%).

The crude *o*-nitroacetophenone was reduced with tin and hydrochloric acid as described by Morgan and Moss. The resulting mixture was made strongly alkaline with sodium hydroxide and submitted to steam distillation. The *o*-aminoacetophenone in the distillate was extracted with ether, dried with calcium chloride, and recovered; it had b. p.  $130.5^{\circ}/14$  mm.,  $124^{\circ}/10$  mm., m. p.  $20^{\circ}$  (compare Morgan and Moss, *loc. cit.*). The pure ketone is almost colourless.

*o*-Aminoacetophenonesemicarbazone crystallises from alcohol in colourless plates, m. p.  $290^{\circ}$  (decomp.) (Found : N, 29.8.  $C_9H_{12}ON_4$  requires N, 29.2%). The *p*-toluenesulphonyl derivative crystallises from alcohol in colourless hexagonal plates, m. p.  $148^{\circ}$  (Found : N, 4.9.  $C_{15}H_{15}O_3NS$  requires N, 4.85%).

From 180 g. of acetophenone were obtained 40 g. of pure *o*-aminoacetophenone and 65 g. of pure *m*-aminoacetophenone.

To obtain *o*-bromoacetophenone (compare Meisenheimer, Zimmermann, and Kummer, *Annalen*, 1926, **446**, 205), *o*-aminoacetophenone (40 g.) was dissolved in hydrobromic acid (36%, 122 c.c.) and water (120 c.c.) and diazotised with a solution of sodium nitrite (21.2 g.) in water (36 c.c.) below  $0^{\circ}$ . The diazotised solution was treated with a solution in hydrobromic acid ( $d$  1.49, 100 c.c.) of cuprous bromide made by reducing copper sulphate crystals (54.2 g.) in water (180 c.c.), mixed with potassium bromide (27.2 g.) dissolved in water (63 c.c.), with sulphur dioxide. After heating for some time on the water-bath, the *o*-bromoacetophenone was removed by steam distillation, extracted from the distillate with ether, washed successively with dilute sodium hydroxide solution, dilute hydrochloric acid, and water, dried with calcium chloride, and recovered. On distillation under reduced pressure it was obtained as a pale yellow liquid, b. p.  $112^{\circ}/10$  mm., which did not solidify above  $-16^{\circ}$ . Yield, 80%.

*o*-Bromoacetophenonesemicarbazone crystallised from alcohol in colourless prisms, m. p.  $177^{\circ}$  (Found : N, 16.7.  $C_9H_{10}ON_3Br$  requires N, 16.4%).

*m*-Bromoacetophenone, obtained from *m*-aminoacetophenone as *o*-bromoacetophenone from *o*-aminoacetophenone, is a pale yellow oil, b. p.  $127.5^{\circ}/14$  mm. and  $131^{\circ}/16$  mm., which solidifies to an almost colourless, crystalline solid, m. p.  $7-8^{\circ}$ . Yield, 54% (Found : Br, 40.5.  $C_8H_7OBr$  requires Br, 40.15%). On oxidation with sodium hypobromite it was converted into *m*-bromobenzoic acid, m. p.  $155^{\circ}$ .

*m*-Bromoacetophenonesemicarbazone crystallised from alcohol in colourless needles, m. p. 232—233° (decomp.) (Found : N, 16.3.  $C_9H_{10}ON_3Br$  requires N, 16.4%).

5-Bromo-2-nitroacetophenone was obtained by adding *m*-bromoacetophenone (10 g.) to well-stirred nitric acid (*d* 1.50, 70 c.c.) below 0° and pouring the mixture on ice; the solid produced crystallised from alcohol (charcoal) in almost colourless needles, m. p. 98° (Found : N, 5.8.  $C_8H_6O_3NBr$  requires N, 5.7%). It gave 5-bromo-2-nitrobenzoic acid, m. p. 138—140°, on oxidation with sodium hypobromite.

3 :  $\omega$ -Dibromoacetophenone.—*m*-Bromoacetophenone (12.2 g.), dissolved in acetic acid (50 c.c.), was treated with bromine (3.08 c.c., 1 mol.). On heating on the water-bath, hydrogen bromide was evolved and the liquid became colourless. It was then poured into water and the 3 :  $\omega$ -dibromoacetophenone was extracted with ether, washed with dilute sodium hydroxide solution and then with water, dried with calcium chloride, recovered, and distilled under reduced pressure, some unchanged material distilling first. The dibromo-ketone, obtained in 40% yield, had b. p. 172—174°/14 mm., solidified on cooling, and crystallised from ligroin (b. p. 60—80°) in long colourless needles, m. p. 51° (Found : Br, 57.1.  $C_8H_6OBr_2$  requires Br, 57.5%). By oxidation with sodium hypobromite it was converted into *m*-bromobenzoic acid, m. p. 154°.

3 :  $\omega$ -Dibromoacetophenonesemicarbazone crystallises in clusters of flattened needles, m. p. 163—164° (decomp.) (Found : N, 13.05.  $C_9H_9ON_3Br_2$  requires N, 12.55%).

*The Nitration of Propiophenone*.—This was carried out exactly similarly to that of acetophenone and the products were also worked up similarly. The *m*-nitropropiophenone crystallises in pale yellow needles, m. p. 98—100°, and on oxidation with potassium permanganate is converted into *m*-nitrobenzoic acid (compare, however, Comanducci and Pescitelli, *Gazzetta*, 1906, 36, ii, 787).

The reduction of *m*-nitropropiophenone was carried out with iron turnings and acetic acid, and the product worked up in the usual manner. *m*-Aminopropiophenone was obtained as a pale yellow oil, b. p. 168—169°/15 mm., which solidified to a yellow solid, m. p. 42° (Found : C, 73.3; H, 7.5.  $C_9H_{11}ON$  requires C, 72.5; H, 7.4%). The yield is variable and may be as high as 60%; in some cases a large quantity of a resinous mass remained after the first distillation.

*m*-p-Toluenesulphonamidopropiophenone crystallised from alcohol in colourless needles, m. p. 97° (Found : N, 4.7.  $C_{16}H_{17}O_3NS$  requires N, 4.6%).

The reduction of the crude *o*-nitropropiophenone with tin and

hydrochloric acid was carried out in the same manner as for the crude *o*-nitroacetophenone. The *o*-aminopropiophenone was isolated by steam distillation and crystallised from the distillate in pale yellow plates, m. p.  $46^{\circ}$  (compare Auwers and Duesberg, *Ber.*, 1920, 53, 1208). From 290 g. of propiophenone were obtained in a state of purity 35 g. of *o*-aminopropiophenone and 73 g. of *m*-aminopropiophenone.

*o*-Aminopropiophenonesemicarbazone, when prepared in the usual manner in the cold, crystallises from alcohol in colourless prisms, m. p.  $190^{\circ}$  (decomp.) (Found: N, 27.3.  $C_{10}H_{14}ON_4$  requires N, 27.2%). When the solution of the reacting substances is heated, the semicarbazone obtained is mixed with the ketazine (see below). *o*-p-Toluenesulphonamidopropiophenone crystallises from alcohol in colourless prisms; it does not appear to have a definite melting point, softening at about  $125^{\circ}$  and then decomposing over a considerable range (Found: N, 4.6.  $C_{16}H_{17}O_3NS$  requires N, 4.6%).

*o*-Bromopropiophenone, prepared from *o*-aminopropiophenone in the same way as the bromoacetophenones from the corresponding amino-compounds, was obtained as a pale yellow oil, b. p.  $125^{\circ}/12$  mm., which does not solidify above  $-16^{\circ}$ ; yield, 75% (Found: Br, 37.3.  $C_9H_9OBr$  requires Br, 37.5%). *o*-Bromopropiophenonesemicarbazone crystallises from alcohol in colourless plates, m. p.  $182^{\circ}$  (Found: N, 15.7.  $C_{10}H_{12}ON_3Br$  requires N, 15.55%).

On bromination of *o*-bromopropiophenone in acetic acid under similar conditions to those described above, what was probably *o*: $\alpha$ -dibromopropiophenone was formed. This was obtained as a pale yellow liquid, b. p.  $154$ – $155^{\circ}/12$  mm., which solidified and crystallised in flat prisms with pyramidal ends, m. p.  $38$ – $39^{\circ}$ ; yield, 75% (Found: Br, 54.0.  $C_9H_8OBr_2$  requires Br, 54.7%). It gave, on oxidation with potassium permanganate, *o*-bromobenzoic acid, m. p.  $147^{\circ}$ .

*m*-Bromopropiophenone, prepared in the usual manner from *m*-aminopropiophenone, is a yellow liquid, b. p.  $143^{\circ}/18$  mm., which sets to a pale yellow solid, m. p.  $36^{\circ}$ ; yield, 52% (Found: Br, 36.7.  $C_9H_9OBr$  requires Br, 37.5%). *m*-Bromopropiophenonesemicarbazone crystallises from alcohol in colourless needles, m. p.  $180^{\circ}$  (Found: N, 15.6.  $C_{10}H_{12}ON_3Br$  requires N, 15.55%).

*n*-Butyrophenone was obtained in 66% yield by the action of *n*-butyryl chloride on benzene in the presence of aluminium chloride. It has m. p.  $13^{\circ}$ . It was nitrated in the manner above described for the analogous compounds (compare Morgan and Hickinbottom, *J.*, 1921, 119, 1882) and the products were worked up in the usual manner. *m*-Nitro-*n*-butyrophenone had m. p.  $62$ – $63^{\circ}$  when recrystallised from alcohol (almost colourless plates) and was

obtained in 42% yield. *m*-Nitro-*n*-butyrophenonesemicarbazone crystallised from alcohol in pale yellow needles, m. p. 166—167° (Found: N, 22.8.  $C_{11}H_{14}O_3N_4$  requires N, 22.4%). The constituents of the crude *o*-nitro-*n*-butyrophenone could not be separated by fractional distillation under reduced pressure.

Pure *m*-nitro-*n*-butyrophenone was reduced with iron turnings and acetic acid in the manner already described, and the reaction product worked up in the usual manner. *m*-Amino-*n*-butyrophenone is a pale yellow liquid, b. p. 179—180°/16 mm., which sets to a yellow solid, m. p. 27—28°. *m*-*p*-Toluenesulphonamido-*n*-butyrophenone crystallises from somewhat diluted alcohol in colourless needles, m. p. 70° (Found: N, 4.3.  $C_{17}H_{19}O_3NS$  requires N, 4.4%).

The crude *o*-nitro-*n*-butyrophenone was reduced with tin and hydrochloric acid and the reduction product was worked up in a similar manner to that employed for the crude *o*-nitroacetophenone, the *o*-amino-*n*-butyrophenone, unlike the corresponding *m*-compound, being volatile in steam. *o*-Amino-*n*-butyrophenone crystallises from alcohol in colourless plates, m. p. 45°; it has b. p. 153°/16 mm. (Found: N, 8.9.  $C_{10}H_{13}ON$  requires N, 8.6%). From 375 g. of *n*-butyrophenone were obtained 55 g. of pure *o*-amino-*n*-butyrophenone and 85 g. of pure *m*-amino-*n*-butyrophenone.

*o*-*p*-Toluenesulphonamido-*n*-butyrophenone crystallises from alcohol in colourless rhombic plates, m. p. 110° (Found: N, 4.35.  $C_{17}H_{19}O_3NS$  requires N, 4.4%).

*o*-Bromo-*n*-butyrophenone, prepared from the *o*-amino-compound in the usual way, is a very pale yellow oil, b. p. 143°/16 mm., which does not solidify above -16°. The yield is 68% (Found: Br, 34.5.  $C_{10}H_{11}OBr$  requires Br, 35.2%).

*o*-Bromo-*n*-butyrophenonesemicarbazone crystallises from alcohol in colourless needles, m. p. 172° (Found: N, 15.15.  $C_{11}H_{14}ON_3Br$  requires N, 15.45%).

What is presumably *o*: $\alpha$ -dibromo-*n*-butyrophenone was obtained by the bromination of *o*-bromo-*n*-butyrophenone in acetic acid solution with bromine (1 mol.). It is a pale yellow oil, b. p. 172°/16 mm., which darkens in the air. It does not solidify above -16° (Found: Br, 51.4.  $C_{10}H_{10}OBr_2$  requires Br, 52.2%). When oxidised with potassium permanganate it is converted into *o*-bromobenzoic acid, m. p. 148°.

When *o*-bromo-*n*-butyrophenone was brominated with bromine (3 mols.), some of the latter remained unabsorbed and was evaporated. The product was poured into water, extracted with ether, and the ether evaporated. The solid residue was crystallised by allowing its solution in alcohol to evaporate slowly and was obtained

in colourless plates, m. p. 27–28° (Found : Br, 61.3.  $C_{10}H_9OBr_3$  requires Br, 62.3%). The substance, probably *o*: $\alpha$ : $\alpha$ -tribromo-*n*-butyrophenone, was not readily oxidised by the ordinary methods.

*m*-Bromo-*n*-butyrophenone, obtained from *m*-amino-*n*-butyrophenone, is a pale yellow liquid, b. p. 152°/20 mm. It solidifies to an almost colourless solid, m. p. 9–10°; yield, 41% (Found : Br, 34.2.  $C_{10}H_{11}OBr$  requires Br, 35.2%). Its semicarbazone crystallises from alcohol in colourless prisms, m. p. 158° (Found : N, 15.4.  $C_{11}H_{14}ON_3Br$  requires N, 15.45%).

*p*-Chloro- $\alpha$ -bromo-*n*-butyrophenone was obtained by treating  $\alpha$ -bromobutyryl chloride (46.4 g.) with chlorobenzene (84.4 g.) in the presence of aluminium chloride (36 g.) and carbon disulphide (46 c.c.). After the vigorous reaction had ceased, the mixture was boiled for 2 hours, poured into water, and extracted with ether and the extract was evaporated after being washed and dried. The product was distilled and had b. p. 162°/14 mm.; yield, 66%. It crystallised from alcohol in colourless rectangular plates, m. p. 43° (Found : 0.3928 g. gave 0.4960 g. of mixed silver halides.  $C_{10}H_{10}OClBr$  requires 0.4974 g.). On oxidation with potassium permanganate, *p*-chlorobenzoic acid, m. p. 236°, was obtained.

On attempting to prepare *p*: $\alpha$ -dibromo-*n*-butyrophenone by the same method, an almost colourless liquid having b. p. 180°/15 mm. and containing 47.1% of bromine ( $C_{10}H_{10}OBr_2$  requires Br, 52.2%) was obtained in a yield of 79%. The substance obtained in 58% yield by the bromination of *m*-bromo-*n*-butyrophenone was a yellow oil, b. p. 180°/18 mm. (Found : Br, 49.9%).

Both of these substances darken rapidly on standing and the low bromine content is due to partial decomposition with elimination of hydrogen bromide from the side chain.

*n*-Propyl-*o*-aminophenylketazine (II).—A mixture of *o*-amino-*n*-butyrophenone (3.4 g.), alcohol (22 c.c.), semicarbazide hydrochloride (2.7 g.), sodium acetate (6 g.), and water (22 c.c.) was kept for several days; yellow needles then separated. The substance, which was formed more rapidly when the mixture was heated on the water-bath, crystallised from alcohol, in which it was readily soluble, in yellow needles, m. p. 135° (Found : C, 74.6; H, 8.0; N, 17.4; *M*, 328.  $C_{20}H_{26}N_4$  requires C, 74.5; H, 8.1; N, 17.4%; *M*, 322).

The compound is insoluble in water and dissolves to a colourless solution in dilute hydrochloric acid, from which, on being made alkaline, an oil, probably *o*-amino-*n*-butyrophenone, is precipitated.

*Ethyl-o*-aminophenylketazine (I).—A mixture of *o*-aminopropiophenone (3.3 g.), semicarbazide hydrochloride (2.7 g.), sodium acetate (6 g.), alcohol (22.5 c.c.), and water (22.5 c.c.) was boiled

for several days; the yellow ketazine then separated together with some colourless semicarbazone. The mixture of solids was boiled with a little alcohol to dissolve the more soluble ketazine, and the solution filtered. The ketazine which crystallised from the filtrate was pure after one further crystallisation from alcohol, forming yellow needles, m. p.  $130^{\circ}$  (Found: C, 73.8; H, 7.8; N, 18.8.  $C_{18}H_{22}N_4$  requires C, 73.5; H, 7.5; N, 19.05%). Like compound (II), it dissolves to a colourless solution in hydrochloric acid; when this solution is made alkaline, an oil, probably *o*-aminopropiophenone, is precipitated.

On heating *o*-aminopropiophenonesemicarbazone for 2 hours at  $230$ – $240^{\circ}$ , a yellow resinous material was produced, ammonia having been evolved. It was not possible to separate any of the expected ketazine from the solid product.

#### CXLIV.—*The Synthesis of Glucosides. Part IV.* *Alizarin Glucoside.*

By ALEXANDER ROBERTSON.

By the interaction of tetra-acetyl- $\alpha$ -glucosidyl bromide and alizarin in the presence of quinoline and silver oxide, Takahashi (*J. Pharm. Soc. Japan*, 1925, 525, 4) prepared the tetra-acetyl glucoside of alizarin, which on deacetylation with alkali yielded a mono-glucoside, m. p.  $230$ – $231^{\circ}$ . Glaser and Kahler (*Ber.*, 1927, 60, 1349), using the acetone-alkali method, seem to have isolated the same tetra-acetyl glucoside, but on deacetylation by means of methyl-alcoholic ammonia they obtained alizarin and a red compound which they considered was the 1:2-diglucoside of 9:10-diamino-1:2:9:10-tetrahydroxyanthracene and was converted by cold hydrochloric acid into 1:2-diglucoalizarin, m. p.  $214^{\circ}$ . The production of a diglucoside in this manner was thought to be highly improbable, and, moreover, would restrict the use of this convenient method of deacetylation. In addition, the results were complicated by the fact that Fischer's method for the preparation of  $\alpha$ -glucosides depends on the use of quinoline (*Ber.*, 1916, 49, 2813). The experiments described in this communication were therefore undertaken.

Zemplén and Müller (*Ber.*, 1929, 62, 2107), using Takahashi's method, have confirmed the results of this investigator. They also found that deacetylation of the tetra-acetyl glucoside as described by Glaser and Kahler gave a red compound of variable composition which on treatment with warm aqueous-alcoholic hydrochloric acid

afforded alizarin monoglucoside identical with that, m. p. 236—237°, obtained by deacetylation with alkali. The experimental results described below agree with the observations of Zemplén and Müller. A convenient procedure for the preparation of the tetra-acetyl glucoside by the acetone-alkali method is described (compare Glaser and Kahler, *loc. cit.*). Since acetylation of alizarin glucoside prepared by either method of hydrolysis and of the tetra-acetyl derivative gave the same penta-acetyl compound, it follows that migration of the glucose residue does not occur.

The fact that the red compound is not instantaneously decomposed by warm dilute acetic acid renders it unlikely that the substance is a simple ammonium salt. In support of this it may be noted that alizarin glucoside is liberated from its sodium salt by cold dilute acetic acid. Deacetylation of *O*-tetra-acetyl-2- $\beta$ -glucosidoxyanthraquinone (compare Müller, *Ber.*, 1929, 62, 2793) with methyl-alcoholic ammonia gave 2- $\beta$ -glucosidoxyanthraquinone identical with that obtained by hydrolysis with alkali.

Previous investigators (Takahashi, *loc. cit.*; Glaser and Kahler, *loc. cit.*; Zemplén and Müller, *loc. cit.*) have suggested that the glucose residue of the tetra-acetyl glucoside of alizarin is attached at the 2-position. This conclusion was based on the well-known fact that in compounds like alizarin the hydroxyl group in the *o*-position to carbonyl is difficult to alkylate. Attempts to confirm this structure by the aid of boroacetic anhydride gave unsatisfactory results (compare Robertson and Waters, J., 1929, 2239). Although the addition of the glucoside or its acetyl compound to a solution of the reagent in acetic anhydride gave a red coloration indicating the formation of a boroacetate, a solid derivative could not be isolated; the red solutions became yellow on addition of water. The isolation of 1-methyl alizarin as a product of the hydrolysis of *O*-tetra-acetyl-2- $\beta$ -glucosidoxy-1-methoxyanthraquinone (I) finally afforded conclusive proof of the constitutions of (I) and of alizarin glucoside; deacetylation of (I) gave the glucoside of 1-methyl alizarin.

Acetylation of the amorphous condensation product of *O*-hepta-acetylmaltosidyl bromide and alizarin gave a crystalline *O*-octa-acetyl maltoside, not identical with the octa-acetyl derivative of ruberythric acid.

The hydroxyxanthone glucosides (Robertson and Waters, *loc. cit.*) are readily decomposed by boiling 10% aqueous sodium hydroxide and in this respect resemble the compounds described in this communication.

#### EXPERIMENTAL.

2- $\beta$ -Glucosidoxyanthraquinone.—*O*-Tetra-acetyl- $\alpha$ -glucosidyl bromide (8.2 g.) was added to a solution of 2-hydroxyanthraquinone

(6 g.) and potassium hydroxide (1.2 g.) in acetone (60 c.c.) and water (20 c.c.). The mixture was kept at room temperature for 16 hours and 12% aqueous potassium hydroxide (10 c.c.) and a further quantity of bromide (8.2 g.) were then added. After 24 hours, the reaction mixture was acidified with acetic acid, and on addition of water (300 c.c.) the tetra-acetyl glucoside (mixed with 2-hydroxy-anthraquinone) separated. Repeated crystallisation from alcohol gave the substance (3.5 g.) in almost colourless, rectangular plates, m. p. 168° (Müller, *loc. cit.*, gives m. p. 164°) (Found in material dried at 100°: C, 60.6; H, 5.0. Calc. for  $C_{28}H_{26}O_{12}$ : C, 60.5; H, 4.7%).

The tetra-acetyl derivative (2 g.), suspended in warm methyl alcohol (80 c.c.), was treated with 10% aqueous sodium hydroxide (16 c.c.) at 60° for 5 minutes. The cooled mixture slowly deposited 2- $\beta$ -glucosidoxyanthraquinone (1 g.), which crystallised from dilute alcohol in pale yellow needles containing  $1H_2O$ , m. p. 248—249° (Found: C, 59.5; H, 5.3.  $C_{20}H_{18}O_8 \cdot H_2O$  requires C, 59.4; H, 5.0%. Found in material dried at 110° in a high vacuum for 2 hours: C, 62.2; H, 4.7.  $C_{20}H_{18}O_8$  requires C, 62.2; H, 4.7%). The compound tends to separate from warm dilute alcohol as a pale yellow gel which gradually crystallises. It is moderately easily soluble in warm water and sparingly soluble in hot alcohol. Acetylation with acetic anhydride and sodium acetate gave the tetra-acetyl derivative, m. p. 168°. In boiling 10% aqueous sodium hydroxide the glucoside decomposes with the formation of the red sodium salt of 2-hydroxy-anthraquinone. It is readily hydrolysed by emulsin and by warm 15% hydrochloric acid to glucose and the anthraquinone.

Deacetylation of the tetra-acetyl glucoside by means of methyl-alcoholic ammonia during 22 hours at 0° afforded the glucoside in almost theoretical yield, m. p. and mixed m. p. 248—249° after crystallisation from dilute alcohol.

2-O-Tetra-acetyl- $\beta$ -glucosidoxy-1-hydroxyanthraquinone.—A mixture of alizarin (18 g.), potassium hydroxide (2.8 g.), and 50% aqueous acetone (400 c.c.) was agitated for  $\frac{1}{4}$  hour to ensure the formation of potassium alizarate. A solution of O-tetra-acetyl- $\alpha$ -glucosidyl bromide (20 g.) in ether (100 c.c.) was then introduced. The mixture was agitated for 12 hours and 7% potassium hydroxide solution (20 c.c.) and a further quantity of bromide (10.5 g.) were then added. After 16 hours, the faintly alkaline reaction mixture was acidified with acetic acid and the glucoside and unchanged alizarin were precipitated by addition of water (200 c.c.). A suspension of the solid in acetic acid (200 c.c.) was refluxed for 5 minutes, cooled, and filtered to remove alizarin. Addition of warm water (1 l. at 65°) to the filtrate precipitated the glucoside, con-

taminated with traces of alizarin. Recrystallisation from alcohol finally gave slender yellow needles, m. p. 206—207° after sintering at 204° (Found : C, 58.8; H, 4.9. Calc. for  $C_{28}H_{26}O_{13}$ : C, 58.9; H, 4.6%). Acetylation with acetic anhydride and pyridine during  $\frac{1}{4}$  hour on the steam-bath yielded the penta-acetyl derivative, which separated from warm alcohol in pale yellow needles, m. p. 196—197° (Glaser and Kahler, *loc. cit.*, gave m. p. 192—193°) (Found : C, 59.1; H, 4.9. Calc. for  $C_{30}H_{28}O_{14}$ : C, 58.8; H, 4.6%).

*2-β-Glucosidoxy-1-hydroxyanthraquinone.*—(A) Deacetylation was effected by the addition of 5% aqueous sodium hydroxide (30 c.c.) to a suspension of the tetra-acetyl glucoside (1.1 g.) in warm methyl alcohol (80 c.c.). The solid rapidly dissolved and the cherry-red solution, maintained at 65° for 10 minutes, deposited the sodium salt of the glucoside in dark red needles. A warm aqueous solution of this salt was acidified with acetic acid and the yellow crystalline solid was collected, washed with water, and dissolved in boiling methyl alcohol (500 c.c.). After removal of the greater part of the alcohol by distillation the glucoside crystallised; repetition of this procedure with ethyl alcohol gave alizarin glucoside in rosettes of slender yellow needles, m. p. 237° (Found : C, 59.2; H, 4.5. Calc. for  $C_{20}H_{18}O_9$ : C, 59.7; H, 4.5%) (compare Zemplén and Müller, *loc. cit.*). Acetylation with acetic anhydride and pyridine on the water-bath gave the penta-acetyl derivative, m. p. 196—197°.

(B) Treatment of the tetra-acetyl glucoside (1.1 g.) with methyl-alcoholic ammonia at 0° for 24 hours gave a dark red solid (0.8 g.) (compare Glaser and Kahler, *loc. cit.*; Zemplén and Müller, *loc. cit.*) which crystallised from a large volume of ethyl alcohol in needles, m. p. 195—196° (decomp.) (Found : C, 53.8; H, 5.3; N, 3.9%). The red solution of this compound (0.2 g.) in hot 10% acetic acid (25 c.c.) was refluxed for 6 minutes. The colour gradually changed to orange-yellow, and alizarin glucoside separated from the cooled solution, m. p. 237° after purification (penta-acetyl derivative, m. p. 196—197°). The red compound dissolved in cold concentrated hydrochloric acid to a yellow solution, and after 5 minutes addition of water precipitated alizarin glucoside, m. p. 237° after purification.

This glucoside is hydrolysed by emulsin and by warm 10% hydrochloric acid to glucose and alizarin. The cherry-red solution of the glucoside in 10% aqueous sodium hydroxide becomes violet on boiling; acidification of the cooled solution gives a precipitate of alizarin.

*2-O-Tetra-acetyl-β-glucosidoxy-1-methoxyanthraquinone.*—A mixture of the tetra-acetyl glucoside (1.2 g.), methyl iodide (3 c.c.), active silver oxide (3 g.), and acetone (30 c.c.) was refluxed for 2 hours; a test with cold alcoholic alkali then showed that methylation

was complete. After separation from the silver salts (wash with acetone), the solvent was removed under diminished pressure. The residual *methyl* ether crystallised from methyl alcohol in elongated, pale yellow prisms, m. p. 155—156°,  $[\alpha]_D^{17} -71.72^\circ$  in acetone (Found: C, 59.1; H, 5.1.  $C_{29}H_{28}O_{14}$  requires C, 59.5; H, 4.8%). It is readily soluble in warm alcohol or acetone, and does not give a coloration with cold alcoholic sodium hydroxide. A solution of the ether (1.2 g.) in a mixture of methyl alcohol (30 c.c.) and concentrated hydrochloric acid (15 c.c.) was refluxed for 2 hours. Addition of water (50 c.c.) to the cooled solution precipitated 1-methyl alizarin, which crystallised from methyl alcohol in orange-yellow needles, m. p. 179°. Acetylation of the latter substance with acetic anhydride and sodium acetate gave 1-methyl-2-acetyl alizarin, yellow needles from methyl alcohol, m. p. 212° (Found: C, 69.1; H, 4.4. Calc. for  $C_{12}H_{12}O_5$ : C, 68.9; H, 4.1%).

*2-3-Glucosidoxy-1-methoxyanthraquinone*.—10% Methyl-alcoholic sodium hydroxide (15 c.c.) was added to a warm solution of the tetra-acetyl derivative (1 g.) in methyl alcohol (30 c.c.). The mixture became red owing to slight decomposition of the glucoside, and after 2 hours at room temperature 10% acetic acid (10 c.c.) was added. On evaporation of the methyl alcohol in a vacuum the *glucoside* gradually separated. After being kept for 12 hours in an ice-chest, the solid was separated from the faintly alkaline mother-liquor and washed with alcohol to remove traces of alkali. On crystallisation from methyl alcohol it formed clusters of slender yellow needles, m. p. 230—231° (Found: C, 60.2; H, 5.0.  $C_{21}H_{20}O_9$  requires C, 60.6; H, 4.8%). The glucoside is sparingly soluble in cold alcohol, water, or acetone, and does not give a coloration with cold alcoholic sodium hydroxide. It is readily hydrolysed by emulsin to 1-methyl alizarin and glucose.

*Alizarin Octa-acetyl Maltoside*.—*O*-Hepta-acetylmaltosidyl bromide was prepared by the following method (compare Zemplén, *Ber.*, 1928, **61**, 927). Acetic anhydride (25 c.c.) was added to a solution of octa-acetyl maltose, m. p. 160° (50 g.) in acetic acid saturated at 0° with hydrogen bromide (100 g.). After 5 hours at room temperature the reaction mixture was diluted with chloroform (400 c.c.) and poured on ice (300 g.) in water (300 g.). The chloroform layer was separated, washed three times with ice-water (300 c.c.), and dried over calcium chloride. On removal of the solvent in a vacuum the bromide remained as a pale straw-coloured syrup (40 g.), which solidified on trituration with ligroin.

A solution of amorphous *O*-hepta-acetylmaltosidyl bromide (20 g.) in ether (150 c.c.) was added to a mixture of alizarin (8 g.), potassium hydroxide (1.2 g.), and 50% aqueous acetone (200 c.c.).

After agitation for 24 hours the faintly alkaline mixture was acidified with acetic acid, and the precipitate of alizarin removed by filtration. The ethereal layer was separated, and the aqueous solution extracted once with ether (100 c.c.). An acetic acid solution of the residue obtained on evaporation of the ether was kept in the ice-chest for 24 hours, filtered to remove alizarin which had crystallised, and then poured into water (500 c.c. at 50°). The orange solid which separated was immediately collected, washed with water, and dissolved in hot alcohol. On cooling, an amorphous, bright yellow solid separated. Purification by hot alcohol was repeated (five times) until a specimen gave a bright cherry-red colour in cold alcoholic sodium hydroxide. Acetylation of the purified amorphous solid with acetic anhydride and sodium acetate on the steam-bath during 6 hours gave *alizarin octa-acetyl maltoside*, which crystallised from alcohol in pale yellow needles (1.6 g.), m. p. 185°,  $[\alpha]_D^{25} -20.05^\circ$  in acetone (Found: C, 55.8; H, 5.1.  $C_{42}H_{44}O_{22}$  requires C, 56.0; H, 4.9%). The substance is readily soluble in warm alcohol or acetone and in cold acetic acid.

The author is indebted to the Chemical Society for a grant which has partly defrayed the cost of this investigation.

## CXLV.—*The Octammines, with Special Reference to Tin.*

By ARTHUR JAMES COOPER and WILLIAM WARDLAW.

So far, no octammine has been prepared by a reaction between a metallic salt and ammonia in the presence of water, whereas under similar experimental conditions very stable hexammines have been isolated. This supports Sidgwick's view ("The Electronic Theory of Valency," p. 156) that covalencies of eight only arise, even with atoms capable of exhibiting them, in exceptionally favourable circumstances.

Nevertheless, by the action of liquid or gaseous ammonia on metallic salts or their solutions in non-aqueous solvents, a number of compounds containing eight molecules of ammonia have been described, and in many text-books they are formulated and considered as typical co-ordination compounds. This formulation, in the case of unstable substances such as  $[Ti, 8NH_3]Cl_4$  and  $[Ca, 8NH_3]Cl_2$ , is difficult to justify, for it implies a covalency of eight for the metallic

atoms when the weight of chemical evidence is against such an assumption. Even with  $\text{BaBr}_2 \cdot 8\text{NH}_3$ , it is questionable whether the formula  $[\text{Ba} \cdot 8\text{NH}_3] \text{Br}_2$  is satisfactory, for it is recorded (Joannis, *Compt. rend.*, 1891, **112**, 339) that on exposure to the air the ammonia is completely liberated. It is possible that here, as in the cases cited above, the molecules of ammonia are polymerised or that some form part of the crystal unit but not of the complex molecule.

The zirconium salt  $[\text{Zr} \cdot 8\text{NH}_3] \text{Cl}_4$ , prepared by Stähler and Denk (*Ber.*, 1905, **38**, 2611) by the passage of ammonia into an ethereal suspension of zirconium chloride, is sufficiently stable to yield correct analytical figures, and therefore may be considered a true co-ordination compound; nevertheless, it readily loses ammonia and is affected by moist air. Octammines of cerium, samarium, and neodymium are stated to be formed as intermediate products in the degradation of compounds of higher ammonia content, but here again the evidence in favour of the formation of a true co-ordination compound is very slight. An octammine of thorium is supposed to exist (Ephraim, "Inorganic Chemistry," p. 280), but the experimental evidence (Chauvenet, *Compt. rend.*, 1910, **151**, 387) is not conclusive for such an assumption.

The remaining case of a supposed octammine is the compound  $[\text{Sn} \cdot 8\text{NH}_3] \text{I}_4$ . It was prepared as a white substance by Ephraim and Schmidt (*Ber.*, 1909, **42**, 3856) on passing ammonia into a solution of stannic iodide in carbon disulphide, the solvent then being evaporated by means of warm water. Their product gave Sn, 15.74;  $\text{NH}_3$ , 16.47 (Calc. for  $\text{SnI}_4 \cdot 8\text{NH}_3$ : Sn, 15.61;  $\text{NH}_3$ , 17.84%). By direct combination of ammonia and stannic iodide in the absence of a solvent, a compound was obtained giving Sn, 15.71, 15.57, 15.01;  $\text{NH}_3$ , 16.91, 16.90%. The formation of the co-ordination compound is inferred, therefore, rather than proved by the experimental results.

As stannic iodide is soluble in other organic solvents, it seemed of interest to reinvestigate the reaction in another medium, as well as to repeat the work of Ephraim and Schmidt with carbon disulphide as a solvent. In no case was an octammine formed of sufficient stability for it to be isolated and analysed as such. It appears, therefore, that only in the case of the zirconium salt,  $\text{ZrCl}_4 \cdot 8\text{NH}_3$ , is there any experimental evidence for the existence of a co-ordination compound of the type  $[\text{R} \cdot 8\text{NH}_3] \text{X}_4$ .

We found, however, that in every case the compound could not consist exclusively of tin, halogen, and ammonia: the analytical figures indicated the necessity for a fourth constituent of the molecule. Water was obviously the only possible addendum, and this view was confirmed by the fact that the hydrogen content of the

compound was in excess of that required by the nitrogen present. Undoubtedly, therefore, the products were of the type  $[\text{Sn}, x\text{NH}_3, y\text{H}_2\text{O}]\text{I}_4$ , and it was found on calculating the value of the different units that  $x + y$  was approximately equal to 8. Thus, although the actual octammine was not capable of isolation under the experimental conditions outlined above, yet there is evidence that such an unstable octammine can exist but that the molecules of ammonia are rapidly replaced in the air by water molecules.

A study has also been made of the reaction between stannic iodide in carbon tetrachloride and organic bases such as aniline, pyridine, and quinoline. In no case was there co-ordination of eight molecules of these substances. It appeared that the stable products obtained were of the type  $\text{SnI}_4 \cdot 2 \cdot 5\text{R}$  ( $\text{R} = \text{aniline or pyridine}$ ).

Scagliarini (*Atti R. Accad. Lincei*, 1925, **1**, 582) records the isolation of  $\text{SnI}_4 \cdot 5\text{C}_6\text{H}_{12}\text{N}_4$  from the reaction of hexamethylene-tetramine with stannic iodide in chloroform solution, and also a deep violet substance of the type  $\text{SnI}_4 \cdot 4\text{C}_6\text{H}_{12}\text{N}_4 \cdot 2\text{CHCl}_3$ , which undergoes little change at  $80^\circ$  or in a vacuum over sulphuric acid but is rapidly decolorised by moist air. Here, if one considers that the non-polar stannic iodide becomes a polar compound after the reaction, a maximum co-ordination number of *six* is attained in the last compound.

#### EXPERIMENTAL.

The experiment of Ephraim and Schmidt (*loc. cit.*) was repeated, gaseous ammonia being passed through stannic iodide dissolved in carbon disulphide, which at the same time was slowly evaporated. The white product was unstable, continually evolving ammonia, and after a state of stability appeared to have been attained, its *maximum* ammonia content was 13.3%, Sn being 15.3% ( $\text{NH}_3 : \text{Sn} = 6.07 : 1$ ). It was noted that a red intermediate compound was formed during the passage of the ammonia through the solution.

A new series of experiments was instituted in which carbon tetrachloride was used as the solvent instead of carbon disulphide. The stannic iodide was dried in a vacuum over phosphoric oxide, and the tetrachloride kept for several days over phosphoric oxide and then distilled from fresh phosphoric oxide. The ammonia was carefully dried by passage over lime and solid caustic potash. The same red intermediate product referred to above resulted and gradually turned white. The tetrachloride could not conveniently be removed by simultaneous evaporation, as in the case of carbon disulphide, so the product was obtained by filtration. An immediate analysis gave Sn, 15.74;  $\text{NH}_3$ , 12.7%. In other experiments, similarly conducted, the figure for ammonia was never exceeded. After the substance had

been kept for several days in a desiccator over calcium chloride, the ammonia content fell to 9.38% and the tin to 15.4%.

The red intermediate compound when dried yielded a dull brown substance which was quite stable in air and gave Sn, 16.23;  $\text{NH}_3$ , 6.63. Since  $\text{SnI}_4 \cdot 3\text{NH}_3$  requires Sn, 17.53;  $\text{NH}_3$ , 7.53, it was evident that the red compound had absorbed moisture from the air in place of liberated ammonia. This view was confirmed by microanalysis of a sample of a white compound which yielded Sn, 15.52; N, 6.8; H, 2.8. Such a substance corresponds to the composition Sn, 15.52; I, 66.4;  $\text{NH}_3$ , 8.25;  $\text{H}_2\text{O}$ , 10.05% ( $\text{Sn} : \text{I} : \text{NH}_3 : \text{H}_2\text{O} = 1 : 4.00 : 3.71 : 4.27$ ; i.e.,  $\text{Sn} : \text{NH}_3 + \text{H}_2\text{O} = 1 : 7.98$ ). Hence the compound can be considered as  $\text{Sn}[x\text{NH}_3 + (8 - x)\text{H}_2\text{O}]\text{I}_4$ , with a co-ordination number of eight. Moreover, a similar expression can be deduced for the composition of each of the white compounds described above.

The white compounds are generally unstable, and dissolve easily in the cold in dilute hydrochloric or nitric acid to a colourless solution. With more concentrated nitric acid they give a copious yield of iodine.

*Stannic Iodide and Pyridine.*—The attempt to prepare a pyridine compound by acting on stannic iodide in carbon tetrachloride proved abortive; the dark red product proved to be stannic iodide. Other solvents were tried, and finally benzene dried by two distillations over phosphoric oxide was chosen. The pyridine was dried by standing for a week over solid caustic potash, followed by two distillations from barium oxide. When the pyridine was added to a benzene solution of stannic iodide, a brown stable precipitate resulted which was insoluble in dry alcohol. It was washed with benzene and with dry alcohol and dried in a desiccator over calcium chloride. The substance was crystalline, and soluble in dilute hydrochloric and sulphuric acids. It was partly soluble in water and underwent hydrolysis on standing. With dilute nitric acid, iodine was liberated.

*Analysis.* The tin was estimated by repeated evaporation with dilute nitric acid and twice with concentrated acid. The residue was ignited slowly at first and afterwards over the blowpipe till of constant weight (Found: Sn, 14.4; I, 61.4; N, 4.37.  $\text{SnI}_4 \cdot 2.5\text{C}_5\text{H}_5\text{N}$  requires Sn, 14.3; I, 61.7; N, 4.25%).

*Stannic Iodide and Aniline.*—Considerable difficulty was found in preparing this compound. A red crystalline substance formed on addition of dry aniline to a solution of the iodide in dry carbon tetrachloride, but immediately on exposure to the air the colour changed to a light fawn. This could not be due to loss of aniline and was attributed to hydrolysis. To obviate exposure to the air, the

preparation flask was attached by means of a wide V-shaped tube, in which the apex was replaced by a ground joint, to a sintered-glass funnel fitted with a rubber stopper. On rotating the flask about the joint, the mixture it contained was transferred to the sintered-glass funnel without exposure to air. Carbon tetrachloride was introduced into the flask through a second side-tube in the cork, and the product washed repeatedly on the funnel. It was then quickly dried on filter paper and transferred to a vacuum desiccator. A rich-brown *substance* resulted which was quite stable. It dissolved in dilute nitric acid on warming, but on boiling, iodine was copiously evolved. It readily dissolved in dilute hydrochloric or sulphuric acid to a yellow solution. It was rapidly hydrolysed by dilute acetic acid.

*Analysis.* Treatment with dilute nitric acid and evaporation was unsatisfactory, for the presence of the aniline produced a somewhat violent reaction on concentration, and the base could not be quantitatively expelled. Finally, the compound was decomposed by treating it with ammonia ( $d\ 0.880$ ), and evaporating the mixture first to dryness on the water-bath, and then several times with water to expel the aniline which had been set free. The residue was treated with concentrated nitric acid, evaporated to dryness on the water-bath, gently heated for some time in an air-bath, and finally heated till of constant weight over the blowpipe (Found: Sn, 13.0; N, 3.76; Sn : N = 1 : 2.45.  $\text{SnI}_4 \cdot 2.5\text{C}_6\text{H}_5 \cdot \text{NH}_2$  requires Sn, 13.7; N, 4.0.  $\text{SnI}_4 \cdot 2\text{C}_6\text{H}_5 \cdot \text{NH}_2$  requires Sn, 14.6; N, 4.35%).

*Stannic Iodide and Quinoline.*—On addition of quinoline to a solution of stannic iodide in carbon tetrachloride, a black solid resulted which, on removal from the solvent, rapidly turned stone-coloured, owing probably to hydrolysis. A stable product was obtained, however, by refluxing the mixture for 2 hours. The product was washed with carbon tetrachloride and dried in a vacuum desiccator for 2 days. It remained unaltered in colour, was sparingly soluble in water, and soluble in dilute hydrochloric or sulphuric acid, whilst dilute nitric acid liberated iodine. Nevertheless, analysis (Found: Sn, 12.8; I, 51.9.  $\text{SnI}_4 \cdot 2.5\text{C}_9\text{H}_7\text{N}$  requires Sn, 12.45; I, 53.5%) indicates that the substance was not pure.

CXLVI.—*On Active Nitrogen. Part VIII. (i) The Influence of Photogens and of Surfaces upon Glow Phenomena in Nitrogen. (ii) The Effects of Addition of Other Gases to Luminous Nitrogen.*

By ERIC JOHN BAXTER WILLEY.

*Section (i).*

It was shown in Part VII (this vol., p. 336) that the decay of the nitrogen after-glow is markedly controlled in its kinetic aspects by the purity of the gas employed, for a number of observations were satisfactorily explained upon the hypothesis that the action of the impurities (which, it now appears, must certainly be present to the extent of about 0.1% in order that the yellow luminescence may be exhibited) is to cover the walls of the reaction vessels, thus converting what would otherwise be a "dark" heterogeneous recombination of atoms into a homogeneous process accompanied by the emission of the after-glow. When adequate quantities of these photogens are present or pressure conditions are such that the walls may be supposed covered by nitrogen, the volume decay process is influenced by the over-all gas pressure in a manner which permits of the reaction being expressed as a third-order change, probably  $N' + N + N_2 \longrightarrow 2N_2 + \text{after-glow}$ , where  $N'$  is a metastable atom with an energy of 2.3 volts, in agreement with calculations given in the same paper.

It follows from this theory that it should be possible to enhance the luminosity of a stream of nitrogen by adding the photogen above or below the discharge, always provided, in the first case, that it be not destroyed by the spark. An attempt made by Lewis (*J. Amer. Chem. Soc.*, 1929, **51**, 654), however, in which nitrogen at a fraction of 1 mm. pressure was subjected to the electrodeless discharge and then rapidly treated with a small amount of oxygen, did not show the effect anticipated. This may have been due either to the hypothetical wall reaction being so rapid that all the atoms had recombined before the oxygen reached the surfaces, or else to too much oxygen having been added, the small glow being catalytically destroyed at once; a further possibility is that suggested by Lewis, *viz.*, that ordinary oxygen plays no part in the production of the after-glow. Experiments are now described which prove directly that the photogens act, at any rate in the case studied, after the nitrogen has been through the discharge, and that their effects can be reproduced by changing the walls of the vessel, probably the most weighty evidence yet presented in favour of the hypothesis that photogens are essentially wall-poisons.

## EXPERIMENTAL.

The observation tube employed in these experiments was  $80 \times 3$  cm., and arrangements were made for the admission to it of (a) nitrogen (purified by hot copper, etc., as described in Part VII, *loc. cit.*), and (b) hydrogen similarly treated; both of these gases could be passed through powerful discharges (condensed or not, as desired), which were operated independently from different electrical circuits. The down-stream end of the tube was closed by means of a rubber bung, faced on the inside with a polished aluminium disc, which was cut to fit the glass tube accurately and held in position by a rod passing through the bung and rendered vacuum-tight by picein wax applied to the outside; the exhaust line was taken off some 20 cm. above this end, and the space between the side tube and the bung disc was filled with tightly packed tin-foil to prevent access of the active nitrogen to any rubber surfaces accidentally exposed. After leaving the discharge, the two gases flowed through some 20 cm. of 5 mm.-bore tubing bent in a W-shape and blackened to prevent light from the discharges reaching the observation tube, the inlet for the hydrogen being about 10 cm. below that for the nitrogen; traps cooled by liquid air were placed in the exhaust line for the collection of products of any reaction between active nitrogen and active hydrogen, it having been stated that under these conditions ammonia is formed (Lewis, *J. Amer. Chem. Soc.*, 1928, 50, 27). The glow was measured by means of the caesium photocells employed in the earlier investigation (Part VII).

*Addition of Photogens below the Discharge.*—Nitrogen (prepared as described in Part VII, and containing 0.3% of argon and less than 0.01% of other gases) was allowed to stream through the apparatus for 3 hours at the rate of 2500 c.c./hour, the discharge being maintained as usual and the pressure kept at 4 mm. of mercury. The after-glow rapidly became faint in the observation tube, and when at the end of this period it had practically vanished, a small current of hydrogen (300 c.c./hour) was fed through the second inlet to the tube. No effect upon the glow was observed as long as the hydrogen was inert, but when the hydrogen discharge was switched on, the yellow nitrogen after-glow appeared with great brilliance, only to disappear in a few seconds when the second (hydrogen) discharge was interrupted.

A second experiment was then performed in which 0.06% of a 1:1 nitrogen-oxygen mixture was fed to the nitrogen above its discharge. The glow was thus developed sufficiently to permit of its being measured, and the corresponding decay curve was of the same form as Curve A, Fig. 1 of Part VII (*i.e.*, steep and strongly

curved); the feed of hydrogen was as before, and the brightening of the glow again appeared when the second discharge was started, the decay curve then showing a closely linear relation between  $1/\sqrt{I}$  and time ( $I$  = glow intensity, here proportional to photo-electric current) exactly as in the figure mentioned. Since, when the hydrogen was sparked alone, the feed of nitrogen being shut off, ammonia condensed in the traps cooled by liquid air in the exhaust line, the hydrogen was analysed; it was found to contain 0.04% of nitrogen, derived from the water in the Boyle-bubbler aspirator in which the hydrogen had been stored. When the air in the constant-pressure reservoir of this device was replaced by hydrogen, tests for nitrogen in the gas stored under the new conditions were negative; and at the same time the pure hydrogen lost its ability to enhance the nitrogen after-glow when sparked, as in the experiments just described. For later experiments, a trap filled with activated charcoal and cooled by liquid air was added to the hydrogen circuit, and this satisfactorily removed the traces of nitrogen. It appeared, then, that a small amount of nitrogen is an essential ingredient of the hydrogen if, upon sparking, this gas is to enhance the glow in fairly pure nitrogen, a supposition verified by experiment.

The explanation of the phenomenon is clear: the discharge in hydrogen containing a trace of nitrogen produces a small amount of ammonia, and this, when added to the nitrogen below the discharge, produces an effect which is simulated exactly by the admission of other photogens above the discharge. It was therefore anticipated that addition of hydrogen to nitrogen above the discharge would lead to a strong glow, and this was in fact observed, provided that a feed of some 1% was employed in order that the nitrogen-hydrogen-ammonia equilibrium should not yield a merely insignificant proportion of the last substance. It may be mentioned that, with the small feed of pure and sparked hydrogen to the glowless nitrogen, mentioned earlier, no ammonia could be detected save after very long runs. With photogenic nitrogen and larger feeds of hydrogen, the yellow after-glow was markedly reduced when the latter gas was sparked, and at the same time small amounts of ammonia condensed in the traps, in agreement with Lewis's observations (*loc. cit.*). It must, however, be emphasised that the hydrogen must be in large excess, otherwise no ammonia is obtained. This matter is now being investigated quantitatively, and it appears that there are probably several factors operating simultaneously which render the case rather complicated.

*The Influence of Surfaces upon the Decay of the After-glow.*—(a) According to the views expressed earlier, *viz.*, that photogens are

wall-poisons and inhibit the non-luminous heterogeneous reassociation of atoms, thus favouring the volume process which gives rise to the after-glow, it follows that a glow should be induced in pure, non-photogenic nitrogen which, at the time of sparking or immediately afterwards, is placed in contact with the right kind of surface.

FIG. 1.

Curve A: "pure" nitrogen, glass surface.

Curve B: photogenic nitrogen, glass surface.

Curve C: "pure" nitrogen, paraffined surface.

Curve D: photogenic nitrogen, paraffined surface.

It would also be expected that the glow decay process in pure nitrogen should pass to that observed in the photogenic gas if the reaction could be studied in vessels with adequately poisoned walls.

A simple modification of the apparatus just described enabled this to be done. Tubes were cut from wide-bore glass tubing, of external diameter such that it just fitted into the main observation tube, and coated on the inside with various waxes and transparent

varnishes, thus enabling the glow decay to be studied as the stream passed over the different treated surfaces. Many organic substances were tried, but in every case save one the glow became blue and hydrogen cyanide condensed in the traps, so that the chemical action rendered true decay studies out of the question. A high-melting wax of the type employed in electrical work was eventually found which reacted a little at first, but upon prolonged exposure to the active nitrogen stream gave hydrogen cyanide in amounts which could be detected only by the guaiacum-copper sulphate method (Anderson, *Z. anal. Chem.*, 1916, **55**, 459) and corresponded to a concentration of less than 0.0003% of the latter gas in the nitrogen. A series of decay runs was then made and the results are shown in Fig. 1.

Curves A and B exhibit the marked difference in form and slope of the  $1/\sqrt{I}-t$  graphs found in the experiments discussed in Part VII for "pure" and photogenic nitrogen, Curve A being of the form which we have ascribed to the superposition of a strong wall decay upon the volume reaction, and Curve B being that corresponding with the bimolecular and homogeneous process; for both of these runs a clean glass tube was fitted in the main observation tube. The results shown in Curves C and D relate to precisely similar experiments wherein the clean glass tube was replaced by one coated on the inside with a thin uniform layer of the wax mentioned above; the decay in the photogenic nitrogen (Curve D) is even less than in the case of Curve B, but Curve C shows that the expected development of a strong glow in pure nitrogen and the retardation of its decay by the influence of highly poisoned walls are actually realised. It is, moreover, noticeable that up to the 15 cm. point, the curve is almost parallel to Curve B (photogenic nitrogen and a clean glass surface), but that subsequently the slope falls off. That this was not due to inequalities in the wax coating, leading to variations in the amount of light transmitted, was proved by reversing the tube, whereupon the effect was seen just as before; further, the galvanometer deflexions were so large that any error in reading must also be ruled out as an explanation of this curious effect. The author suggests that it is due to the formation of a trace of hydrogen cyanide in the first few cm. of the waxed tube; this gas then acts as photogen and further poisons the paraffin surface, since the effect is not seen in Curve D where larger concentrations of photogen are present. Even if one ignores the possible influence of very small quantities of hydrogen cyanide, it is clear that the paraffined surface is able *per se* to reproduce the effects associated with photogens, thus affording strong confirmatory evidence as to the probable truth of the wall-poison theory.

It followed from the observations described above that it should be possible to vary the decay rate of a stream of glowing nitrogen by drawing it first over clean glass and then over an inactive surface of the type just employed. The waxed tube used earlier was therefore cut in two, one half was carefully cleaned, and further decay runs were made in which glow streams obtained from gases containing 0.03% and *ca.* 0.15% of oxygen as photogen were drawn first over

FIG. 2.

the clean and then over the paraffined glass, the tubes being slipped into the main observation tube to occupy the same position as that taken by the single tube from which they were made. With 0.03% of photogen present, the graph of  $1/\sqrt{I}$  against the distance along the tube (proportional to time) was markedly curved for the glass surface (Fig. 2, Curve A), but linear for the paraffin; increase of the quantity of photogen to 0.15% gave a plot which was linear and showed no discontinuity, as in the former case, at the

junction of the two surfaces. The tubes were then reversed so that the glow came into contact first with the paraffin and then with the glass, and a decay run here revealed that, although with 0.15% photogen the  $1/\sqrt{I-t}$  plot was linear over the entire length of both tubes as in the corresponding experiment just given, yet with the 0.03% photogen content the break again occurred at the junction of the two surfaces (Fig. 2, Curve B), and that the graph was linear for both the paraffin and the glass but steeper in the latter case. The linearity for the glass may here be due to a trace of hydrogen cyanide being produced when the active nitrogen is in contact with the wax, this gas acting to a certain extent as a photogen and repressing the wall reaction. This shows that with a high photogen concentration the decay rate is, so far as paraffin and glass are concerned, independent of the nature of the surfaces, but with purer nitrogen the decay is very susceptible to wall influence.

A final and conclusive piece of evidence upon this point was provided by the observation that the amounts of hydrogen cyanide formed in the experiments by interaction of the active nitrogen and the paraffin were much less when the photogenic gas was employed than with the purer material; this clearly suggests that the photogens cover the paraffin with a film protective against the active nitrogen.

#### *Section (ii).*

The theory that the after-glow results from a ternary reaction,  $2N + N_2 \longrightarrow 2N_2 + \text{after-glow}$ , was advanced about the same time by Fri. Sponer (*Z. Physik*, 1925, **34**, 622) and by Willey and Rideal (Part I, J., 1926, 1804). The first author based her opinion upon spectroscopic observations, considered in conjunction with the old idea of Clausius, revived by Herzfeld (*Z. Physik*, 1922, **8**, 132), Born and Franck (*Ann. Physik*, 1925, **76**, 225), and others, as to the necessity for the presence of an acceptor for the energy of association of atoms in order that a stable molecule might be formed. On the other hand, Willey and Rideal were influenced by the long life of the glow-emission reaction, comparable in speed with the slow ternary process  $2NO + O_2 \longrightarrow 2NO_2$ , and by the negative temperature coefficient of the glow decay, another feature of the termolecular change just quoted. In both cases the rôle of the third entity was considered specific, and the possibility was not envisaged of the molecule of nitrogen being replaced by one of another element without affecting the glow, although it was admitted that in some examples (but not the majority) of the excitation of metallic spectra by active nitrogen, a metal atom might act as the entity concerned (Part IV, J., 1927, 2831).

According to this theory, therefore, the initial intensity of the

after-glow should be increased at the expense of its duration if nitrogen is added; the luminosity per unit volume of nitrogen should be unaffected, however, if the diluent gas is of another kind and is such as not to react chemically with the active nitrogen or, by reason of its excitation potentials, is not likely to be able to accept energy from the molecule emitting the after-glow radiation, and thus interfere with the normal glow decay process (compare Part II, J., 1927, 669). As mentioned in Part VII (*loc. cit.*, p. 343), there is divergence of experimental evidence upon this point,

FIG. 3.

Kneser having obtained a positive result which Bonhoeffer and Kaminsky had been unable to observe earlier. Kneser has extended the original hypothesis in view of his finding that the addition of argon produces the same effect as nitrogen, and according to his work the third substance need not necessarily be nitrogen; the present author has also described experiments (Part VII) which show that the walls of the apparatus may under appropriate conditions act in the same way. An experimental study of the addition of other gases to the glow has therefore been made, and the conclusion is reached that the ternary reaction with nitrogen as the specific third entity is most probably responsible for the glow emission.

#### EXPERIMENTAL.

The gases were admitted from a calibrated gas burette and capillary backed by a fine adjustment tap, and entered the glow

stream at the inlet B (see Part VII, p. 337), *i.e.*, below the discharge, and the quantity added was, in all cases, 15% of the flow of nitrogen, *i.e.*, 300 c.c. of diluent to 1950 c.c. of nitrogen per hour; the glow decay was, as usual, measured with the caesium photocells. The results are illustrated in Figs. 3 and 4.

In Fig. 3 are shown the curves obtained with equal feeds of carefully purified hydrogen, carbon monoxide, nitrous oxide, carbon dioxide, and nitrogen, and in Fig. 4 are given corresponding results obtained by using the nitrogen containing *ca.* 0.07% of oxygen as photogen. It will be seen that with feeds of nitrous oxide and carbon dioxide, the decay curves are practically coincident and

FIG. 4.

linear for both photogenic and "pure" nitrogen, but with carbon monoxide and hydrogen the curves are much flatter when 0.07% oxygen is present in the nitrogen than when only 0.03% is there. Moreover, with the first two gases the glow is brightened during the whole of its passage down the observation tube. The results agree in a striking manner with both the three-body collision theory and the view advanced as to photogens being wall-poisons.

Let us first consider the results with the "pure" nitrogen, temporarily ignoring the results obtained with the inert nitrogen as diluent. It has already been shown that the introduction of a photogen *below* the discharge enhances the glow, and as photogens are almost certainly gases which are strongly adsorbed by glass, we should expect, making the usual assumption that at these pressures the adsorption of a gas varies inversely as its boiling point, that

easily condensable gases (*e.g.*, nitrous oxide, carbon dioxide) would reduce wall activity and thus intensify the glow more than those difficult to liquefy (*e.g.*, carbon monoxide, nitrogen); this is actually observed (Fig. 3), the decay curves with feeds of the two last-named gases being of the type associated with "pure" nitrogen (compare Curves A and B, Fig. 1, Part VII), while with the other pair the plot is typically that of a glow stream produced in highly photogenic nitrogen, and, most of all, the retardation of the rate of decay is in exactly the inverse order of the boiling points of the gases concerned (hydrogen, b. p.  $-253^{\circ}$ ; nitrogen,  $-196^{\circ}$ ; carbon monoxide,  $-191^{\circ}$ ; nitrous oxide,  $-90^{\circ}$ ; carbon dioxide,  $-78^{\circ}$ ).

With photogenic nitrogen (0.07% oxygen) the walls are fairly well covered, and hence the decay with feeds of carbon monoxide and nitrogen approximates to that observed in the less pure nitrogen alone, while with feeds of carbon dioxide and nitrous oxide the adsorption is complete. It would thus be expected that with a glow stream of high photogen concentration the decay curves obtained with feeds of all these four gases should be linear and coincident, and this has actually been found for nitrogen containing 0.12% of oxygen.

The case where the gas added is nitrogen is more complicated, for two factors have to be considered, *viz.*, (i) the adsorption or photogen effect, and (ii) the direct participation by the added nitrogen in the homogeneous glow-emission process, in accordance with the specific three-body collision theory. These two factors are considered separately. (i) It has already been shown (Part VII) that the wall effect is probably much reduced at higher over-all pressures of nitrogen, and we should therefore expect that the addition of nitrogen would reduce the rate of decay of the glow in the moderately pure gas, and, by diminishing the surface reactions, automatically lead to a straightening of the  $1/\sqrt{I-t}$  graph, which should (in this consideration alone) lie between the curves for hydrogen and carbon monoxide; in photogenic nitrogen, however, nitrogen should have no more effect than any of the other gases when added to the glow stream. (ii) It being assumed that the glow emission results either from a triple impact  $N + N' + N_2 \longrightarrow 2N_2 + \text{after-glow}$ , or a reaction  $N + N' \longrightarrow N_2'$ , followed rapidly by  $N_2' + N_2 \longrightarrow 2N_2 + \text{after-glow}$ ,  $N'$  being a metastable 2.3-volt atom and  $N_2'$  an excited or metastable molecule (11 volts), it follows that the initial intensity of the glow should be increased and its duration diminished by addition of nitrogen. We might thus expect that with the combined operation of both these factors, the decay should correspond with that observed in nitrogen at a fairly high over-all pressure, *i.e.*, would give a linear  $1/\sqrt{I-t}$  plot

of fairly steep slope, whereas Fig. 3 shows that the graph is slightly curved and nearly parallel to that for the experiments wherein the gases added were nitrous oxide and carbon dioxide; apparently, then, in this case the greater part of the influence of the added nitrogen goes to suppress the wall reaction.

In Fig. 4 a different state of affairs is revealed, the surfaces being to a large extent "poisoned"; the action of the added nitrogen is then apparent in the gas phase, for the  $1/\sqrt{I}-t$  plot, although linear, is rather steeper than that for the runs where the diluent gases were carbon dioxide and nitrous oxide, i.e., the initial glow intensity and its rate of decay are increased and the duration of the luminosity is diminished by the addition of nitrogen, as demanded by the ternary reaction theory.

A second set of experiments, in which the feeds of gas added were increased to 30%, gave the same types of decay curve, with the exception that, as would be expected, the positive result of the triple-collision theory test by addition of nitrogen, as in the experiments illustrated in Fig. 4, was more marked than when only 15% of diluent was employed.

#### Discussion.

The experiments upon the influence of a waxed surface upon glow phenomena described in the first part of this paper afford fairly conclusive proof of the theory that photogens are wall-poisons as suggested in Part VII, and further comment is unnecessary.

The observations upon the addition of other gases to the after-glow may be considered in conjunction with the work of Constantinides (*Physical Rev.*, 1927, 30, 95) and of Bonhoeffer and Kaminsky (*loc. cit.*). The former, in the course of some investigations upon ionisation in active nitrogen, studied the diminution in the life of the after-glow brought about by addition of helium, nitrogen, hydrogen, and oxygen, and found their destructiveness to increase in the order given; helium was remarkable in that it had practically no action. As no mention is made in his paper of any precautions to keep absolutely constant the composition of the nitrogen in which the glow was produced, it is doubtful whether his results can be compared with those of the author given in Part VII and in the present communication, but it is noticeable that the rate of decay increased from nitrogen to hydrogen, as in the experiments here described when the gas was not rich in photogens. Oxygen appears to participate in the glow-emission reaction because of the many levels it possesses at which it can absorb energy, and hence it should not be considered in purely kinetic studies; in the case of helium, however, it appears either that, as Constantinides points out, its

lowest excitation level (20 volts) is so high that it cannot acquire energy from the active nitrogen and hence has no effect whatever upon the glow, or that, in this particular experiment, highly photogenic nitrogen was being used and no influence upon the rate of decay was noticed, since the helium could influence neither the state of the walls nor the volume reaction, in accordance with the specific three-body collision theory.

Bonhoeffer and Kaminsky added inert nitrogen to a stream of the glowing gas, and, observing no enhancement of the glow and a diminution of its life, concluded that the decay of the after-glow is not a third-order reaction. This may have been due partly to the design of the apparatus they employed, which would lead to very gradual mixing of the added gas with the glow stream (see footnote, p. 243 of Kneser's article, "Der aktive Stickstoffe," *Ergebnisse der exakten Naturwissenschaften*, 1929, 8, 229; an admirable summary of work to date) or to their experimental conditions having been comparable with those of the author in the studies described under Fig. 3, i.e., clean glass surfaces and fairly non-photogenic nitrogen; addition of inert nitrogen here produces only a small increase in initial glow intensity, and the duration of the after-glow is somewhat prolonged rather than shortened, both of which might easily escape detection by ordinary visual methods.

#### *Summary.*

It is shown (i) that the introduction of a photogen *after* nitrogen has been sparked induces the after-glow in pure nitrogen, (ii) that a strong glow appears if the same gas be placed in contact with a paraffined surface, and (iii) that the amount of chemical reaction between the wax and the active nitrogen is much less in photogenic than in non-photogenic nitrogen. These observations are considered to furnish proof of the correctness of the theory that photogens are wall-poisons and convert the non-luminous heterogeneous re-association of atoms into a homogeneous reaction accompanied by emission of light. Studies are also described upon the addition of other gases to the after-glow, and the results are shown to be in accordance with the three-body collision theory of the emission of the after-glow, provided that the condition of the walls is such that they do not interfere.

The author's acknowledgments are due to Mr. W. A. Bayliss for much technical assistance in these experiments.

CXLVII.—*Orientation Effects in the Diphenyl Series.*  
*Part VIII. The Nitration of 4:4'-Difluorodiphenyl.*

By RAYMOND JAMES WOOD LE FÈVRE and EUSTACE EBENEZER TURNER.

THE earliest papers in this series were concerned with showing that certain 4:4'-disubstituted diphenyl derivatives underwent unsymmetrical dinitration. This was notably so with the dichloro- and the dibromo-compound, each of which formed first the 2-nitro-derivative, which then gave, on further nitration, the corresponding 2:3'-dinitro-compound.\* Attention was directed to the fact that these substitutions were as nearly quantitative as possible.

At the above period, similar and comparative experiments on 4:4'-difluoro- and 4:4'-di-iodo-diphenyl had not been reported. Nevertheless it was felt that a simple application of results, obtained in other investigations of the phenomena of aromatic substitution, to the mechanism of nitration of disubstituted diphenyl derivatives consistently envisaged in this series (compare Parts I and IV) would give an accurate forecast of the facts. For instance, in a 4:4'-disubstituted diphenyl compound (I), the position in which

the first nitro-group enters is determined only by the relative powers of X and  $p\text{-X}\cdot\text{C}_6\text{H}_4$  in facilitating ortho-substitution. When X is chlorine or bromine, it happens that  $p$ -chloro- or  $p$ -bromo-phenyl easily outweighs chlorine or bromine in this respect, and the 2-nitro-derivative is therefore produced ( $I \longrightarrow II$ ). Similarly, the second entrant nitro-group is affected only by the competing ortho-facilitations of  $p\text{-X}\cdot o\text{-NO}_2\cdot\text{C}_6\text{H}_3$  and X; in the examples cited, it enters the 3'-position.

From what is known regarding the relative orienting influences of the halogens, it would be expected that 3-mononitration should become less likely as one passes down the series: 4:4'-di-iodo-, 4:4'-dibromo-, 4:4'-dichloro-, 4:4'-difluoro-diphenyl. Actually, Hodgson (J., 1926, 2384), by the dinitration of 4:4'-di-iododiphenyl, obtained only the 2:3'-dinitro-derivative, indicating that the first nitro-group enters only the 2-position. Since, therefore,

\* Borsche and Scholten (*Ber.*, 1917, 50, 609) state that the product of dinitrating 4:4'-dichlorodiphenyl is identical with the 4:4'-dichloro-2:2'-dinitrodiphenyl obtained by heating 2:5-dichloronitrobenzene with copper powder. Actually, a mixture of the two compounds concerned melts at a temperature well below the m. p. of either individual.

4 : 4'-dibromo- and -dichloro-diphenyl undergo no 3-mononitration, it seems certain that 4 : 4'-difluorodiphenyl would be nitrated quantitatively in position 2.

In the further nitration of 4 : 4'-difluoro-2-nitrodiphenyl, we should expect the second nitro-group to enter the 3'-position for three reasons: (1) By analogy with the three parallel cases in which the other halogens are present, (2) because, although it may be the weakest ortho-directing halogen, fluorine still possesses this power, and (3) because this substitution would be more open to the steric influence of the 2-nitro-group.

With these considerations before us, we had no doubt that Schiemann and Bolstad's statement (*Ber.*, 1928, **61**, 1403), that the nitration of 4 : 4'-difluorodiphenyl gives a 3-mononitro-derivative only, was inaccurate. Their evidence for this constitution was that by the action of potassium methoxide a methoxy-derivative was formed. For this, however, they give neither preparative details nor analyses.

We accordingly reinvestigated this problem, with the following results: 4 : 4'-Difluorodiphenyl (III), prepared by a process analogous to but simpler than that described by Schiemann and co-workers, was shown not to react with boiling piperidine. It gave a mononitro-derivative melting at 94—95°, as described by the previous investigators. This substance did not react with boiling piperidine, and was identical with 4 : 4'-difluoro-2-nitrodiphenyl (IV) obtained by thermal decomposition of the *bisdiazonium borofluoride* (V) obtained from 2-nitrobenzidine. The mononitro-compound was therefore the 2-nitro-derivative. This conclusion was confirmed by the production, on further nitration of the mononitro-compound, of a substance (also produced by dinitration of 4 : 4'-difluorodiphenyl) which rapidly reacted with piperidine, even in the cold, to give a fluorodinitropiperidinodiphenyl. The dinitro-compound must therefore be 4 : 4'-difluoro-2 : 3'-dinitrodiphenyl (VI),

and that no appreciable quantity of any isomeride accompanies it is shown by the fact that the crude nitration product melts only  $1^{\circ}$  lower than the pure compound.

As the scheme on p. 1159 indicates, the nitration of 4 : 4'-difluoro-diphenyl follows a course exactly similar to that of the analogous chloro- and bromo-compounds.

Schiemann and Bolstad (*loc. cit.*) converted their supposed 4 : 4'-difluoro-3-nitrodiphenyl into the corresponding amino-compound and thence into a trifluorodiphenyl by the diazoborofluoride method. These two compounds must be respectively 4 : 4'-difluoro-2-amino- and 2 : 4 : 4'-trifluoro-diphenyl. Schiemann and Roselius (*Ber.*, 1929, 62, 1805) nitrated the trifluoro-compound, reduced the product, and again replaced the amino-group by fluorine. Their evidence for the constitution of the trifluoronitrodiphenyl consisted in showing that the derived tetrafluorodiphenyl was oxidised to *p*-fluorobenzoic acid, and they accordingly regarded it as 3 : 4 : 5 : 4'-tetrafluorodiphenyl. Accepting the evidence of oxidation, it seems probable that the reactions in question are more correctly represented as follows :

but further investigation appears desirable.

#### EXPERIMENTAL.

**4 : 4'-Difluorodiphenyl.**—The method described by Balz and Schiemann (*Ber.*, 1927, 60, 1186) for the replacement of amino-groups by fluorine atoms considerably simplifies this process. We have found that the difficultly accessible hydroborofluoric acid may be replaced by the readily obtainable sodium borofluoride. The following method gave excellent results : A solution of benzidine (46 g.) in concentrated hydrochloric acid (150 c.c.) and water (150 c.c.) was bisdiazotised, a solution of 35 g. of sodium nitrite in 60 c.c. of water being used and 200 g. of ice added during the process. The solution was filtered and added to a filtered solution of 85 g. of sodium borofluoride in 150 c.c. of water. On stirring, the bisdiazonium borofluoride separated in cream-coloured needles ; a further quantity was obtained on addition of more sodium borofluoride. The precipitate was collected, dried at  $100^{\circ}$ , and decomposed by being heated in an open flask, fitted with an air-condenser, the temperature being slowly raised to  $150^{\circ}$ . Steam distillation of the product gave 21 g. of pure difluorodiphenyl. After being crystallised from alcohol, it had m. p.  $92-93^{\circ}$ .

*Mononitration of 4:4'-Difluorodiphenyl.*—A solution of 5 g. of difluorodiphenyl in 10 c.c. of warm glacial acetic acid was cooled and treated with a mixture of 7 c.c. of nitric acid of *d* 1.4 and 2 c.c. of nitric acid of *d* 1.52. The whole was left over-night, then warmed to 60°, cooled, and glacial acetic acid added; 4.5 g. of a product, m. p. 85—95°, were obtained. After crystallisation from light petroleum-benzene, the substance had m. p. 94—95°. The 4:4'-difluoro-2-nitrodiphenyl so obtained depressed the m. p. of 4:4'-difluorodiphenyl (Found: C, 61.4; H, 2.9; N, 6.1. Calc.: C, 61.3; H, 3.0; N, 6.0%). The nitro-compound was recovered unchanged from a piperidine solution which had been boiled for several minutes.

*4:4'-Difluoro-2-nitrodiphenyl.*—2-Nitrobenzidine (11.5 g.) was warmed with 35 c.c. of concentrated hydrochloric acid until it was completely converted into the hydrochloride; 30 c.c. of water were then added. The suspension was bisdiazotised (7 g. of sodium nitrite in 12 c.c. of water) and the solution was filtered and added to a filtered solution of 30 g. of sodium borofluoride in 50 c.c. of water. After a few minutes, 2-nitro-4:4'-diphenylbisdiazonium borofluoride separated as matted needles which, after being dried at 100°, became a yellow sandy powder; this turned brown at about 125° and decomposed with effervescence at 129° (Found: N, 16.5.  $C_{12}H_7O_2N_5F_3B_2$  requires N, 16.4%).

Conversion of the diazonium borofluoride into the difluoronitrodiphenyl was effected by mixing it with fine purified sand, or with barium sulphate, and heating gradually in a bath to 190°, the whole operation occupying  $\frac{1}{2}$  hour. The mixture obtained was distilled in steam, and the cooled distillate filtered. The 4:4'-difluoro-2-nitrodiphenyl so isolated melted at 94—95°, either alone or when mixed with the substance obtained by the nitration of difluorodiphenyl (Found: N, 6.4, 6.3. Calc.: N, 6.0%).

*Dinitration of 4:4'-Difluorodiphenyl.*—The difluorodiphenyl (2 g.) was gradually added to 15 c.c. of nitric acid (*d* 1.5), kept cool in tap water. The solution was warmed to 100° during 5 minutes, cooled slightly, and treated with 2 vols. of glacial acetic acid and a little water. On being kept, it deposited crystals, which, after being crystallised from diluted acetic acid, formed cream-coloured leaflets, m. p. 109—110° (Found: C, 51.4; H, 2.1; N, 9.7.  $C_{12}H_6O_4N_2F_2$  requires C, 51.4; H, 2.1; N, 10.0%).

*Mononitration of 4:4'-Difluoro-2-nitrodiphenyl.*—(a) The nitro-compound obtained from 2-nitrobenzidine was added to 20 parts of nitric acid (*d* 1.5), the solution obtained being heated to 100° during 5 minutes. On cooling, crystallisation set in. Glacial acetic acid was added, the whole warmed, and then allowed to cool slowly. The dinitro-compound so obtained was crystallised from diluted

acetic acid, and then melted at 109—110°, either alone or when mixed with the product of the same m. p. described above.

(b) The mononitration product of difluorodiphenyl was gradually added to 20 parts of nitric acid (*d* 1.5), and the solution was slowly heated to 100° during 5 minutes. An equal volume of glacial acetic acid was now added, and then water, until no further precipitation occurred. The crude filtered and washed product melted at 108—109°. Crystallisation from diluted acetic acid raised the m. p. to 109—110°. A mixture of this substance with the dinitration product of difluorodiphenyl also melted at 109—110°.

*Action of Piperidine on 4:4'-Difluoro-2:3'-dinitrodiphenyl.*—A solution of the dinitro-compound (2 g.) in 5 c.c. of piperidine was boiled for 2 minutes to complete the reaction which began in the cold. Water was added and the solid precipitated was crystallised from alcohol, 4-fluoro-2:3'-dinitro-4'-piperidinodiphenyl being obtained as orange rhombohedra, m. p. 126.5—127.5° (Found: C, 59.0; H, 4.6; N, 12.2.  $C_{17}H_{16}O_4N_3F$  requires C, 59.1; H, 4.6; N, 12.2%).

## CXLVIII.—*Studies in "Strainless" Rings. Part II.* *The Effect of the trans-Decalin Nucleus on the Carbon Tetrahedral Angle.*

By KESHAVIAH ASWATH NARAIN RAO.

PERHAPS the most successful attempt that has been made to explain the numerous discrepancies in the relative ease of formation and the stability of different types of ring, for which Baeyer's simple conception of strain failed to account satisfactorily, is that of Thorpe and Ingold, on the basis of their "valency-deflexion" hypothesis, which rests on the fundamental assumption that, when the normal angle between two of the valencies of a carbon atom is changed through any cause, *e.g.*, their inclusion in a ring, the other two valencies apparently take up an altered relative position; more definitely, the hypothesis suggested that when the angle between two of the valencies is greater than the normal angle, the angle between the other two valencies will be less than this amount, and *vice versa* (J., 1915, 107, 1080; 1922, 121, 650, etc.). Experimental investigation has in general given very good support to the hypothesis.

It seemed desirable, therefore, to examine the rings of dicyclic

compounds on the basis of this hypothesis with the view of gaining an insight into the condition of strain in such rings.

The discovery that five- and six-membered rings can unite together by their *cis*- as well as by their *trans*-valencies satisfied the requirements of Mohr's hypothesis with regard to isomerism. But it is unsound to conclude from the fact of the existence of these isomerides that they are necessarily strainless. As Haworth (*Ann. Reports*, 1927, 24, 98) has pointed out, the existence of this type of isomerism is in no way inconsistent with the supposition that the isomerides are in a state of strain. *trans*-Decalin [decahydronaphthalene] (I), being the most interesting substance from this point of view, has been chosen in the first instance for examination. If it consists of two uniplanar and strained *cyclohexane* rings interlocked in the ortho-position, and is in consequence itself highly strained, there should be no difference between the effects of *trans*-decalin and *cyclohexane* on the carbon tetrahedral angle; if, on the contrary, it relieves its strain by causing the component *cyclohexane* rings to assume multiplanar and strainless forms, its effect

should be similar to that of *cyclopentane* on this angle. The experiments which have been carried out on derivatives of *trans*-decalin-2:2-diacetic acid (II) prove conclusively that *trans*-decalin relieves its strain almost completely, diminishing in consequence the convergence of the two acetic acid residues towards each other.

As in the *cyclohexane* and *cycloheptane* series, it has not been possible to prepare the *monobromo-ester* (III) by bromination of *trans*-decalin-2:2-diacetic acid. The ester is, however, readily prepared by bromination of *ethyl hydrogen trans-decalin-2:2-diacetate* (IV); but it cannot be purified, since it undergoes partial conversion into the lactonic ester on distillation. Some *monobromo-acid ester* (V) is always formed during the bromination. On hydrolysis with concentrated aqueous potassium hydroxide, the neutral and the acid products of bromination lose hydrogen bromide and form the stereoisomeric *spiro-cyclopropane acids*, the yield, about 38% of the theoretical, being the same as in the *cyclohexane* and *cycloheptane* series. The remainder of the material is converted into a mixture of lactonic acids.

*trans*-Decalin- $\beta$ -*spiro-cyclopropane*-1:2-dicarboxylic acid can

exist in four stereoisomeric forms, two *cis*- (VI and VII) and two *trans*- (VIII and IX). Three of these (the *trans*-A- and -B-acids and the *cis*-A-acid) have been isolated from the products of hydrolysis

of the neutral and the acid monobromo-esters. The mixture of *trans*-spiro-acids has been separated by repeated fractional crystallisation from aqueous acetone into two acids: (1) the less soluble *A*-acid (VIII), which, as thus obtained, is amorphous, and (2) the more soluble *B*-acid (IX), which is highly crystalline. The two *trans*-spiro-acids should give rise to a mixture of the *cis*-acids (A) and (B) by the directional change of either of the carboxyl groups. Although evidence of the formation of a mixture of *cis*-anhydrides by the distillation of these acids—the *trans*-acids are unchanged on melting—has been obtained, only the *cis*-A-anhydride (X) can be obtained pure from the mixture. The *cis*-A-acid (VI) is formed by hydration of the *cis*-anhydride.

It is in the stability of these *trans*-spiro-acids that the remarkable difference between *trans*-decalin and *cyclohexane* in their effects on the carbon tetrahedral angle is revealed. Both the *trans*-spiro-acids from *trans*-decalin are equally stable (or unstable) towards hydrochloric acid, thus demonstrating that the stability of the spiran-structure depends almost entirely on the ring with which it is associated and very little on other factors. They are unattacked by 5% hydrochloric acid at 240° and by 10% acid at 200°, but are completely decomposed by the latter at 240°; 20% acid decomposes them at a much lower temperature, *viz.*, 200°, within two hours: the *cyclohexane* analogue is unaffected by concentrated hydrochloric acid at 240° during several hours. No definite substance can, however, be isolated, carbon being the chief product of such a decomposition. It is remarkable that of all the analogous compounds, caronic acid (XI) should be the only one to give a definite

product of decomposition, *viz.*, terebic acid (XII). That the observed decomposition of the *trans*-*spiro*-acids is due to the instability of

the *spiro*-cyclopropane ring and not of *trans*-decalin *per se* is proved by the fact that *trans*-decalin-2 : 2-diacetic acid, after being subjected

to similar treatment, is recovered unchanged. The *spiro*-acids are stable to cold acid or alkaline permanganate and are decomposed only after prolonged boiling.

It has already been shown (Rao, J., 1929, 1954) that in *cis*- and *trans*-decalins of the type  $C_9H_{16} > C \begin{smallmatrix} X \\ < \\ Y \end{smallmatrix}$  only one isomeride corresponding to each decalin is formed when X and Y are identical or are replaced by a symmetrical ring. Further, when X and Y are different, two isomerides (A and B) corresponding to each decalin are obtained, the replacement of X and Y by an unsymmetrical ring not causing any reduction in the number of isomerides. It is therefore to be expected that, when a monosubstituted unsymmetrical ring takes the place of X and Y, four isomerides from each decalin will be produced. This expectation has been realised in the case of *trans*-decalin, for, when the neutral and the acid monobromo-ester (III and V respectively) are hydrolysed with aqueous sodium carbonate, the four stereoisomeric lactones of  $\alpha$ -hydroxy-*trans*-decalin-2 : 2-diacetic acids are formed.

The neutral monobromo-ester (III) is converted into the two lactones (A) and (B), the acid monobromo-ester (V) into two other stereoisomerides (C) and (D). The formation of two different pairs of lactones from the two bromo-esters is probably due to the different configurations of the latter. On examining the model of *trans*-decalin-2 : 2-diacetic acid, it is found that the two carboxyl groups are not equidistant from the tertiary carbon atom ( $\alpha$ ), which is in the  $\beta$ -position to the carbon attached to the acetic acid residues. Two bromo-acid chlorides (XIII and XIV) are formed from the stereoisomeric acid esters (IV). In one of these (XIV), the hydrogen attached to the tertiary carbon atom  $\alpha$ , the bromine, and the acid chloride group are all crowded into a small volume, resulting probably in the development of some sort of steric hindrance. This would resist any further crowding such as would be caused by the introduction of an ethyl group in place of the chlorine. The latter would therefore undergo preferential replacement by hydroxyl, the bromo-acid ester being formed. This would give rise to the two lactones (XVII and XVIII). On the other hand, there is no such abnormal condition in the stereoisomeric bromo-acid chloride (XIII), which would therefore form the neutral ester easily; this neutral bromo-ester forms the two other lactones (XV and XVI).

It was intended to confirm the correctness of this interpretation by the formation of the dianilides (XXI) of the parent hydroxy-acids (XIX and XX) by the interaction of the lactones with aniline.

Lactones (A) and (B), which are descended from the hydroxy-acid (XIX), would give one dianilide, different from that produced from the acid (XX) formed from the lactones (C) and (D). But unfortunately all the lactones are converted into their *monoanilides* (XXII) on being heated with *excess* of aniline at 200—220°. The uniform stability of the *spiro-cyclopentane* (heterocyclic) ring in all the isomerides is but another illustration of the stability of the *spiro-cycloid* being dependent only on the ring with which it is associated.

The formation of the *monoanilides* illustrates an interesting difference between *trans*-decalin and *cyclohexane*, where the dianilide is easily formed by the action of aniline on the lactones at 200°. Since the internal angle of *trans*-decalin (which is a strainless ring) is very nearly the same as the normal angle, the angle between the extracyclic valencies would be of nearly the same value. While this angle (*ca.* 109·5°) makes the associated *cyclopropane* ring (which requires an angle of 60° for stability) unstable (as illustrated by the instability of the *spiro-cyclopropane* acids), it is of the optimum value for the formation of a stable *cyclopentane* ring (stability of the lactones). In *cyclohexane*, on the contrary, the angle between the extracyclic valencies is 107·2°, which is less than the normal angle. This angle increases the stability of *spiro-cyclopropane*, but has a reverse effect on the stability of the associated *cyclopentane*, since it causes the distance between the terminal carbon atoms to increase through overlapping. The work of Dickens, Kon, and Thorpe (J., 1922, **121**, 1499) on *cyclopentanediones* and of Sircar (J., 1927, 1253) on the stability of heterocyclic compounds also illustrates this progressive decrease in stability due to the increased distance between the terminal carbon atoms through overlapping.

So far as the author is aware, this is the first instance in this type of dicyclic ring of the preparation of four stereoisomerides from one parent. Their existence is in complete harmony with Mohr's hypothesis. Orientation of these isomerides is not possible, as there is no known method by which this can be accomplished.

The *dibromo-ester* (XXIII) is readily prepared by the dibromination of *trans*-decalin-2 : 2-diacetic acid, very little acid product being formed when the bromination is carried out under strictly defined conditions. The remarkable difference between *cyclohexane* and *trans*-decalin is again clearly demonstrated by a study of the hydrolysis of the *dibromo-ester* with potassium hydroxide. When ethyl *trans*-decalin-2 : 2-dibromoacetate is hydrolysed with 64% aqueous potassium hydroxide, there is formed mainly (49%)  $\alpha$ -*keto-trans*-decalin-2 : 2-diacetic acid (XXIV), together with a

small quantity (under 4%) of the unsaturated acid (XXV). No trace of the hydroxy-*spiro*-acid (XXVI) could be detected. The

rest of the material is converted into a mixture of the stereoisomeric hydroxy-lactonic acids (XXVII), which cannot be induced to solidify even after 12—18 months. Hydrolysis of the dibromo-ester with 15% sodium hydroxide does not yield any unsaturated acid.

When methyl-alcoholic potash is used for the hydrolysis, the dibromo-ester is converted into a mixture of *cis*- and *trans*-methoxy-*spiro*-acids (XXVIII and XXIX respectively).

The two acids probably do not belong to the same series, because their melting points lie very close to each other and, moreover, it has not been possible to convert the *trans*-acid into the *cis*-isomeric, which readily gives an *anhydride* (XXX) on melting. The *trans*-methoxy-*spiro*-acid (XXIX) is converted into the keto-acid (XXIV) on boiling with hydrobromic acid. The hydroxy-*spiro*-acid (XXVI) is undoubtedly first formed by the hydrolysis of the methoxy-group, but as soon as the necessary mobile hydrogen atom is introduced into the system the ring acid is converted into the stable open-chain isomeric. The stability of the latter is further demonstrated by the fact that after boiling for 4 hours in 64% potassium hydroxide solution, it is recovered entirely unchanged.

It may be recalled that, in the *cyclohexane* series, considerable quantities of hydroxy-*spiro*-acid (type XXVI), unsaturated acid (type XXV), and hydroxy-lactonic acid (type XXVII) were formed by the hydrolysis of the dibromo-ester (or its bromo-lactones);

no keto-acid (type XXIV) was formed during the change. In the *cyclopentane* series, on the other hand, the main product of the hydrolysis was the keto-acid (type XXIV), small quantities of *cyclopentylideneacetic acid* (type XXXIII) and the hydroxy-lactonic acid also being formed; no hydroxy-*spiro*-acid was encountered. When methyl-alcoholic potash was used for the hydrolysis, however, a mixture of the hydroxy-*spiro*-acid and its methoxy-derivative was produced, both of which were completely converted into the keto-acid on hydrolysis with hydrobromic acid; moreover, the hydroxy-*spiro*-acid was found to be a *cis*-acid, unlike analogous compounds in the other series. Finally, in the *cycloheptane* series, the product of hydrolysis of the dibromo-ester with aqueous potash consisted of about 90% of the hydroxy-lactonic acid, 3% of the hydroxy-*spiro*-acid, and 7% of the *cycloheptylideneacetic acid* (type XXXIII); the hydroxy-*spiro*-acid or its methoxy-derivatives pass into the keto-acid (99%) on hydrolysis with hydrobromic acid.

*trans*- $\beta$ -Decalone condenses with ethyl bromoacetate in presence

of zinc to form the *hydroxy*-ester (XXXI), which on dehydration and subsequent hydrolysis is converted into  $\Delta^{2(\text{or } 1)}$ -*trans-octa-hydronaphthalene-2-acetic acid* (XXV), identical with the unsaturated acid obtained by the hydrolysis of the dibromo-ester. *trans-Decahydronaphthylidene-2-acetic acid* (XXXIII) is prepared by dehydration of the *hydroxy*-acid (XXXII). That the  $\alpha\beta$ -acid is first formed during the hydrolysis of the dibromo-ester and is subsequently converted into the  $\beta\gamma$ -isomeride by the strong alkali has been proved by boiling a solution of the former in 64% potash, whereby it is completely converted into the  $\beta\gamma$ -acid.

The formation of the unsaturated acid from the dibromo-ester probably involves the elimination of one of the (hydroxy)acetic

acid residues as glyoxylic acid, which is then oxidised to oxalic acid (see J., 1915, 107, 1080). The last-named substance arising from

this oxidative fission has actually been isolated from the products of hydrolysis.

Hydrolysis of the dibromo-ester (XXIII) with aqueous sodium carbonate produced a mixture of acids from which a crystalline substance, m. p. 182—183°, having properties usually associated with hydroxy-lactonic acids, was isolated, but the quantity obtained was too small for investigation. From the rest of the material, which showed no tendency to crystallise during several months, small quantities of the keto-acid were isolated by various methods; no other solid product was obtained.

The explanation of this unexpected formation of the keto-acid by the sodium carbonate hydrolysis of the dibromo-ester is not immediately obvious. One simple way is to assume that the product of dibromination is really an unsymmetrical dibromo-ester (XXXIV). This, on replacement of the bromine atoms by hydroxyl, would give the dihydroxy-compound (XXXV), which is the hydrated

form of the keto-acid. But, although numerous substituted glutaric acids have been brominated, in no case has the formation of an unsymmetrical dibromo-derivative been observed. The one substance, *viz.*, ethyl hydrogen dibromo- $\beta\beta$ -dimethylglutarate (Perkin and Thorpe, J., 1901, 79, 729), which was assumed to be of such a type because it gave the keto-acid (XXXVI) on hydrolysis with alkali, was later considered by Kon, Stevenson, and Thorpe (J., 1922, 121, 657) to be the  $\alpha\alpha'$ -dibromo-derivative (XXXVII).

The explanation must therefore be sought in another direction. Ingold (J., 1921, 119, 314) has shown that the sequence of changes, dibromo-ester  $\longrightarrow$  bromo-ring acid  $\longrightarrow$  keto-acid, takes place in presence not only of alkali hydroxide but also of sodium carbonate. It was found that when methyl, ethyl, or *isopropyl* dibromoglutarate was hydrolysed by 2*N*-sodium carbonate a small quantity of the bromocyclopropanedicarboxylic acid (XXXVIII) was produced. On prolonged boiling, however, replacement of the bromine

atom by hydroxyl occurred, with the formation of cyclopropanoldicarboxylic acid (XXXIX).

Such a change is what in all probability occurs in the present instance. It was found necessary to boil the dibromo-ester with a solution of sodium carbonate (saturated at 105°) during 60 hours, before there was appreciable hydrolysis. Under these conditions, the hydroxy-ring acid (XXVI) would be first produced, and, being unstable, be immediately converted into the keto-acid (XXIV).

The hypothetical existence of the two multiplanar forms of cyclohexane, (a) the "boat" (XL) and (b) the "arm-chair" (XLI), may be assumed to explain the formation of decalin. The "boat"

is a loose shape which cannot pass into the other form without strain, but is itself capable of passing through a series of vibrating phases by strain-free relative rotations. The number of decalins that can exist by a combination of these forms through their *cis*- as well as their *trans*-valencies is large. But Mohr's postulate is probably applicable, and then all the *cis*-forms can be reduced to one configuration, and the *trans*- to another (Wightman, J., 1925, 127, 1421; Hückel, "Fortschritte der Chemie, Physik und Physikalischen Chemie," Bd. 19, Heft 4, 1927, 27—30). All these forms are probably different phases (the decalin made of two uniplanar cyclohexanes is probably one of these, though of much shorter duration) of the vibrating molecule, no phase having more than a transitory existence. The substance behaves stereochemically as if its configuration were the average condition of the limiting states. Moreover, the further the uniplanar form departs from the strainless phase, the more will the molecule behave as a strainless ring.

On examining a model of *trans*-decalin, it is readily seen that it would be very greatly strained if the component cyclohexanes were uniplanar; on the other hand, almost complete relief of this strain takes place if the two rings are multiplanar. *trans*-Decalin should therefore be expected to behave like a strainless ring, and this is exactly what has been demonstrated by the present investigation. The instability of the *spiro*-cyclopropane acids, the non-existence of the hydroxy-ring acid, and the stability of the keto-acid all show that *trans*-decalin occupies a place in the table midway between cyclopentane and cycloheptane, rather than near cyclohexane. This evidence is in perfect agreement with that from other sources, including the measurement of the heats of combustion (Roth and Lassé, *Annalen*, 1925, 441, 48).

Brief reference may be made to the strain in *cyclohexane* which has been the subject of controversy in recent years (Hückel, *op. cit.*). The non-existence of two stable strainless forms (Wightman, J., 1926, 2541; Werner and Conrad, *Ber.*, 1899, **32**, 3046) which would be expected on the basis of Sachse's hypothesis (*Ber.*, 1890, **23**, 1363) was explained by Mohr (*J. pr. Chem.*, 1918, **98**, 315; 1922, **103**, 316) by assuming that the temporary strain involved in the interconversion of Sachse's strain-free structures is sufficiently slight to be overcome by forces due to molecular cohesion; yet the fact remains that there is no experimental proof whatever of the existence of strainless *cyclohexane*. Moreover, the data obtained from X-ray examination (Hendricks and Bilicke, *J. Amer. Chem. Soc.*, 1926, **48**, 3007) of benzene hexahalides do not indicate the existence of a multipplanar *cyclohexane*. It has been argued that because decalin exists in *cis*- and *trans*-forms and may therefore be considered fairly free from strain, *cyclohexane* itself should lie in more than one plane. There is no justification for this view, because the condition which exists in dicyclic compounds, *e.g.*, *trans*-decalin, where the strain would be very great if the component *cyclohexanes* were uniplanar, is quite different from that in *cyclohexane*, where the strain would not be excessive.

Hückel (*op. cit.*, p. 90) contends that the "valency-deflexion" hypothesis "steht und fällt mit der willkürlicher Annahme eines ebenen gespannten Sechsrings" and suggests, "eine weitere Ausdehnung des Vergleichs auf substituierte Cyclohexanringe und auf Derivate des *trans*-Dekalins, in denen der Sechsring sicher nicht eben sein kann, wäre von Bedeutung." The marked contrast in the effects of *cyclohexane* and *trans*-decalin on the carbon tetrahedral angle demonstrated by this investigation, which was begun long before Hückel's publication appeared, can only be due to a large difference in strain in the two rings; it should be noted that the polar influences, whatever their nature, would be expected to be similar in the two rings. *trans*-Decalin is obviously strainless, on the evidence from all sources; it seems probable, therefore, that the average condition of the vibrational limits of *cyclohexane* possesses appreciable strain.

One of the characteristics of the analogous derivatives of *cyclopentane* (Becker and Thorpe, J., 1920, **117**, 1584) and *cycloheptane* (Baker and Ingold, J., 1923, **123**, 127) is their remarkable lack of tendency to crystallise. The derivatives of *trans*-decalin display this characteristic even more prominently. This, and the formation of a number of stereoisomerides in all the reactions, has made the experimental investigation extremely difficult. None of the substances described in this paper can be accumulated in any con-

siderable quantity, and even their isolation is possible only when the directions given in the experimental part are closely followed.

# EXPERIMENTAL.

*Ethyl Hydrogen trans-Decalin-2:2-diacetate* (IV).—A solution of sodium (35 g.) in absolute ethyl alcohol (500 c.c.) was added slowly with stirring to a solution of the anhydride of *trans*-decalin-2:2-diacetic acid (356 g.), also dissolved in absolute ethyl alcohol (175 c.c.). After the reaction became slow, the alcohol was removed in a vacuum, and the aqueous solution of the sodium salt acidified with dilute hydrochloric acid. The heavy oil which was precipitated was extracted with pure ether, dried thoroughly, recovered, and kept at 100° under vacuum for 1 hour (420 g.). The *acid ester* [Found: equiv., 280.  $C_{10}H_{16}(CH_2 \cdot CO_2Et) \cdot CH_2 \cdot CO_2H$  requires equiv., 282] is a thick, almost colourless syrup; on distillation under reduced pressure, it is reconverted into the anhydride.

Methyl hydrogen *trans*-decalin-2:2-diacetate was prepared in a similar way (Found: Ag in the *silver* salt, 27.0.  $C_{15}H_{23}O_4Ag$  requires Ag, 28.8%).

*Monobromination.* When the ethyl acid ester (420 g.) was cautiously mixed with phosphorus pentachloride (330 g.), a vigorous reaction occurred and hydrogen chloride was evolved: the conversion into the acid chloride was completed by heating on the steam-bath for 1 hour. Dry bromine (82 c.c.; 1.1 mols.) was then added portionwise during 6 hours, the mixture being kept at 50—60°. When the evolution of hydrogen bromide had ceased, the whole was poured into absolute ethyl alcohol (2 l.), kept at 25°. After the vigorous reaction had subsided, the solution was boiled for  $\frac{1}{2}$  hour and then mixed with excess of water. The precipitated bromo-ester was extracted with ether, the acid product removed with a 5% solution of sodium carbonate, and the extract then dried over calcium chloride and evaporated. The residual neutral *monobromo-ester* (III) was kept over concentrated sulphuric acid in a vacuum during several days (yield, 80—83%) (Found: Br, 19.1.  $C_{18}H_{29}O_4Br$  requires Br, 20.5%). On distillation even under 2 mm., it (b. p. 180—200°/2 mm.) was partly converted into the lactonic ester, the distillate being a thick viscid syrup (Found: C, 61.9; H, 8.2. The lactonic ester,  $C_{16}H_{24}O_4$ , requires C, 68.6; H, 8.6%. The monobromo-ester,  $C_{18}H_{29}O_4Br$ , requires C, 53.7; H, 7.2%).

The acid product of the monobromination extracted by aqueous sodium carbonate (above) was obtained as a heavy oil on acidification (yield, 17—20%); it could not be purified by distillation (Found: Br, 21.6.  $C_{16}H_{25}O_4Br$  requires Br, 22.1%). This acid

monobromo-ester is formed even under conditions most conducive to the complete esterification of the bromo-acid chloride.

*Stereoisomeric Lactones of  $\alpha$ -Hydroxy-trans-decalin-  
2 : 2-diacetic Acids.*

*Lactones (A) (XV) and (B) (XVI).*—These lactones are the only products of the action of boiling sodium carbonate solution on the neutral monobromo-ester (III). A suspension of the mixture of the monobromo-ester and lactonic ester (30 g.), obtained by the distillation of the monobromo-ester, in a solution (saturated at 105°) of sodium carbonate (60 g.) was boiled for 72 hours. The solution was diluted and extracted with ether to remove any unchanged ester. The oil precipitated on acidification was thrice extracted with pure ether, dried, recovered, and kept at 90° for 2 hours. After remaining for 2 weeks in a vacuum over sulphuric acid, it was dissolved in benzene, to which was then added as much light petroleum (b. p. 60—80°) as possible without producing a turbidity. The solid which had separated during 1 week was collected (A). On further addition of light petroleum to the filtrate, an oil (B) was precipitated, from which the supernatant liquid was poured off.

After several months, the mother-liquor deposited colourless nodules. These separated from benzene-light petroleum (b. p. 60—80°) in crystalline lumps, m. p. 137—140°. Titration with *N*/20-barium hydroxide showed that this substance was a mixture of lactone and the hydroxy-acid; the latter, however, could not be obtained sufficiently pure for analysis.

*Lactone (A)* crystallised from benzene in colourless silky needles, m. p. 156° (Found: C, 66.7; H, 7.9; equiv., by titration with *N*/20-barium hydroxide, 256.  $C_{14}H_{20}O_4$  requires C, 66.7; H, 7.9%; equiv., for monobasic acid, 252).

When concentrated aqueous solutions of the lactone and aniline were mixed, the *aniline* salt separated in long silky needles, m. p. 126° (Found: C, 69.1; H, 7.9.  $C_{14}H_{20}O_4 \cdot C_6H_5 \cdot NH_2$  requires C, 69.6; H, 7.8%).

The lactone and excess of aniline were heated together at 200—210° for 1.5 hours. The gum obtained on cooling was triturated with dilute hydrochloric acid; it then solidified. Crystallised from dilute ethyl alcohol, the *monoanilide* separated in long, colourless, feathered needles, m. p. 154° (Found: C, 73.4; H, 7.8; N, 4.5.  $C_{20}H_{25}O_3N$  requires C, 73.4; H, 7.6; N, 4.3%).

*Lactone (B) (XVI).* The oil (B, above) solidified after some weeks and then separated from benzene in stellate clusters of soft needles, m. p. 163° (Found: C, 66.6; H, 8.1%; equiv., 252). It is sparingly

soluble in cold benzene. A mixture of lactones (A) and (B) melts at 123—125°.

The *aniline* salt of lactone (B) crystallised from benzene in long silky needles, m. p. 147° (Found : C, 69.6; H, 7.5%). The *monoanilide* separated from dilute methyl alcohol in dirty white, spherical nodules, m. p. 172° (Found : C, 73.2; H, 7.9; N, 4.5%).

*Lactones (C) (XVII) and (D) (XVIII).*—A sodium carbonate solution (25 g. in 225 c.c. of water) of the acid bromo-ester (V) (40 g.) was boiled for 8 hours, diluted and acidified, and the precipitated oil collected in ether. The ethereal solution having been partly dried over calcium chloride, the substance (29 g.) was recovered : it showed no signs of crystallising and therefore was esterified with ethyl alcohol (120 c.c.) and concentrated sulphuric acid (12 c.c.). The product was isolated in the usual way and after two fractional distillations in a vacuum was separated into two fractions : (1) 210—211°/6 mm., (2) 215°/6 mm.

*Lactone (C).* The ethyl ester, b. p. 210—211°/6 mm., was boiled with concentrated hydrochloric acid for 10 hours. (The hydrolysis of the esters of these acids with hydrochloric acid is extremely slow, chiefly owing to their insolubility in the acid.) The residue obtained on removal of the acid was dried at 90° for 2 hours and dissolved in benzene-light petroleum (b. p. 60—80°). Even after 10 weeks, only a small quantity of the crystalline lactone (m. p. 110°) had separated. On recrystallisation from benzene-light petroleum (b. p. 60—80°), the lactone (C) separated in hard granular cubic masses of thick plates, m. p. 164°. These are hydrated and the anhydrous *lactone (C)*, m. p. 165—166°, is obtained from them by heating at 100° (Found : C, 66.4; H, 8.0%; equiv., 255). This lactone is sparingly soluble in both hot and cold benzene. In admixture with lactone (A) or (B), its m. p. is depressed by 20—30°.

The *monoanilide* crystallised from dilute ethyl alcohol in shimmering leaflets, m. p. 166° (Found : N, 4.4%).

*Lactone (D).* The ethyl ester, b. p. 215°/6 mm., was boiled with concentrated hydrochloric acid for 8 hours and the lactonic acid produced was isolated in the usual way, dried, and dissolved in benzene-light petroleum (b. p. 60—80°). After 8 weeks, during which time a small quantity of light petroleum was added daily to prevent turbidity in the solution, the *lactone (D)* which had been deposited was collected and recrystallised from benzene; it then separated in short colourless needles, m. p. 132° (Found : C, 66.5; H, 8.0; equiv., 249).

The *aniline* salt crystallised from benzene in silky needles, m. p. 122°.

*Hydrolysis of the Neutral Monobromo-ester with Concentrated Potassium Hydroxide Solution at 150°.*—A solution of potassium hydroxide (450 g.) in water (250 c.c.) was evaporated until the boiling point reached 150°. The bromo-ester (150 g.) was then added to the boiling solution as rapidly as possible. The reaction was not vigorous, but after 15–20 minutes' boiling the ester dissolved; at the same time a potassium salt separated. The solution was then diluted freely with water and acidified while hot. The precipitated oil was extracted from the cold solution, partly dried over calcium chloride, recovered, and dried at 90° for 3 hours. The mixture of acids (80 g.), which had partly solidified, was mixed with benzene (125 c.c.) and the precipitated *spiro*-acids (29 g.) were collected after 1 hour: the mother-liquor, mixed with light petroleum (b. p. 60–80°) and kept for 1 week, usually deposited a further quantity of the *spiro*-acids (6 g.).

The mixture of acids, m. p. usually 215–220°, was very difficult to separate into its constituents. The best results were obtained by dissolving the mixture in a large excess of acetone and carefully adding water. A small first crop (A) separated in nodules, m. p. 250–253°; the second crop (B) separated in pearly laminæ, m. p. 243°. The later crops were mixtures (m. p. 225–230°).

*trans-spiro-Acid (A) (VIII).* The first crop (A) was amorphous and separated in nodules from most of the solvents in which it was soluble; from a solution in 5% hydrochloric acid at 240°, however, the acid separated, on cooling, in lustrous fern-like forms. After crystallisation from aqueous acetone, *trans-decalin-β-spiro-cyclopropane-trans-1:2-dicarboxylic acid* melted at 264° (Found: C, 66.6; H, 8.0; equiv., 126.  $C_{14}H_{20}O_4$  requires C, 66.7; H, 7.9%; equiv., 126).

The *dianilide* crystallised from ethyl alcohol, in which it was very sparingly soluble, in soft colourless needles, m. p. 307° (decomp.) (Found: C, 77.2; H, 7.7.  $C_{26}H_{30}O_2N_2$  requires C, 77.6; H, 7.5%).

*trans-spiro-Acid (B) (IX).* The second crop (B, above) crystallised from aqueous acetone in lustrous ferns, m. p. 250° (Found: C, 66.5; H, 7.9%; equiv., 126). The *trans-spiro-acid (B)* is more soluble in solvents than its stereoisomeride (A) and melts at 220–225° when mixed with it.

The *dianilide*, m. p. 303° (Found: C, 77.4; H, 7.6%), resembled the isomeride (A) in its solubility in alcohol and in its crystalline form and melted at 280° when mixed with it.

Both the *trans-spiro*-acids are insoluble in water, benzene, and chloroform, sparingly soluble in xylene, and moderately easily soluble in acetone, ethyl acetate, and glacial acetic acid. They are

converted into the same *cis*-A-anhydride (see below) on distillation. They are, however, unchanged on melting.

The benzene-light petroleum mother-liquor from which the *trans*-*spiro*-acids had been removed (see p. 1176) was evaporated and the residue, since it showed no tendency to solidify, was esterified with ethyl alcohol and sulphuric acid in the usual way. The ethyl esters produced were twice fractionally distilled; in addition to small quantities of low-boiling esters, the following fractions were then isolated: (1) 200°/7 mm., (2) 214—215°/7 mm., (3) 224°/7 mm.

*Fraction (1).* This was boiled with concentrated hydrochloric acid for 11 hours, the residue obtained by evaporation of the acid was dissolved in benzene-light petroleum, and after several days the *cis*-*spiro*-acid (A) (VI) which had been deposited (less than 2 g.) was collected; m. p. 183—184°. The rest of the oil could not be induced to solidify.

The same acid was also prepared (a) by boiling *trans*-*spiro*-acid (A) or (B) and decomposing the anhydride thus produced, (b) from the above mixture of *spiro*-acids, m. p. 180—240°, which could not be separated by fractional crystallisation. This mixture was heated as rapidly as possible until it melted and was then boiled at the ordinary pressure for a few minutes. The unchanged acid was removed with sodium carbonate, and the anhydride distilled under reduced pressure. It boiled at 212—225°/14 mm. and the viscous distillate, after being kept in contact with light petroleum (b. p. 40—60°) for several days, deposited needles which on decomposition with alkali gave the *cis*-*spiro*-acid (A), m. p. 183—184°.

Being sparingly soluble in benzene, the *cis*-*spiro*-acid (A) is best crystallised from chloroform-light petroleum (b. p. 60—80°), from which it separates in lustrous prisms, m. p. 185—186° (efferv. and formation of anhydride) (Found: C, 66.7; H, 8.0%; equiv., 131).

The *anhydride* (X), prepared by melting the *cis*-acid or by treating it with acetyl chloride, or by any of the other methods described above, crystallised from light petroleum (b. p. 60—80°) in long silky needles, m. p. 107° (Found: C, 71.8; H, 7.5.  $C_{14}H_{18}O_3$  requires C, 71.8; H, 7.7%).

*Fraction (2).* The ester was boiled with excess of hydrochloric acid, glacial acetic acid being added until it dissolved: the hydrolysis was complete in 4 hours. The lactone, isolated in the usual way, was kept in a vacuum for several days and then dissolved in benzene-light petroleum (b. p. 60—80°); after 10 weeks, the crystals (m. p. 110°) which had separated were found on recrystallisation to be identical with lactone (C), m. p. 165—166°.

*Fraction (3).* The lactone which was obtained by the hydrolysis

of this ester was found, on purification, to be identical with lactone (A), m. p.  $156^{\circ}$ .

*Hydrolysis of the Acid Product of Monobromination by Concentrated Potassium Hydroxide Solution at  $150^{\circ}$ .*—The acid monobromomonoester (120 g.) was treated with a boiling solution of potassium hydroxide (360 g.) at  $150^{\circ}$  in the same way as the neutral bromomonoester, but in this case the reaction was very vigorous. The acids were isolated in the usual way, dried (83 g.), and mixed with benzene (150 c.c.). From the mixture of *spiro*-acids (27 g.) obtained, only the *trans*-*spiro*-acid (A), m. p.  $264^{\circ}$ , could be separated by crystallisation from aqueous acetone.

The acids soluble in benzene were esterified and the following fractions were collected: (1)  $232^{\circ}/19$  mm., (2)  $240^{\circ}/19$  mm., (3)  $246-248^{\circ}/19$  mm.

*Fraction* (1) (35 g.) was hydrolysed with hydrochloric acid, and the product treated with benzene-light petroleum (b. p.  $60-80^{\circ}$ ); a small quantity of the *cis*-*spiro*-acid, m. p.  $185-186^{\circ}$ , was obtained after several weeks.

*Fraction* (2) (8 g.) gave the lactone (C), m. p.  $165-166^{\circ}$ , when hydrolysed.

*Fraction* (3) (25 g.) gave a mixture of lactones (C) and (D).

#### *Dibromination of trans-Decalin-2:2-diacetic Acid.*

The reaction which started when *trans*-decalin-2:2-diacetic acid (200 g.) was mixed with phosphorus pentachloride (400 g.) was completed by gentle heating on the steam-bath for 4–5 hours. Dry bromine (88 c.c., 2.2 mols.) was then added to the mixture, which was kept at  $50-60^{\circ}$  during 8 hours. After 20 hours, when the evolution of hydrogen bromide had ceased, the mixture was cooled, poured into absolute ethyl alcohol (1300 c.c.) at  $0^{\circ}$ , and, when the vigour of the reaction had abated, boiled for 1 hour. The whole was then freely diluted with water and the precipitated *dibromomonoester* (XXIII) was extracted with a large volume of ether, freed from the acid product by extraction with a 5% solution of sodium carbonate, dried over calcium chloride, and recovered (350 g.). The specimen for analysis was kept in a vacuum over sulphuric acid for 4 weeks (Found: Br, 32.1.  $C_{18}H_{28}O_4Br_2$  requires Br, 34.1%).

The acid fraction (above) never amounted to more than 5 g. In the earlier experiments, where the usual conditions of bromination were followed, considerable quantities of the acid monobromomonoester (V) were obtained (Found: Br, 21.6. Calc.: Br, 22.1%).

*trans-Decalin-2:2-dibromoacetic Acid* (formula as XXIII).—When the dibromo-acid chloride was poured into anhydrous formic

acid, there was a vigorous evolution of hydrogen chloride. The gummy residue obtained on evaporation of the solution was triturated with chloroform-light petroleum (b. p. 40–60°). A small quantity of a dirty white powder was obtained which, after crystallisation from the same solvent mixture, melted at 199° (decomp.) (Found: C, 40.7; H, 5.0.  $C_{14}H_{20}O_4Br_2$  requires C, 40.8; H, 4.8%).

*Hydrolysis of the Dibromo-ester (XXIII) with 64% Potassium Hydroxide Solution.*—When the dibromo-ester (110 g.) was added as rapidly as was consistent with safety to a boiling solution of potassium hydroxide (420 g.) in water (240 c.c.), it dissolved and a potassium salt separated. The solution was boiled for 5 minutes; diluted, and acidified while hot with hydrochloric acid. The precipitated heavy oil was extracted with ether (thrice), partly dried over calcium chloride, and recovered. After being kept at 90° for 2 hours and in a vacuum for 1 week, when it had become partly solid, it was mixed with benzene-light petroleum (b. p. 60–80°) (equal volumes). After 12 hours, the precipitated  $\alpha$ -keto-trans-decalin-2:2-diacetic acid (XXIV) was collected (25 g.). It crystallised from benzene in short colourless needles and from chloroform in long silky needles, m. p. 156° (Found: C, 62.7; H, 7.5; equiv., 135.  $C_{14}H_{20}O_5$  requires C, 62.7; H, 7.4%; equiv., 134).

The keto-acid decolorises alkaline permanganate slowly in the cold, but rapidly when hot. It is easily soluble in acetone and ethyl acetate. It is also soluble in hot water, from which it cannot be crystallised since it becomes hydrated and is obtained as a syrup on removal of the solvent. The *quinoxaline* derivative, prepared by heating equal quantities of the keto-acid and *o*-phenylenediamine in glacial acetic acid for 1 hour, was obtained after two crystallisations from ethyl alcohol in dirty white nodules, m. p. 230° (Found: C, 70.6; H, 7.2.  $C_{20}H_{24}O_3N_2$  requires C, 70.6; H, 7.1%).

The *semicarbazone* of the monosodium salt\* separated in rhombic plates when a mixture of the keto-acid, semicarbazide hydrochloride, and sodium acetate in concentrated aqueous solution was kept for 24 hours. The crystals, after being washed with water and alcohol, were hydrated (Found:  $H_2O$ , 3.0.  $C_{15}H_{22}O_5N_3Na \cdot 1/2H_2O$  requires  $H_2O$ , 2.6%), but became anhydrous when kept at 110°

\* It has frequently been observed that some  $\alpha$ -keto-acids fail to combine with semicarbazide (or other ketonic reagents). The reason for this abnormal behaviour probably lies in the strong acidity of these acids, which act as hydrolysing agents: one molecule forms the semicarbazone and another immediately hydrolyses it. Semicarbazones are readily formed when the carboxyl groups attached to the keto-group are neutralised.

for 3 hours. The semicarbazone then melted with frothing and decomposition at  $255^{\circ}$  (Found : Na, 6.35.  $C_{15}H_{22}O_5N_3Na$  requires Na, 6.6%).

The keto-acid does not combine with semicarbazide, phenylhydrazine, 2 : 4-dinitrophenylhydrazine, or diphenylbarbituric acid.

The *methyl* ester, prepared by boiling a solution of the keto-acid (5 g.) in methyl alcohol (40 c.c.) and concentrated sulphuric acid (4 c.c.) for 4 hours, or from the silver salt and methyl iodide, boiled at  $228^{\circ}/21$  mm. (Found : C, 64.5; H, 8.1.  $C_{16}H_{24}O_5$  requires C, 64.9; H, 8.1%). It did not give a semicarbazone, nor react with phenylhydrazine in acetic acid or alcohol. The *phenylhydrazone*, however, was obtained by heating a mixture of the keto-ester and phenylhydrazine in benzene solution on the steam-bath for 4 hours. On addition of light petroleum (b. p.  $60-80^{\circ}$ ) to the cooled product, thick plates were obtained. The phenylhydrazone is sparingly soluble in alcohol and benzene, moderately easily soluble in chloroform, and crystallises from dilute acetic acid in long, colourless, rectangular prisms, which are pale yellow in bulk; m. p.  $235^{\circ}$  (decomp.) (Found : C, 68.3; H, 7.6.  $C_{22}H_{30}O_4N_2$  requires C, 68.4; H, 7.8%). After 1 g. of the keto-acid had been boiled with 20 c.c. of 64% potassium hydroxide solution for 4 hours, 0.9 g. was recovered unchanged by dilution, acidification, and extraction with ether.

*Oxidation of the Keto-acid with Hydrogen Peroxide.*—A solution of the keto-acid in sodium carbonate was warmed during 3 hours, with frequent additions of hydrogen peroxide. Acidification then produced a crystalline precipitate which, after purification, was identified as 2-carboxy-*trans*-decahydronaphthalene-2-acetic acid (A), m. p.  $197^{\circ}$ , by comparison with a genuine specimen (J., 1929, 1959).

On distillation under reduced pressure, the keto-acid loses carbon monoxide and gives an oily substance, which is probably a mixture of the anhydrides of 2-carboxy-*trans*-decahydronaphthalene-2-acetic acids (A) and (B).

$\Delta^{2or 1}$ -*trans-Octahydronaphthalene-2-acetic Acid* (XXV).—The benzene solution from which the keto-acid had been removed (p. 1179) was evaporated and the residue, which showed no signs of crystallising after several months, was esterified with methyl alcohol (500 c.c.) and concentrated sulphuric acid (50 c.c.). After two fractional distillations of the product, various fractions, b. p.  $170-220^{\circ}/15$  mm., were obtained in addition to a fraction, b. p.  $154^{\circ}/15$  mm. (1.7 g.). This fraction was mixed with 40 c.c. of cold 10% aqueous potassium hydroxide, and enough alcohol added to form a clear solution. After 4 days, the oil precipitated on acidifica-

ation was extracted with ether, dried, and recovered and the mixture of oil and solid obtained was drained. The solid, which separated from light petroleum (b. p. 60—80°) in rhombic plates, m. p. 100—101°, was identified as  $\Delta^{2(\text{or } 1)}$ -*trans-octahydronaphthalene-2-acetic acid* by analysis (Found: C, 73.9; H, 9.4.  $\text{C}_{12}\text{H}_{18}\text{O}_2$  requires C, 74.2; H, 9.3%), and by comparison with a genuine specimen (see later). The dibromide, m. p. 183°, was identical with the dibromide of the above-mentioned acid.

The other fractions were hydrolysed with concentrated hydrochloric acid. From the resulting acids, after standing in benzene solution for 14—18 months, small quantities of the keto-acid were isolated; the remainder did not solidify and decomposed on distillation.

The aqueous solution from which the above acids had been removed by extraction with ether was evaporated to dryness. From the residue, ether extracted a mixture of oil and solid; the latter crystallised from water in prisms, m. p. 102° (not depressed by admixture with crystalline oxalic acid), and gave the usual reactions of oxalic acid.

*Hydrolysis of the Dibromo-ester (XXIII) with Methyl-alcoholic Potash.*—The dibromo-ester (100 g.) was added as quickly as possible to a boiling solution of potassium hydroxide (200 g.) in methyl alcohol (600 c.c.). The solution was boiled for 20 minutes and then evaporated to dryness. The residue was dissolved in water and acidified, and the precipitated oil extracted with ether. The residue after removal of the dried ether was kept at 100° in a vacuum for 2 hours; it then partly solidified. It was mixed with a small quantity of benzene, and the resulting *trans-decalin- $\beta$ -spiro-trans-1-methoxycyclopropane-1:2-dicarboxylic acid* (XXIX) collected; crystallised once from ethyl acetate and once from aqueous acetone, this separated in clusters of fine silky needles, m. p. 213° (Found: C, 63.7; H, 8.0; equiv., 141.  $\text{C}_{15}\text{H}_{22}\text{O}_5$  requires C, 63.8; H, 7.8%; equiv., 141). When the *trans-methoxy-spiro-acid* was boiled with hydrobromic acid ( $d$  1.45; 30 c.c.) for 4 hours, it was converted into the keto-acid (XXIV), m. p. 156° after crystallisation from chloroform.

The low-melting acid, together with the liquid acids obtained by evaporation of the benzene solution, was refluxed with acetyl chloride, the excess of which was then removed. The residue was dissolved in a large volume of ether, and the unchanged acid removed by a dilute solution of sodium bicarbonate. The anhydride distilled at 210—220°/12 mm. It was decomposed with sodium hydroxide and the liquid acid precipitated on acidification of the alkaline solution was triturated with methyl alcohol; it then partly

solidified. The solid was freed from the oil by draining on porous earthenware and crystallised from aqueous acetone. The resulting solid (m. p. 190—193°) was reconverted into the anhydride by melting, the unchanged acid being removed by sodium carbonate. After three crystallisations from light petroleum (b. p. 60—80°), the *anhydride* (XXX) separated in long, colourless, flattened needles, m. p. 145° (Found: C, 68.2; H, 7.5.  $C_{15}H_{20}O_4$  requires C, 68.2; H, 7.5%).

The *cis-methoxy-spiro-acid* (A), which was obtained by decomposing the anhydride, crystallised from aqueous acetone in short colourless needles, m. p. 204° (Found: C, 63.7; H, 7.8; equiv., 143). Mixed with the *trans-methoxy-spiro-acid* (B), it melted at 190—194°.

The substances so far described have a great tendency to retain ether, with the result that when they are placed in a vacuum they swell up, filling the whole of the desiccator, leading to considerable loss of material. This difficulty has been overcome by keeping them at 90° or 100° in a vacuum; all the ether is then completely removed. Even if they solidify in the desiccator, the lactonic acids become oils when exposed to the atmosphere or treated with sodium-dried solvents. The only method of getting them as crystalline solids has been to dissolve them in benzene—light petroleum (b. p. 60—80°) and allow the solution to stand during several months; even so, only a fraction of the material is obtained crystalline.

*Synthesis of trans-Decahydronaphthylidene-2-acetic and*  
 $\Delta^{2(\text{or } 1)}\text{-trans-Octahydronaphthalene-2-acetic Acids.}$

*Condensation of trans- $\beta$ -Decalone with Ethyl Bromoacetate: Ethyl 2-Hydroxy-trans-decalin-2-acetate (XXXI).—*Zinc (75 g.) was added to a mixture of *trans- $\beta$ -decalone* (152 g.) and ethyl bromoacetate (106 g.) in dry benzene (375 c.c.). The reaction which started after 2 hours' heating on the steam-bath was allowed to proceed without the application of heat and was then completed by heating again for  $\frac{1}{2}$  hour. The zinc compound having been decomposed with ice and dilute sulphuric acid, the benzene layer was separated, washed successively with dilute sulphuric acid, 10% sodium hydroxide solution, and water, and dried over calcium chloride. On distillation under reduced pressure, after removal of benzene, the main fraction boiled at 184°/26 mm., small quantities of esters boiling at lower and higher temperatures being also obtained. On redistillation, pure *ethyl 2-hydroxy-trans-decalin-2-acetate* boiled at 179—180°/20 mm. (Found: C, 70.0; H, 10.0.  $C_{14}H_{24}O_3$  requires C, 69.9; H, 10.1%); it had  $d_4^{25}$  1.045,  $n_D^{25}$  1.4832, whence  $[R_L]_D$  65.54 (calc., 65.63).

The hydroxy-ester was hydrolysed by boiling with 50% potassium hydroxide solution for a few minutes; the oily acid obtained on acidification partly solidified after a few hours. The solid was isolated by filtration and draining on porous earthenware. *2-Hydroxy-trans-decalin-2-acetic acid* (XXXII) is readily soluble in hot water (from which it separates in long needles) and alcohol, but is best crystallised from benzene; m. p.  $102^{\circ}$  (Found: C, 67.7; H, 9.9; equiv., 211.7.  $C_{12}H_{20}O_3$  requires C, 67.9; H, 9.5%; equiv., 212). The oil, which probably consisted of the stereoisomeride and would not solidify, was used for the preparation of the  $\alpha\beta$ -acid.

*Dehydration of the Hydroxy-acid: trans-Decahydronaphthylidene-2-acetic Acid* (XXXIII).—The hydroxy-acid (84 g.) was dissolved in acetic anhydride (220 g.; 5 mols.) and boiled for 3 hours. The residue obtained on removal of acetic anhydride under reduced pressure was diluted with water and boiled for 2 hours (distillation in steam was extremely slow and tedious). The acid, which partly solidified on cooling, was collected and drained on porous earthenware. Crystallised from light petroleum (b. p.  $60-80^{\circ}$ ), *trans-decahydronaphthylidene-2-acetic acid* separated in long colourless prisms, m. p.  $145^{\circ}$  (Found: C, 74.3; H, 9.2; equiv., 194.  $C_{12}H_{18}O_2$  requires C, 74.2; H, 9.3%; equiv., 194).

The *dibromide*,  $C_9H_{16}>CBr\cdot CHBr\cdot CO_2H$ , was prepared by keeping a mixture of the acid and bromine in chloroform solution for 2 days. The crystals obtained by evaporation of the solvent were boiled with light petroleum (b. p.  $60-80^{\circ}$ ) to remove the small quantity of the low-melting stereoisomeride that had also been formed. The dibromide separated from benzene-light petroleum (b. p.  $60-80^{\circ}$ ) in diamond-shaped crystals, m. p.  $170^{\circ}$  (Found: Br, 45.7.  $C_{12}H_{18}O_2Br_2$  requires Br, 45.2%).

A solution of the  $\alpha\beta$ -acid in sodium carbonate was immediately oxidised by a 1% solution of potassium permanganate. The resulting ketone, which was taken up in ether, was identified as *trans- $\beta$ -decalone* by its characteristic odour and in the form of its semicarbazone, m. p. and mixed m. p.  $193^{\circ}$ .

*Dehydration of the Hydroxy-ester.*—A solution of the hydroxy-ester (100 g.) in dry benzene (100 c.c.) was mixed with phosphorus oxychloride (28 g.) and heated on the steam-bath for  $4\frac{1}{2}$  hours; evolution of hydrogen chloride had then ceased. The oil precipitated on dilution with water was extracted with ether, washed with sodium carbonate and water, dried over calcium chloride, and recovered by removal of the solvent. The  $\beta\gamma$ -ester obtained (72 g.) boiled at  $170^{\circ}/24$  mm.

Alcohol was added to a mixture of the foregoing ester (77 g.)

and a solution of potassium hydroxide (25 g.) in water (100 c.c.) until a clear solution was formed. After 48 hours, the alcohol having been removed, the solution was diluted with water, and any unchanged ester extracted with ether. The oily acid precipitated on acidification partly solidified after a few hours. It was collected, drained on porous earthenware, and crystallised from light petroleum (b. p. 60—80°),  $\Delta^{2(\text{or } 1)}\text{-trans-octahydronaphthalene-2-acetic acid}$  (XXV) separating in colourless rhombic plates, m. p. 100—101° (Found: C, 74.2; H, 9.5%; equiv., 193). The acid decolorised permanganate and instantly absorbed bromine in chloroform solution. The *dibromide*,  $\text{C}_9\text{H}_{15}\text{Br} > \text{CBr} \cdot \text{CH}_2 \cdot \text{CO}_2\text{H}$ , obtained on evaporation of the solvent crystallised from chloroform—light petroleum (b. p. 60—80°) in thick plates, m. p. 183° (Found: Br, 45.3%).

*Conversion of the  $\alpha\beta$ -Acid into the  $\beta\gamma$ -Isomeride.*—The  $\alpha\beta$ -acid (m. p. 145°) was boiled with 64% potassium hydroxide solution for 1 hour. The precipitate obtained on acidification of the diluted solution crystallised from light petroleum (b. p. 60—80°) in rhombic plates, m. p. 100—101°, of the  $\beta\gamma$ -acid.

I desire to express my thanks to Professor J. F. Thorpe, C.B.E., F.R.S., for his kind interest in this investigation, and to the Chemical Society for generous grants towards its heavy cost.

## CXLIX.—*The Essential Oil of Backhousia angustifolia.*

### *Part II. The Isolation of Naturally Occurring $\beta$ -Diketones: Angustione and Dehydroangustione.*

By CHARLES STANLEY GIBSON, ARTHUR RAMON PENFOLD, and JOHN LIONEL SIMONSEN.

DURING an investigation of the constituents of the essential oil derived from the leaves and terminal branchlets of *Backhousia angustifolia*, which grows in Queensland, Penfold (*J. Proc. Roy. Soc. New South Wales*, 1924, **57**, 300) observed that the portion of the oil which was soluble in alkali contained a substance or a mixture of substances giving crystalline derivatives with ammonia and copper carbonate. Although the boiling point of this constituent of the oil was the same for different samples of the oil, the other physical constants, more especially the refractive index, showed somewhat large variations ( $n_D$  1.5288 and 1.5130) (*loc. cit.*, p. 308). This difference was not due solely to contamination with

some other substance, since two individual ammonia derivatives, m. p. 135—137° and 153°, were prepared. Analyses and molecular-weight determinations appeared to indicate that the parent substances had the composition  $C_{10}H_{14}O_3$ , and this formula was provisionally adopted, although it was emphasised that evidence for the homogeneity of the substance analysed was lacking. We have now subjected the alkali-soluble fraction of this oil to a detailed investigation and have found that, depending upon conditions which remain to be determined, the substance is homogeneous and consists of either one or the other of two closely related ketones, which we have designated *angustione* and *dehydroangustione*. The constitution of the former has been rigidly established and we are able to suggest one for the latter which we regard as probably correct.

Angustione,\* identical with the substance originally analysed, has now been found to have the composition  $C_{11}H_{16}O_3$  and not  $C_{10}H_{14}O_3$  and this has been substantiated by the preparation and analysis of a number of derivatives. The most characteristic of these is formed by the action of ammonia on angustione; this substance, m. p. 130—131°, for which we suggest the name *aminoangustione*, is not an ammonium salt but has the composition  $C_{11}H_{17}O_2N$ . The formation of a substance of this composition, together with the fact that a crystalline *copper* derivative,  $C_{22}H_{30}O_6Cu$ , m. p. 192—193°, can also be prepared, suggested that angustione was a  $\beta$ -diketone (compare Haas, J., 1906, **89**, 187). The existence of this structure in angustione was supported by the preparation of a *piperonylidene* derivative and by the properties of the products formed on interaction with hydroxylamine, phenylhydrazine, and *p*-bromophenylhydrazine, whereby an *anhydro-oxime*, *anhydrophenylhydrazone*, and *anhydro-p-bromophenylhydrazone* resulted. The presence of a pyrazole ring structure in the last derivative was proved by its reduction to a pyrazoline giving the well-known Knorr reaction. With semicarbazide an *anhydro-semicarbazone* was obtained, which, for reasons to be discussed later, we consider probably differs in constitution from the anhydro-phenylhydrazones.

In the course of his preliminary experiments Penfold (*loc. cit.*, p. 311) had observed that the ketone underwent extensive degradation when oxidised with potassium permanganate. We therefore examined the action of milder reagents. On digestion with ferric chloride in acetic acid-water solution an unsaturated crystalline substance,  $C_9H_{12}O_2$ , m. p. 159—160°, was obtained, which was

\* Angustione probably occurs also in the essential oil from *Boronia thujona*, var. "A" (compare Penfold, *J. Proc. Roy. Soc. New South Wales*, 1929, **62**, 231).

soluble in sodium bicarbonate solution and gave with ferric chloride an amethyst coloration. Oxidation of this substance with potassium permanganate gave dimethylmalonic acid, and on reduction with sodium amalgam addition of two hydrogen atoms occurred with the formation of a substance,  $C_9H_{14}O_2$ , m. p.  $130-131^\circ$ . This reduction product also gave an amethyst coloration with ferric chloride and was readily oxidised by potassium permanganate in alkaline solution, yielding  $\alpha\gamma$ -trimethylglutaric acid (III). The formation of this acid left no doubt that the substance, m. p.  $130-131^\circ$ , was the  $\beta$ -diketone, 1:1:3-trimethylcyclohexane-4:6-dione (I), and this view was confirmed by its oxidation with potassium hypobromite to the above-mentioned substituted glutaric acid. It followed from this that the substance, m. p.  $159-160^\circ$ , which can also be prepared by the oxidation of 1:1:3-trimethylcyclohexane-4:6-dione with ferric chloride, must be the corresponding unsaturated  $\beta$ -diketone, 1:1:3-trimethyl- $\Delta^2$ -cyclohexene-4:6-dione (II), which would on oxidation give dimethylmalonic acid (IV). Confirmation of this structure was obtained by the conversion of the unsaturated dione into 4:6-dichloro-1:2:3-trimethylbenzene (V) by the action of phosphorus trichloride, a reaction analogous to the preparation of this dichlorotrimethylbenzene by the action of phosphorus pentachloride on 1:1:2-trimethylcyclohexane-3:5-dione (VI) (Crossley, J., 1901, **79**, 144; Crossley and Hill, J., 1906, **89**, 881).

With the proof of the constitution of the product formed by the oxidation of angustione with ferric chloride and the indirect evidence that the saturated dione (I) was the primary product of the reaction,

the relative positions of 9 out of the 11 carbon atoms were fixed together with those of 2 of the oxygen atoms. Although there was no direct evidence of the nature of the third oxygen, it appeared probable that the diketone contained the group  $\text{Me-CO-}$ , since if this were the case, the two remaining carbon atoms would also be accounted for. Angustione is not hydrolysed when boiled for some hours with aqueous potassium hydroxide (20%), but, when heated with an alcoholic solution of potassium hydroxide at  $150^\circ$  under pressure, it is degraded, yielding a mixture of 1:1:3-trimethylcyclohexane-4:6-dione (I) and acetic acid. This reaction proceeds very smoothly and the yield is almost quantitative; there can therefore be no doubt that angustione must be the triketone represented by (VII). Unfortunately at this stage our material was exhausted and since later distillations have given only dehydroangustione, we have been unable to examine its reactions with potassium hypobromite and potassium permanganate. It is desirable here, before proceeding to consider the constitution of dehydroangustione, to refer to the constitution of some of the derivatives of angustione mentioned above.

The product which is obtained by the action of hydroxylamine on the ketone (p. 1193) is insoluble in alkali and gives no colour with ferric chloride; it dissolves, however, in strong mineral acids and is reprecipitated on dilution. It is probably therefore either *anhydroangustione-4-oxime* (VIII) or *anhydroangustione-6-oxime* (IX).

Similarly, two structures are possible for the products obtained by the action of phenylhydrazine and *p*-bromophenylhydrazine on angustione, namely, *anhydroangustione-4-phenylhydrazone* (X) or *anhydroangustione-6-phenylhydrazone* (XI). We have not attempted to determine the structure of these substances. As was mentioned above, the reaction with semicarbazide probably proceeds in a different manner. By the action of this reagent under suitable conditions (p. 1192) a substance is obtained which from its analysis is clearly an anhydro-derivative. It differs, however, very markedly in its properties from the anhydro-oxime and anhydro-phenyl-

hydrazones. Although quite colourless when powdered, the crystals show a blue fluorescence and a solution of the substance in chloroform, from which it readily separates as a gel, has a marked blue colour. It is readily soluble in alkali and gives with ferric chloride an intense indigo-blue coloration. We would suggest that this derivative is either *anhydroangustione-4-semicarbazone* (XII) or

*anhydroangustione-ω-semicarbazone* (XIII): the presence of the potential enolic group in position 6 would account for the solubility in alkali and for the coloration with ferric chloride.

For aminoangustione, two formulæ (XIV) and (XV) are possible and in this case also we have no evidence which is correct.

The reduction of angustione with sodium and alcohol (p. 1197) proceeds in a somewhat complex manner and we have only been able to identify two of the products: one is 1:1:3-trimethylcyclohexane-4:6-dione (I) resulting from the hydrolysis of the ketone, and the other, the main product of the reduction, is a bimolecular alcohol,  $\text{C}_{22}\text{H}_{42}\text{O}_6$ , probably (XVI).

With aluminium amalgam an amorphous pinacol,  $\text{C}_{22}\text{H}_{34}\text{O}_6$ , m. p.  $153^\circ$ , is obtained, which has not been further studied.

The ketone yielding the crystalline amino-derivative, m. p.  $151^\circ$ , was at first thought to be isomeric with angustione, but careful analyses of the ketone itself and of a large number of its derivatives have shown it to contain two hydrogens less, having the composition  $\text{C}_{11}\text{H}_{14}\text{O}_3$ . Angustione and dehydroangustione are undoubtedly very closely related. Dehydroangustione is a  $\beta$ -diketone yielding an *anhydro-oxime*, *anhydro-semicarbazone*, and *anhydro-p-bromophenylhydrazone*; further, it contains a reactive  $\text{CH}_2$ - group, since it forms

a *piperonylidene* derivative. Unlike angustione, dehydroangustione is very resistant to the action of alkali and at 150° only slight hydrolysis occurs with the formation of 1 : 1 : 3-trimethyl- $\Delta^2$ -cyclohexene-4 : 6-dione (II) : this substance is, however, obtained in excellent yield when the ketone is warmed on the water-bath with sulphuric acid (50%). Since the saturated dione (I) is not oxidised under these conditions, it is obviously not an intermediate product and it became probable, therefore, that the primary product in both reactions was a hydroxycyclohexanedione. A consideration of the various possibilities has led us to the conclusion that dehydroangustione is the  $\beta$ -oxide (XVII), in which case the degradation to 1 : 1 : 3-trimethyl- $\Delta^2$ -cyclohexene-4 : 6-dione would proceed with the intermediate formation of (XVIII) and (XIX).

When dehydroangustione is oxidised with potassium permanganate, it yields a mixture of  $\alpha\gamma$ -trimethylglutaric acid and dimethylmalonic acid, the latter being formed in greater quantity. With potassium hypobromite 1- $\alpha\gamma$ -trimethylglutaric acid is obtained together with a substance having the composition  $\text{C}_8\text{H}_{10}\text{O}_3$ . The constitution of this substance has not been determined, but it is derived apparently from 1 : 1 : 3-trimethyl- $\Delta^2$ -cyclohexene-4 : 6-dione, since preliminary experiments have shown that it can be prepared by the action of potassium hypobromite on this. The formation of  $\alpha\gamma$ -trimethylglutaric acid by the oxidation of dehydroangustione can be explained only if we assume that during the oxidation hydration occurs to some extent in the reverse direction, yielding the hydroxy-ketone (XX). We recognise that this reaction is unusual and when further material becomes available we propose to attempt to establish rigidly the constitution of dehydroangustione.

A substance having the alternative formula (XXI) would probably give a *piperonylidene* derivative and would undoubtedly yield  $\alpha\gamma$ -trimethylglutaric acid on oxidation, but its hydrolysis to the

unsaturated dione involves obvious difficulties. Furthermore it would be unlikely to yield a copper derivative.

As is the case with angustione, two formulæ are possible for all the derivatives of dehydroangustione which have been prepared. It is, however, unnecessary to consider these in detail, as we have been unable to distinguish between them. Attention may perhaps be directed to the properties of the anhydro-semicarbazone which resemble closely those of anhydroangustionesemicarbazone. It has, however, been prepared in two isomeric forms, m. p. 138—139° and 173—175° (see p. 1199). On reduction with sodium and alcohol dehydroangustione yields the same products as angustione.

Mention has been made already of the fact that angustione and dehydroangustione differ in their physical constants and this difference is shown also in their molecular refractions, that of angustione being 54.09 and of dehydroangustione 54.5. If we accept formula (VII) for angustione, the molecular refraction calculated from the Eisenlohr 1910 values (Eisenlohr, "Spectrochemie Organischen Verbindungen," p. 48) is 50.59 and the ketone therefore shows the large molecular exaltation of 3.5 units. It is difficult to find a substance of similar structure to determine how far such an exaltation is abnormal, since the *cyclohexanediones* are usually solids. A somewhat similar substance is 4-acetyl-1-methylcyclohexan-3-one, which was prepared by Léser (*Ann. Chim.*, 1902, **26**, 239). The molecular refraction of this ketone is 44.07 and the calculated value is 41.38, giving an exaltation of 2.79. Since this substance contains only two carbonyl groups, the exaltation is evidently of the same order. With dehydroangustione the molecular exaltation is even more marked, since the calculated value in this case is 49.53 if no allowance is made for the oxide ring. A high value is perhaps to be anticipated owing to the presence of the extracyclic ethylenic linkage. Any theoretical deductions from these values would be premature, but it appears justifiable to assume that a large molecular exaltation is to be expected in all *cyclohexanediones*.

In angustione and dehydroangustione we have, so far as we are aware, the first instance of the occurrence in nature of  $\beta$ -diketones. Since they contain eleven carbon atoms, they are obviously not simple derivatives of isoprene, but the formulæ which have been

assigned to them are built up from two isoprene nuclei, as will be seen by reference to the partial formula (XXII). Whether the

ketones are formed by condensation with a molecule of formaldehyde or by the degradation of a substance containing fifteen carbon atoms, we have no means of determining. It is, however, of interest to note that they contain the "ionone" ring the presence of which has recently been shown to occur in carotin (Karrer and Helfenstein, *Helv. Chim. Acta*, 1929, **12**, 1142).

Although the two ketones described in this communication are the first natural  $\beta$ -diketones to be investigated in detail, the presence of substances having similar reactions has been observed in other eucalyptus oils. Of these the most important and most readily available is leptospermol, which occurs in the oil derived from the leaves and terminal branches of *Leptospermum flavescens* (Penfold, *J. Proc. Roy. Soc. New South Wales*, 1921, **45**, 51). This ketone is at present being studied by one of us (A. R. P.) and Dr. W. F. Short and it has been found to be a  $\beta$ -diketone.

## EXPERIMENTAL.

### *Angustione.*

The ketone, which had been separated from the oil by the method described previously (*loc. cit.*, p. 308), was purified either through its amino- or copper derivative. It was regenerated from the former by gentle warming with dilute aqueous alkali (10%), the temperature not being allowed to rise above 50° and the liberated ammonia being removed under diminished pressure. The solution was acidified with dilute sulphuric acid, and the ketone isolated by extraction with ether. From the copper derivative the ketone was obtained by the decomposition of an ethereal solution with dilute sulphuric acid. When purified by either of these methods *angustione* had b. p. 129°/15 mm.,  $d_{20}^{20}$  1.089,  $n_D^{20}$  1.5137,  $[\alpha]_{5461} -5.56^\circ$ ,  $[R_L]_D$  54.09 [Found \*: (from amino-derivative) C, 67.2; H, 8.0; (from Cu derivative) C, 67.5; H, 8.1.  $C_{11}H_{16}O_3$  requires C, 67.3; H, 8.1%].

*Angustione* is a colourless viscid oil with a faint and somewhat unpleasant smell; when pure it can be kept in a loosely stoppered bottle for months without becoming discoloured. It does not yield a crystalline bromide or react with hydrogen bromide in acetic acid solution at 0°, but with hydrogen iodide it gives an unstable crystalline derivative. It was recovered unchanged after digestion with acetic anhydride, and a benzoyl derivative could not be prepared. Its alcoholic solution gives with ferric chloride an intense orange-red coloration.

*Aminoangustione* (XIV or XV).—When *angustione* in light

\* The majority of the analyses recorded in this paper are microanalyses and where two analyses are given they were made with different preparations.

petroleum solution was treated with dry ammonia, an amorphous white solid, probably an ammonium salt, separated. This was readily soluble in water and when the aqueous solution was warmed the sparingly soluble amino-derivative was precipitated. This can however, be prepared more conveniently by the method described previously (*loc. cit.*, p. 309). It is best purified by crystallisation from *cyclohexane*, in which it is somewhat sparingly soluble, and from which it separates in well-formed massive prisms, m. p. 130—131°. In absolute alcohol solution ( $c = 0.9163$ ,  $l = 4$ ),  $\alpha_{5461} = 0.31^\circ$  was observed, whence  $[\alpha]_{5461} = -8.6^\circ$  (Found : C, 68.0, 67.9; H, 8.6, 8.8; N, 7.2.  $C_{11}H_{17}O_2N$  requires C, 67.7; H, 8.7; N, 7.2%).

*Aminoangustione* is readily soluble in all the ordinary organic solvents with the exception of light petroleum, but it is very sparingly soluble in water, melting under this solvent when heated. It gives with ferric chloride the same coloration as the parent ketone. It is stable to mineral acids, but it is readily decomposed by hot alkalis with liberation of ammonia. It cannot apparently be acetylated by digestion with acetic anhydride. When it is treated in chloroform solution with bromine, a sparingly soluble oil separates, which crystallises rapidly in leaflets melting below  $0^\circ$ . This substance is probably a perbromide, since, on removal of the solvent under diminished pressure, a red gum remains from which aminoangustione can be recovered on trituration with ammonia.

The *copper* derivative of angustione was prepared most conveniently by the treatment of a light petroleum solution of the ketone with copper acetate, ammonia being added to neutralise the acetic acid liberated. The derivative, which was very readily soluble in ether and alcohol, crystallised from either benzene or dilute alcohol in blue prisms, m. p. 192—193° (Found : C, 58.5, 58.2; H, 6.5, 6.9; Cu, 14.0.  $C_{22}H_{30}O_6Cu$  requires C, 58.2; H, 6.6; Cu, 14.0%). It does not react with methyl iodide in benzene solution.

*Anhydroangustione-4(or  $\omega$ )-semicarbazone* (XII or XIII).—When a mixture of angustione (4 g.), semicarbazide hydrochloride (3.75 g.), dissolved in the minimum quantity of water, and sodium bicarbonate (2.8 g.) was kept for 3 days with occasional shaking, a viscid oil formed. The solution was cleared by the addition of alcohol and after 2 days the crystalline solid which had separated was collected; a further quantity was obtained by addition of water to the filtrate (yield, 3.2 g.). After trituration with ether, which removed a small quantity of a yellow impurity, the *semicarbazone* was recrystallised by solution in hot chloroform and addition of an equal volume of hot benzene. If allowed to cool slowly, the semicarbazone crystallised in soft serrated needles, m. p. 145° (decomp.), but if the solution was rapidly cooled, a gel was obtained: the same pheno-

menon was observed when a hot concentrated chloroform solution was rapidly cooled. The solution showed a marked blue fluorescence (Found: C, 61.6; H, 7.4.  $C_{12}H_{17}O_2N_3$  requires C, 61.3; H, 7.2%). The semicarbazone is readily soluble in water, giving a colourless solution, which on boiling clouds with the separation of an oil; it is soluble in alkali and its alcoholic solution gives with ferric chloride an intense indigo-blue coloration. In aqueous solution it reduces an ammoniacal solution of silver oxide with the formation of a silver mirror.

*Anhydroangustione-4(or 6)-phenylhydrazone* (X or XI).—This derivative was obtained in a somewhat poor yield when an alcoholic solution of the ketone was kept for some days with an excess of phenylhydrazine acetate. It crystallised from alcohol, in which it was readily soluble, in small plates, m. p. 119–120° (Found: C, 76.0; H, 7.4.  $C_{17}H_{20}ON_2$  requires C, 76.1; H, 7.5%).

*Anhydroangustione-4(or 6)-p-bromophenylhydrazone* (X or XI) crystallised from alcohol, in which it was somewhat sparingly soluble, in faintly brown prisms, m. p. 191° (Found: C, 58.5; H, 5.3; Br, 23.1.  $C_{17}H_{19}ON_2Br$  requires C, 58.8; H, 5.5; Br, 23.0%). The *p*-bromophenylhydrazone was insoluble in alkali and gave no colour with ferric chloride in alcoholic solution. When it was reduced with sodium and alcohol, a substance was obtained which gave Knorr's pyrazoline reaction.

*Anhydroangustione-4(or 6)-oxime* (VIII or IX).—A mixture of angustione (9 g.), hydroxylamine hydrochloride (3.5 g.), and sodium acetate (4.1 g.) in alcohol (35 c.c.) was heated on the water-bath for 2 hours. After about 15 minutes a blue colour developed which disappeared on further heating. The reaction mixture was distilled in steam, the volatile oil extracted with ether, the ether dried and evaporated, and the residual oil distilled under diminished pressure (22 mm.): the whole boiled at 150–152°. The colourless viscid oil, which had a strong basic smell, partly crystallised on keeping. The solid was collected, drained on porous porcelain, and recrystallised from dilute methyl alcohol; it was then obtained in needles melting not quite sharply at 41–43° (Found: C, 68.0; H, 7.6.  $C_{11}H_{15}O_2N$  requires C, 68.4; H, 7.8%). The *anhydro-oxime* was insoluble in alkali but readily soluble in concentrated hydrochloric acid, being reprecipitated on dilution. It did not give a crystalline picrate or chloroplatinate.

*Piperonylideneangustione*.—To a mixture of equimolecular proportions of angustione and piperonal dissolved in alcohol, piperidine (one drop) was added, and the solution heated to boiling. After some days a yellow crystalline solid had been deposited; it crystallised from alcohol, in which it was very sparingly soluble, in bright

sulphur-yellow, soft needles, m. p. 166—167° (Found: C, 69.6; H, 5.9.  $C_{13}H_{20}O_5$  requires C, 69.5; H, 6.0%).

*Oxidation of Angustione.*—(A) *With ferric chloride.* 1:1:3-*Trimethyl- $\Delta^2$ -cyclohexene-4:6-dione* (II). A mixture of the ketone (15 g.), ferric chloride (40 g.), acetic acid (60 c.c.), and water (130 c.c.) was boiled for 8 hours and, after remaining over-night, distilled in steam until the aqueous distillate no longer deposited a solid on saturation with ammonium sulphate. A red resinous solid remained in the distillation flask. The distillate, after saturation with ammonium sulphate, was extracted with ether, the extract dried over sodium sulphate, and the solvent evaporated; the residual red oil was warmed under diminished pressure until free from acetic acid and the crystalline solid which separated was mixed with light petroleum (b. p. 40—60°) and collected. The filtrate on distillation under diminished pressure (11 mm.) boiled at 125—135° and gave an oil from which, on cooling, a further quantity of solid could be obtained, but which consisted mainly of unchanged angustione.

1:1:3-*Trimethyl- $\Delta^2$ -cyclohexene-4:6-dione* crystallised from dilute alcohol in long needles or from light petroleum-benzene in soft needles, m. p. 159—160° (Found: C, 71.0; H, 7.8.  $C_9H_{12}O_2$  requires C, 71.1; H, 7.9%). It was readily soluble in the ordinary organic solvents with the exception of ether, in which it was somewhat sparingly soluble, and of light petroleum, in which it was very sparingly soluble. It was somewhat soluble in hot water and the solution gave with ferric chloride an amethyst coloration. It was not readily attacked by concentrated sulphuric acid and could be heated with this reagent to 110° without marked discoloration. In chloroform solution the dione rapidly absorbed bromine with the liberation of hydrogen bromide and on evaporation of the solvent 5-bromo-1:1:3-trimethyl- $\Delta^2$ -cyclohexene-4:6-dione remained, which crystallised from dilute alcohol in iridescent prisms, m. p. 126—127° (Found: C, 46.9; H, 4.8; Br, 34.3.  $C_9H_{11}O_2Br$  requires C, 46.7; H, 4.7; Br, 34.6%).

When the dione was warmed with phosphorus trichloride, evolution of hydrogen chloride occurred, and a pasty solid separated on cooling. This was dissolved in benzene, and the solution decanted from phosphorous acid, washed with alkali, and evaporated. The residual solid crystallised from dilute acetone in glistening leaflets, m. p. 77—78° (Crossley and Hills, *loc. cit.*, give 76.5°), and was evidently 4:6-dichloro-1:2:3-trimethylbenzene (V) (Found: C, 57.3; H, 5.4. Calc.: C, 57.1; H, 5.3%).

When an alcoholic solution of equimolecular proportions of the dione and piperonal was treated with a drop of piperidine and

warmed for a few minutes, a crystalline solid was obtained. This separated from alcohol in prisms, decomp.  $208-210^{\circ}$ . Although the substance itself was quite colourless, it dissolved in hot alcohol to yield a bright yellow solution, the colour disappearing on cooling. The constitution of this substance was not determined, but it consists apparently of two molecules of the dione combined with one of piperonal and analysis indicates that it is a reduction product (compare p. 1196) (Found: C, 70.9; H, 7.5.  $C_{26}H_{32}O_6$  requires C, 70.9; H, 7.3%).

(B) *With potassium ferricyanide.* A mixture of the ketone (13 g.), potassium ferricyanide (176 g.), water (400 c.c.), and potassium hydroxide solution (10%; 600 c.c.) was gently boiled for 3 hours. The cooled solution was acidified, saturated with ammonium sulphate, and extracted with ether. After removal of the solvent the residual oil was distilled in steam; a crystalline solid passed over, leaving a red resinous residue (3.7 g.). The distillate, after saturation with ammonium sulphate, was extracted with ether, and the extract dried and evaporated. The residue, which crystallised, was drained on porous porcelain to remove some adhering oil and recrystallised from dilute alcohol; it was then obtained in soft needles which were apparently homogeneous and melted sharply at  $141^{\circ}$ . Specimens from two distinct preparations were analysed and showed the substance to be a mixture of 1:1:3-trimethylcyclohexane-4:6-dione and 1:1:3-trimethyl- $\Delta^2$ -cyclohexene-4:6-dione (Found: C, 70.4, 70.5; H, 8.4, 8.7%). This was confirmed by bromination of the mixture, the bromide, m. p.  $126-127^{\circ}$  (p. 1194), being readily obtained, and by reduction with sodium amalgam, whereby it was converted quantitatively into the saturated dione, m. p.  $130-131^{\circ}$  (compare p. 1196). The 1:1:3-trimethylcyclohexane-4:6-dione present in the mixture was optically active; in alcoholic solution,  $c = 5.453$ ,  $l = 2$ ,  $\alpha_{5461} + 0.12^{\circ}$ ,  $[\alpha]_{5461} + 1.04^{\circ}$ .

*Oxidation of 1:1:3-Trimethyl- $\Delta^2$ -cyclohexene-4:6-dione.*—The dione (2 g.), dissolved in sodium carbonate solution, was oxidised with potassium permanganate (2.5%) at  $0^{\circ}$ , a current of carbon dioxide being passed through the solution. On completion of the oxidation (250 c.c.  $KMnO_4$ ) the manganese dioxide sludge was separated, and the liquid evaporated to a small bulk in a current of carbon dioxide. The acidified solution was repeatedly extracted with ether, the solvent dried and evaporated, and the residue, which immediately solidified, crystallised from hot water; it separated in glistening tablets, decomp.  $185-186^{\circ}$ . This decomposition point was not depressed on admixture with an authentic specimen of dimethylmalonic acid (Found: C, 45.7; H, 5.8. Calc.: C, 45.4; H, 6.1%).

*Reduction of 1:1:3-Trimethyl- $\Delta^2$ -cyclohexene-4:6-dione.* 1:1:3-Trimethylcyclohexane-4:6-dione (I).—The unsaturated dione (0.5 g.), dissolved in sodium carbonate solution, was reduced with sodium amalgam (2.5%; 80 g.), a current of carbon dioxide being passed through the solution during the reaction. After completion the aqueous solution was concentrated and acidified with dilute sulphuric acid and the solid (0.35 g.) which separated was collected and recrystallised from light petroleum (b. p. 60–80°); it was then obtained in glistening prisms, m. p. 130–131° (Found: C, 70.2; H, 8.9.  $C_9H_{14}O_2$  requires C, 70.1; H, 9.1%). 1:1:3-Trimethylcyclohexane-4:6-dione is readily soluble in all the ordinary organic solvents with the exception of light petroleum; it is somewhat sparingly soluble in water and its solution gives with ferric chloride an amethyst coloration. In chloroform solution it readily absorbs bromine with evolution of hydrogen bromide and on removal of the solvent a gum remains which cannot be induced to crystallise.

With piperonal the saturated dione reacts in an exactly analogous manner to the unsaturated dione (p. 1195) to yield a substance crystallising from alcohol in soft glistening prisms, m. p. 192–193°. Its solution in hot alcohol is bright yellow, although the substance itself is colourless. Analysis appears to show that it is formed by the interaction of two molecules of the dione with one of piperonal with loss of water and addition of four atoms of hydrogen (Found: C, 70.6; H, 8.3.  $C_{26}H_{36}O_6$  requires C, 70.3; H, 8.1%).

*Oxidation of 1:1:3-Trimethylcyclohexane-4:6-dione.*—(A) *With ferric chloride.* A mixture of the dione (1 g.), ferric chloride (4 g.), water (15 c.c.), and acetic acid (3 c.c.) was boiled for 4 hours and then distilled in steam; an oil passed over, which crystallised, and a red resin remained in the distillation flask. After saturation of the distillate with ammonium sulphate the solid which separated was collected and recrystallised from dilute alcohol, forming needles, m. p. 158–159°. It was identified as 1:1:3-trimethyl- $\Delta^2$ -cyclohexene-4:6-dione by the method of mixed melting point and by the preparation of the bromide, m. p. 126–127°.

(B) *With potassium permanganate.* The dione (4 g.), dissolved in sodium carbonate solution, was treated at 0° with potassium permanganate (2.5%), a current of carbon dioxide being passed through the solution during the oxidation. On completion of the reaction (370 c.c.  $KMnO_4$ ) the manganese dioxide sludge was removed, and the filtrate evaporated to a small bulk, acidified, and extracted with ether. On removal of the solvent an oil was obtained which partly crystallised. The solid was separated by solution in hot light petroleum (b. p. 40–60°), in which the oil was insoluble, and it was finally crystallised from water, from which it was obtained in

leaflets, m. p. 97° (Found : C, 55.0; H, 8.1. Calc. : C, 55.1; H, 8.0%). This acid was identical (mixed m. p.) with the acid prepared by oxidation of the dione with potassium hypobromite (see below) and consisted of  $\alpha\gamma$ -trimethylglutaric acid.

(C) *With potassium hypobromite.* A solution of the dione (2 g.) in potassium hydroxide solution (10 c.c.; KOH, 1 g.) was added all at once to a potassium hypobromite solution ( $\text{Br}_2$ , 6.5 g.; KOH, 6 g.;  $\text{H}_2\text{O}$ , 30 c.c.); bromoform separated immediately and the temperature rose to about 30°. After 1 hour, the bromoform was drawn off, the excess of hypobromite removed with sulphur dioxide, and the solution concentrated, acidified, and extracted with ether. On removal of the solvent a crystalline solid (2.2 g.) remained, m. p. 95–97°. It crystallised from water in leaflets, m. p. 97° (not depressed by admixture with acid from B). The identity of this acid with  $\alpha\gamma$ -trimethylglutaric acid was confirmed by the preparation of the anhydride, needles, m. p. 95°, and the anilide, needles, m. p. 165° (Auwers and Meyer, *Ber.*, 1890, **23**, 305; Auwers, *Annalen*, 1896, **292**, 224, give 95–96° and 165° respectively). The anilide was analysed (Found : N, 5.6. Calc. : N, 5.6%).

*Action of Potassium Hydroxide on Angustione.*—A mixture of the ketone (11.7 g.), potassium hydroxide (7 g.), water (6 c.c.), and alcohol (14 c.c.) was heated at 150° in a sealed tube for 3 hours. The liquid, which contained a crystalline potassium salt in suspension, was diluted with water, the alcohol removed on the water-bath, and the cold solution acidified; a crystalline solid mixed with some oil then separated. The solid (4.1 g.) was collected and washed with light petroleum (b. p. 40–60°) to remove the oil; when recrystallised from petroleum (b. p. 60–80°), it separated in glistening prismatic needles, m. p. 131–132° (Found : C, 70.4; H, 8.8.  $\text{C}_9\text{H}_{14}\text{O}_2$  requires C, 70.1; H, 9.1%). This substance was identified as 1 : 1 : 3-trimethylcyclohexane-4 : 6-dione by the preparation of the piperonal derivative, m. p. 192–193°.

The filtrate from which the dione had been separated was extracted with ether and, after being made alkaline with sodium carbonate solution, evaporated to dryness on the water-bath. The residual salts were extracted with absolute alcohol, and the alcohol evaporated after filtration. The crystalline residue consisted essentially of sodium acetate, since on admixture with alcohol and sulphuric acid ethyl acetate was formed, whilst on the addition of silver nitrate to an aqueous solution silver acetate was precipitated. After recrystallisation from hot water the silver salt was analysed (Found : Ag, 64.9. Calc. : Ag, 64.7%).

*Reduction of Angustione with Sodium and Alcohol.*—To a solution of the ketone (20 g.) in gently boiling alcohol (300 c.c.), sodium

(30 g.) was gradually added. After all the sodium had dissolved, steam was passed through the solution; after removal of the alcohol, a very pungent-smelling oil (A) distilled. The residue in the flask consisted of a viscid oil (B), which partly solidified.

The oil (A) was dissolved in ether, dried, recovered (6 g.), and distilled under diminished pressure (12 mm.). The first fraction, a mobile pungent oil, distilled mainly at about 90°, and the remainder, which was very viscid, at 140–150°. All attempts to prepare crystalline derivatives of these substances have been unsuccessful and they have not been identified.

The residue (B) was shaken with a little ether, and the solid (4.1 g.) collected and recrystallised from ethyl acetate, in which it was somewhat sparingly soluble. The *alcohol* crystallised in soft needles, m. p. 196–197°, which were levorotatory in alcohol,  $c = 0.4467$ ,  $l = 2$ ,  $\alpha_{5461} - 0.09^\circ$ ,  $[\alpha]_{5461} - 10.23^\circ$  [Found: C, 65.3; H, 10.7;  $M$  (Rast), 406.  $C_{22}H_{42}O_6$  requires C, 65.6; H, 10.4%;  $M$ , 404].

The alkaline solution from which the alcohol had been separated was acidified; the oil deposited partly crystallised. After draining on porous porcelain, the solid was recrystallised from light petroleum (b. p. 60–80°), separating in prismatic needles, m. p. 130–131°, and was identified as 1:1:3-trimethylcyclohexane-4:6-dione (Found: C, 70.3; H, 9.1. Calc.: C, 70.1; H, 8.7%).

### *Dehydroangustione* (XVII).

*Dehydroangustione*, after purification through its copper derivative, had b. p. 126–127°/11 mm.,  $d_{20}^{20.5^\circ} 1.103$ ,  $n_D^{20.5^\circ} 1.5255$ ,  $[\alpha]_{5461} - 2.03^\circ$ ,  $[R_L]_D 54.5$  (Found: C, 67.9; H, 7.5.  $C_{11}H_{14}O_3$  requires C, 68.0; H, 7.2%). It gives in alcoholic solution with ferric chloride the same orange-red coloration as angustione. The following derivatives were prepared by methods identical with those used for the preparation of the analogous derivatives of angustione.

*Aminodehydroangustione* crystallised from cyclohexane in glistening prismatic needles or from much hot water in leaflets, m. p. 151°. It was levorotatory in alcoholic solution,  $c = 3.98$ ,  $l = 2$ ,  $\alpha_{5461} - 0.41^\circ$ ,  $[\alpha]_{5461} - 1.76^\circ$  (Found: C, 68.3, 68.2; H, 8.0, 7.8.  $C_{11}H_{15}O_2N$  requires C, 68.4; H, 7.8%).

*Aminodehydroangustione* cannot be acetylated, being recovered unchanged after prolonged digestion with acetic anhydride. When kept for some days in alcoholic solution with semicarbazide acetate, it is converted into anhydrodehydroangustionesemicarbazone.

The *copper* derivative crystallised from benzene, in which it was somewhat more soluble than the corresponding derivative of angustione, in blue needles, m. p. 188–190° (Found: 58.8, 58.5; H, 6.0, 6.0.  $C_{22}H_{26}O_6Cu$  requires C, 58.7; H, 5.8%).

*Anhydrodehydroangustione-4(or 6)-semicarbazone* was obtained in two forms. The  $\alpha$ -semicarbazone crystallised from chloroform-benzene in prismatic needles, decomp.  $138-139^{\circ}$  (Found: N, 17.7.  $C_{12}H_{15}O_2N_3$  requires N, 18.0%). When a hot concentrated solution of the  $\alpha$ -semicarbazone was rapidly cooled, a gel was obtained which crystallised on gentle warming. The solid, m. p.  $164^{\circ}$ , obtained was now very sparingly soluble in chloroform and quite colourless, no longer showing the blue fluorescence of the  $\alpha$ -semicarbazone. The  $\beta$ -semicarbazone crystallised from dilute alcohol in small prisms, decomp.  $173-175^{\circ}$  (Found: C, 57.8; H, 6.9.  $C_{12}H_{15}O_2N_3 \cdot H_2O$  \* requires C, 57.4; H, 6.8%). Both semicarbazones gave the same deep blue colour with ferric chloride.

*Anhydrodehydroangustione-4(or 6)-p-bromophenylhydrazone* crystallised from alcohol in almost colourless prisms, m. p.  $247-248^{\circ}$  (Found: C, 59.1; H, 5.0.  $C_{17}H_{17}ON_2Br$  requires C, 59.1; H, 4.9%).

*Anhydrodehydroangustione-4(or 6)-oxime*. A mixture of the ketone (2.1 g.), hydroxylamine hydrochloride (2.5 g.), and sodium hydroxide (1.5 g. in water, 5 c.c.) with sufficient alcohol to give a clear solution was kept for 3 hours and then diluted with water. The *anhydro-oxime* thus precipitated crystallised from dilute alcohol in glistening needles, m. p.  $79-80^{\circ}$ . It was dextrorotatory in alcoholic solution:  $c = 3.09$ ,  $l = 2$ ,  $\alpha_{5461} + 0.15^{\circ}$ ,  $[\alpha]_{5461} + 4.95^{\circ}$  (Found: C, 69.1; H, 7.0.  $C_{11}H_{13}O_2N$  requires C, 69.1; H, 6.8%).

*Piperonylidenedehydroangustione* separated from alcohol in yellow needles, m. p.  $169-170^{\circ}$  (Found: C, 70.0; H, 5.8.  $C_{19}H_{18}O_5$  requires C, 69.6; H, 5.5%).

*Oxidation of Dehydroangustione*.—(A) *With potassium permanganate*. A mixture of the ketone (5 c.c.) and acetone (200 c.c.) was cooled to  $0^{\circ}$ , and finely powdered potassium permanganate gradually added. After the addition of 6 g. the oxidation became very slow; water (20 c.c.) was added and a further quantity of permanganate (10 g.). After the whole had remained over-night in the ice-box, the manganese dioxide sludge was separated and thoroughly washed with boiling water and the aqueous extract was evaporated to a small bulk in a current of carbon dioxide. The acetone on evaporation left a brown liquid, which was added to the main extract. The aqueous solution was acidified and extracted with ether (10 times), the extract dried, and the solvent evaporated. The residual oil, which had a strong odour of acetic acid, slowly crystallised when kept in a vacuum over potassium hydroxide. The solid was mixed with acetyl chloride and warmed on the water-bath for 2

\* Sufficient material was not available to determine whether this addition of water was constitutional.

hours, and the excess of acetyl chloride removed. When the residual solid was triturated with ice-cold sodium bicarbonate solution, a portion dissolved. The residue,  $\alpha\gamma$ -trimethylglutaric anhydride, m. p.  $95^\circ$ , was dissolved in boiling water; on cooling,  $\alpha\gamma$ -trimethylglutaric acid crystallised in leaflets, m. p.  $97^\circ$  (Found: C, 55.3; H, 8.0. Calc.: C, 55.1; H, 8.0%).

The sodium bicarbonate solution was acidified and extracted with ether; the solid which remained after removal of the solvent crystallised from water in tablets, decomp.  $185$ – $186^\circ$ , and was identified as dimethylmalonic acid by the method of mixed melting point.

(B) *With potassium hypobromite.* Dehydroangustione (9.8 g.) in potassium hydroxide solution (40 c.c.; KOH, 3.7 g.) was added to a solution of potassium hypobromite (KOH, 17 g.;  $\text{Br}_2$ , 24 g.;  $\text{H}_2\text{O}$ , 100 c.c.); bromoform was immediately deposited with considerable rise in temperature. After 1 hour, the excess of the hypobromite was removed with sulphur dioxide and the bromoform (4–5 g.) separated. The solution was acidified, saturated with ammonium sulphate, and extracted with ether (10 times) and the ether was dried and evaporated. The residual oil was distilled in steam and the distillate, which contained a heavy oil, was saturated with ammonium sulphate and extracted with ether. The oil (5 g.) left on removal of the solvent was distilled under diminished pressure (11 mm.); it boiled at  $125$ – $130^\circ$  and partly crystallised on keeping. The solid was collected, washed with light petroleum, and recrystallised from this solvent, separating in long prismatic needles, m. p.  $88.5^\circ$  (Found: C, 62.3; H, 6.6.  $\text{C}_8\text{H}_{10}\text{O}_3$  requires C, 62.3; H, 6.5%). This substance, which, as has already been mentioned, has not been identified, gives no colour with ferric chloride in aqueous solution.

The filtrate from which the substance, m. p.  $88.5^\circ$ , had been removed did not crystallise on keeping and was found to consist essentially of unchanged dehydroangustione.

The aqueous residue from the steam distillation was made alkaline, concentrated, acidified, and extracted with ether. On evaporation of the solvent an oil was obtained which partly crystallised. On trituration with hot light petroleum the greater part dissolved, leaving a red resinous residue; evaporation of the light petroleum left colourless crystals which separated from hot water in glistening leaflets, m. p.  $91$ – $92^\circ$ . There can be no doubt that this acid was 1- $\alpha\gamma$ -trimethylglutaric acid; in water,  $c = 1.123$ ,  $l = 2$ ,  $\alpha_{5461} = 0.19^\circ$ ,  $[\alpha]_{5461} = 16.9^\circ$  (Found: C, 55.2; H, 8.0.  $\text{C}_8\text{H}_{14}\text{O}_4$  requires C, 55.1; H, 8.0%).

*Action of Potassium Hydroxide on Dehydroangustione.*—Dehydro-

angustione was heated with an alcoholic solution of potassium hydroxide under the same conditions as those used for the hydrolysis of angustione. On completion of the reaction the tube contained a sparingly soluble potassium salt which crystallised in prisms. The reaction product, which was an oil, was dissolved in light petroleum (b. p. 40–60°) and kept for some days in the ice-box; the crystalline solid (yield, 0.3 g. from 10 g.) that had separated was recrystallised from light petroleum–benzene; it separated in felted needles, m. p. 159–160°, and was identified as 1 : 1 : 3-trimethyl- $\Delta^2$ -cyclohexene-4 : 6-dione by the method of mixed melting point and by analysis (Found : C, 71.2; H, 8.0. Calc. : C, 71.1; H, 7.9%).

*Action of Sulphuric Acid on Dehydroangustione.*—A mixture of the ketone (5 c.c.), sulphuric acid (10 c.c.), and water (10 c.c.) was heated on the water-bath for 8 hours. The oil slowly dissolved and a deep red colour developed, some sulphur dioxide being liberated. The cooled solution was diluted with water and the solid which separated (3.4 g.) was recrystallised from dilute alcohol; it was obtained in needles, m. p. 159–160°, and was identified as 1 : 1 : 3-trimethyl- $\Delta^2$ -cyclohexene-4 : 6-dione. The hydrolysis can also be effected with dilute sulphuric acid (10%), but owing to the sparing solubility of the ketone the time required is very much longer.

*Reduction of Dehydroangustione.*—Dehydroangustione was reduced with sodium and alcohol in the same manner as angustione (p. 1197). The products obtained were identical, but in this case a considerable quantity of a viscid red oil was also formed. The yields of the various products from 20 g. of ketone were : dione, 2 g.; bimolecular alcohol, 3 g.; oil volatile in steam, 5 g.

We have to express our thanks to Prof. Robinson for many valuable suggestions. We are indebted to the Government Grant Committee of the Royal Society for a grant which has defrayed part of the cost of this investigation.

### CL.—*The Effect of Gas Pressure on the Colour of Halogen Vapours.*

By ALEXANDER SHEARER and ROBERT WRIGHT.

It was recently shown (J., 1929, 1364) that the deeper colour of iodine vapour in the presence of a gas as compared with that in a vacuum was independent of the nature of the gas used, and took

place even when the iodine vapour was unsaturated. It was suggested that this "Dewar" effect might be attributed simply to the pressure of the inactive gas.

A further series of absorption spectra photographs has now been made, in which the iodine vapour was submitted to different air pressures ranging from zero to about 2 atm. The iodine was contained in a Lilburn flask, as previously described, but in the present case the flask was connected to a manometer and a compression pump. Throughout the whole series a deepening of colour was produced step by step with increase of pressure (see Fig. 1).

Bromine vapour was examined under its own vapour pressure and when mixed with air at atmospheric pressure. The presence of the air produced a very slight increase in absorption (see Fig. 2). The ultraviolet absorption spectrum of chlorine was also examined, in a tube of about 20 cm. length with quartz ends. The pressure of the chlorine was reduced to about 0.5 atm., and its absorption spectrum photographed; air was then admitted and a second photograph taken. The pressure of the air produced no change in the absorptive power of the chlorine (see Fig. 3).

### CLI.—*The Bromination of 2-Nitro- and 2-Acetamidodiphenyl Ether.*

By HAMILTON MCCOMBIE, WILLIAM GEORGE MACMILLAN, and  
HAROLD ARCHIBALD SCARBOROUGH.

THE bromination of 2-nitrodiphenyl ether proceeded in three stages: 4-bromo-2'-nitrodiphenyl ether was formed in acetic acid solution, 2:4-dibromo-2'-nitrodiphenyl ether by the action of dry bromine in diffused light, and 2:4:4'-tribromo-2'-nitrodiphenyl ether (I) by the action of dry bromine in bright sunlight. Similarly, 2-bromo-2'-nitro-, 4-bromo-2-nitro-, and 5-bromo-2-nitro-diphenyl ethers when brominated in acetic acid solution yielded dibromo-derivatives in which the entering bromine atom occupies the 4-position in the non-nitrated nucleus. The action of dry bromine on 2:4-dibromo- and 4:4'-dibromo-2'-nitrodiphenyl ethers was to yield 2:4:4'-tribromo-2'-nitrodiphenyl ether; and 4:5'-dibromo-2'-nitrodiphenyl ether yielded 2:4:4':5'-tetrabromo-2'-nitrodiphenyl ether.

The bromination of 2-acetamidodiphenyl ether in acetic acid solution gave 5-bromo-2-acetamidodiphenyl ether as the sole product; a second bromine atom could, however, be introduced under the same conditions to give 4:5'-dibromo-2'-acetamidodiphenyl ether.

FIG. 1.

FIG. 2.

*Bromine in a vacuum and in air at 15°.*  
*Reference spectrum and three sets of exposures.*

FIG. 3.

*Chlorine in a vacuum and in air.*  
*Reference spectrum and three sets of exposures.*

The direct introduction of a third bromine atom into the molecule was not attempted. Further it was found that 2-, 4-, and 4'-bromo-2'-acetamidodiphenyl ethers were also brominated in the 5'-position; 4:4'-dibromo- and 2:4:4'-tribromo-2'-acetamidodiphenyl ethers behaved in the same manner. Under similar conditions it was found that 2:5'-dibromo-2'-acetamidodiphenyl ether was converted into 2:4:5'-tribromo-2'-acetamidodiphenyl ether (II).

The structures of the monobromo-2-nitro- and 2:4-dibromo- and 4:4'-dibromo-2'-nitrodiphenyl ethers were established by the condensation of appropriately substituted *o*-halogenonitrobenzenes with sodium or potassium halogenophenoxide. The reduction of the nitro-compound to the base and subsequent acetylation also determines the structure of the corresponding bromoacetamidodiphenyl ethers. Since both 2:4- and 4:4'-dibromo-2'-nitrodiphenyl ethers yield the same tribromo-compound, it must have the constitution 2:4:4'-tribromo-2'-nitrodiphenyl ether, and the structure of the acetamido-derivative also follows. The further bromination of 5-bromo-2-nitrodiphenyl ether, reduction and acetylation yielded a product identical with that obtained by the further bromination of 4-bromo-2'-acetamidodiphenyl ether and thus established the structure of 4:5'-dibromo-2'-nitrodiphenyl ether and of the corresponding acetamido-derivative. The orientation of the bromine atoms in 2:4:4':5'-tetrabromo-2'-nitrodiphenyl ether and of the acetyl derivative of the derived base was fixed by brominating 2:4:4'-tribromo-2'-acetamidodiphenyl ether and proving that the product was identical with that obtained by introducing three bromine atoms into the molecule of 5-bromo-2-nitrodiphenyl ether and reducing and acetylating the product.

The results show that the bromination of 2-nitro- or of a monobromo-2-nitrodiphenyl ether proceeds in stages until the 2:4-positions in the non-nitrated and the 4-position in the nitrated nucleus are substituted; a definite sequence is followed and substitution in the nitrated nucleus does not take place until the other two positions are substituted. The introduction of the third bromine atom into the 4-position in the nitrated nucleus as the sole product to be isolated was unexpected and thus in the case of both 2- and 4-nitrodiphenyl ethers there seems to be a marked steric factor which limits substitution in the positions adjacent to the oxygen linkage. A marked difference is shown between the behaviour of 2- and 4-acetamidodiphenyl ethers on bromination;

whereas 2-acetamidodiphenyl ether yielded as the sole product a compound substituted in the same nucleus as the acetamido-group, 4-acetamidodiphenyl ether yielded a single product substituted in the opposite nucleus. Further, a dibromo-derivative of 4-acetamidodiphenyl ether was obtained only with great difficulty, yet 2-acetamidodiphenyl ether yielded a dibromo-derivative with the greatest ease. The loading of the 2-acetamidodiphenyl ether molecule with bromine atoms did not appear in any way to hinder substitution in the 5-position in the same nucleus as the acetamido-group. Two factors would seem to influence the positions taken by the bromine atoms; first, the strong directive effect of the acetamido-group, which exceeds that of any other group in the molecules considered, and secondly a strong steric factor, which would almost seem to inhibit substitution in the positions ortho to the acetamido-group.

Certain substituted derivatives of 2-aminodiphenyl ether have been converted into the corresponding diphenylene oxides. It is proposed to extend the work along these lines.

#### EXPERIMENTAL.

2-Nitrodiphenyl ether was prepared by heating, at  $160^{\circ}$  for 12 hours, a mixture of 2 parts of *o*-chloronitrobenzene and 1 part of sodium phenoxide in the presence of copper powder. The product was distilled in steam to remove excess *o*-chloronitrobenzene and the residue was taken up in ether, washed with dilute soda solution and water, dried, and distilled under diminished pressure.

2-Bromo-2'-nitrodiphenyl ether was obtained when *o*-chloronitrobenzene was condensed with potassium *o*-bromophenoxide. It distilled at  $250^{\circ}/20$  mm., and separated from methyl alcohol in faintly yellow prisms, m. p.  $54^{\circ}$  (Found: Br, 27.35.  $C_{12}H_8O_3NBr$  requires Br, 27.2%).

4-Bromo-2-nitrodiphenyl ether was prepared by the condensation of 2:5-dibromonitrobenzene with potassium phenoxide. Excess 2:5-dibromonitrobenzene was removed by prolonged distillation with steam. The product was a light yellow oil, b. p.  $210^{\circ}/15$  mm. (Found: Br, 27.4.  $C_{12}H_8O_3NBr$  requires Br, 27.2%).

4-Bromo-2'-nitrodiphenyl ether was obtained when 2-nitrodiphenyl ether was treated, in carbon tetrachloride or acetic acid solution, with a slight excess of bromine as a 10% solution. The reaction was completed by warming the mixture on a water-bath for 30 minutes and then pouring it into a dilute solution of sodium sulphite. It separated from methyl alcohol in faintly yellow needles, m. p.  $72^{\circ}$  (Found: Br, 27.05.  $C_{12}H_8O_3NBr$  requires Br, 27.2%). The same

product was obtained when *o*-chloronitrobenzene was condensed with potassium *p*-bromophenoxide.

*5-Bromo-2-nitrodiphenyl Ether*.—2 : 4-Dibromonitrobenzene (1.1 mols.) was condensed with sodium phenoxide (1 mol.), in the presence of phenol and copper powder, at 150° for 18 hours. The compound, extracted in the usual manner, crystallised from methyl alcohol in yellow plates, m. p. 108° (Found : Br, 26.95.  $C_{12}H_9O_3NBr$  requires Br, 27.2%).

*2 : 4-Dibromo-2'-nitrodiphenyl ether* was obtained when 2-nitro- or 4-bromo-2'-nitrodiphenyl ether was treated with an excess of dry bromine, and the solution kept until it solidified. The product was warmed with a dilute solution of sodium sulphite and crystallised from methyl alcohol. 2 : 4-Dibromo-2'-nitrodiphenyl ether separated from light petroleum (b. p. 40—60°) in small yellow needles, m. p. 80°. The condensation of *o*-chloronitrobenzene with potassium 2 : 4-dibromophenoxide, at 200° for 24 hours, yielded the same product (Found : Br, 43.0.  $C_{12}H_7O_3NBr_2$  requires Br, 42.9%).

*4 : 4'-Dibromo-2-nitrodiphenyl ether* was prepared by treating 4-bromo-2-nitrodiphenyl ether with a slight excess of bromine in acetic acid solution. It separated from methyl alcohol in pale yellow needles, m. p. 94° (Found : Br, 42.9.  $C_{12}H_7O_3NBr_2$  requires Br, 42.9%). The same product was obtained when 2 : 5-dibromonitrobenzene was condensed with potassium *p*-bromophenoxide.

*4 : 5'-Dibromo-2'-nitrodiphenyl ether* was obtained when 5-bromo-2-nitrodiphenyl ether was treated with a slight excess of bromine in acetic acid solution. It crystallised from methyl alcohol in yellow plates, m. p. 99° (Found : Br, 42.8.  $C_{12}H_7O_3NBr_2$  requires Br, 42.9%).

*2 : 4 : 4'-Tribromo-2'-nitrodiphenyl ether* was obtained when 2-nitro-, 4-bromo-2'-nitro-, 4-bromo-2-nitro-, or 2 : 4-dibromo-2'-nitro-diphenyl ether was dissolved in dry bromine, and the solution kept in sunlight until a solid mass was formed. Excess bromine was removed with dilute aqueous sodium sulphite, and the product crystallised from acetic acid. It separated from methyl alcohol in pale yellow prisms, m. p. 102° (Found : C, 31.65; H, 1.5; Br, 53.3.  $C_{12}H_6O_3NBr_3$  requires C, 31.85; H, 1.35; Br, 53.1%).

*2 : 4 : 4' : 5'-Tetrabromo-2'-nitrodiphenyl ether* was prepared by dissolving 5-bromo-2-nitrodiphenyl ether in excess of dry bromine and keeping the solution in sunlight until a solid mass was obtained. It crystallised from ethyl alcohol or acetic acid in yellow needles, m. p. 170° (Found : Br, 59.95.  $C_{12}H_5O_3NBr_4$  requires Br, 60.2%).

*2-Acetamidodiphenyl Ether*.—2-Nitrodiphenyl ether was reduced with stannous chloride in ethereal hydrogen chloride solution by refluxing for 3 hours. The ether was removed and the base was

liberated with 30% sodium hydroxide solution, taken up in ether, and distilled under diminished pressure. 2-Aminodiphenyl ether was obtained as a light yellow oil, b. p.  $173^{\circ}/20$  mm., m. p.  $44^{\circ}$ . It was acetylated with acetic acid (4 parts) and acetic anhydride (1 part) by refluxing for 20 hours. On pouring the solution into water an oil was obtained which solidified slowly. The acetyl derivative crystallised from dilute methyl alcohol or light petroleum (b. p.  $60-80^{\circ}$ ) in prisms, m. p.  $81^{\circ}$ .

*2-Bromo-2'-acetamidodiphenyl Ether.*—2-Bromo-2'-nitrodiphenyl ether was reduced with stannous chloride in ethereal hydrogen chloride solution, and the base extracted in the usual manner. 2-Bromo-2'-aminodiphenyl ether crystallised from light petroleum (b. p.  $40-60^{\circ}$ ) in clustered needles, m. p.  $60^{\circ}$  (Found: Br, 30.3.  $C_{12}H_{10}ONBr$  requires Br, 30.3%). The base was acetylated by refluxing it for 2 days with acetic anhydride (1 part) and acetic acid (10 parts); the product crystallised from methyl alcohol or light petroleum (b. p.  $60-80^{\circ}$ ) in needles, m. p.  $95^{\circ}$  (Found: Br, 26.3.  $C_{14}H_{12}O_2NBr$  requires Br, 26.1%).

2-Bromo-2'-diacetamidodiphenyl ether was obtained when 2-bromo-2'-aminodiphenyl ether was refluxed with a mixture of acetic anhydride (1 part) and acetic acid (3 parts) for 36 hours. It separated from methyl alcohol or light petroleum in heavy prisms, m. p.  $105^{\circ}$  (Found: Br, 23.1.  $C_{16}H_{14}O_3NBr$  requires Br, 23.0%).

*4-Bromo-2-aminodiphenyl Ether.*—4-Bromo-2-nitrodiphenyl ether was reduced in the usual manner. The base distilled at  $222^{\circ}/15$  mm. and the light yellow oil slowly solidified; it separated from light petroleum in clustered needles, m. p.  $54^{\circ}$  (Found: Br, 30.3.  $C_{12}H_{10}ONBr$  requires Br, 30.3%). Acetylation of the base was attempted under various conditions, but the product was invariably a thick oil which would neither solidify nor crystallise from any of the usual solvents.

4-Bromo-2'-aminodiphenyl ether was obtained, by the reduction of 4-bromo-2'-nitrodiphenyl ether in the usual manner, as a light yellow oil, b. p.  $211^{\circ}/15$  mm. (Found: Br, 30.5.  $C_{12}H_{10}ONBr$  requires Br, 30.3%). The acetyl derivative was obtained by refluxing the base with a mixture of acetic anhydride and acetic acid; it separated from methyl alcohol in prisms, m. p.  $106^{\circ}$  (Found: Br, 25.95.  $C_{14}H_{12}O_2NBr$  requires Br, 26.1%).

*5-Bromo-2-acetamidodiphenyl Ether.*—2-Acetamidodiphenyl ether was brominated in acetic acid solution in the presence of fused sodium acetate, or 5-bromo-2-nitrodiphenyl ether was reduced and the base acetylated. The acetyl derivative separated from methyl alcohol in prisms, m. p.  $146^{\circ}$  (Found: Br, 25.95.  $C_{14}H_{12}O_2NBr$  requires Br, 26.1%).

5-Bromo-2-aminodiphenyl ether was obtained by the reduction of the nitro-compound or by refluxing the acetyl derivative with ethyl-alcoholic hydrochloric acid for 4 hours. It separated from light petroleum (b. p. 40—60°) in plates, m. p. 46° (Found: Br, 30.15.  $C_{12}H_{10}ONBr$  requires Br, 30.3%). The *hydrochloride* crystallised from a solution of the base in dilute hydrochloric acid in needles, m. p. 186° (Found: HCl, 12.15.  $C_{12}H_{10}ONBr \cdot HCl$  requires HCl, 12.15%).

2:4-Dibromo-2'-aminodiphenyl ether was prepared by reducing the corresponding nitro-compound in the usual manner and was liberated as a thick yellow oil which did not solidify. It was purified by conversion into the *hydrochloride*, which separated from dilute hydrochloric acid solution in plates, m. p. 180° (Found: HCl, 9.5.  $C_{12}H_9ONBr_2 \cdot HCl$  requires HCl, 9.6%). The base was acetylated with a mixture of acetic acid and anhydride; the *acetyl* derivative crystallised from light petroleum (b. p. 60—80°) in needles, m. p. 117° (Found: Br, 41.3.  $C_{14}H_{11}O_2NBr_2$  requires Br, 41.5%).

2:5'-Dibromo-2'-acetamidodiphenyl Ether.—2-Bromo-2'-acetamidodiphenyl ether was treated with a slight excess of bromine in acetic acid solution in the presence of fused sodium acetate. It separated from light petroleum (b. p. 80—100°) in clustered needles, m. p. 112° (Found: Br, 41.5.  $C_{14}H_{11}O_2NBr_2$  requires Br, 41.5%).

4:4'-Dibromo-2'-aminodiphenyl ether was prepared by the reduction of 4:4'-dibromo-2'-nitrodiphenyl ether and obtained as an oil, b. p. 240°/15 mm., which slowly solidified and then crystallised from methyl alcohol in needles, m. p. 70° (Found: Br, 46.5.  $C_{12}H_9ONBr_2$  requires Br, 46.65%). The *acetyl* derivative, prepared in the usual manner, separated from methyl alcohol or benzene in needles, m. p. 142° (Found: Br, 41.35.  $C_{14}H_{11}O_2NBr_2$  requires Br, 41.55%).

4:5'-Dibromo-2'-acetamidodiphenyl ether was obtained when 4:5'-dibromo-2'-nitrodiphenyl ether was reduced and the base acetylated; or when 4-bromo-2'-acetamidodiphenyl ether was brominated in acetic acid solution in the presence of fused sodium acetate. It crystallised from methyl alcohol in needles, m. p. 144° (Found: Br, 41.55.  $C_{14}H_{11}O_2NBr_2$  requires Br, 41.55%). 4:5'-Dibromo-2'-aminodiphenyl ether was prepared by refluxing the *acetyl* derivative with alcoholic hydrochloric acid for 3 hours; it separated from methyl alcohol in needles, m. p. 82° (Found: Br, 46.4.  $C_{12}H_9ONBr_2$  requires Br, 46.65%). The *hydrochloride* separated from dilute hydrochloric acid solution in needles, m. p. 202° (Found: HCl, 9.65.  $C_{12}H_9ONBr_2 \cdot HCl$  requires HCl, 9.6%).

2:4:4'-Tribromo-2'-aminodiphenyl ether, obtained by the reduc-

tion of 2:4:4'-tribromo-2'-nitrodiphenyl ether with stannous chloride in ethereal hydrogen chloride solution, separated from methyl alcohol or light petroleum in rosetted needles, m. p. 83° (Found: Br, 57.1.  $C_{12}H_8ONBr_3$  requires Br, 56.9%). It was acetylated in the usual manner and the *acetyl* derivative separated from methyl alcohol in needles, m. p. 127° (Found: Br, 51.65.  $C_{14}H_{10}O_2NBr_3$  requires Br, 51.7%).

2:4:5'-Tribromo-2'-acetamidodiphenyl ether was obtained when 2:4- or 2:5'-dibromo-2'-acetamidodiphenyl ether was treated with bromine in acetic acid solution in the presence of fused sodium acetate. It separated from methyl alcohol in needles, m. p. 147° (Found: Br, 51.7.  $C_{14}H_{10}O_2NBr_3$  requires Br, 51.7%).

4:4':5'-Tribromo-2'-acetamidodiphenyl ether was obtained from 4:4'-dibromo-2'-acetamidodiphenyl ether by bromination in the usual manner; and also from 5-bromo-2'-acetamidodiphenyl ether by bromination in acetic acid solution on the water-bath. It crystallised from methyl alcohol in needles, m. p. 167° (Found: Br, 51.6.  $C_{14}H_{10}O_2NBr_3$  requires Br, 51.7%). 4:4':5'-Tribromo-2'-aminodiphenyl ether, obtained by deacetylation in alcoholic hydrochloric acid solution, crystallised from methyl alcohol or light petroleum in needles, m. p. 120° (Found: Br, 56.7.  $C_{12}H_8ONBr_3$  requires Br, 56.85%). The *hydrochloride* of the base separated from methyl-alcoholic hydrochloric acid solution in needles, m. p. 222° (Found: HCl, 7.7.  $C_{12}H_8ONBr_3 \cdot HCl$  requires HCl, 7.9%).

2:4:4':5'-Tetrabromo-2'-acetamidodiphenyl ether was prepared by treating 2:4:4'-tribromo-2'-acetamidodiphenyl ether with excess of bromine in acetic acid solution in the presence of fused sodium acetate; after standing in the sunlight and warming to 70°, a partly brominated product was obtained, from which the unchanged tribromo-compound was separated by refluxing with light petroleum. The residue crystallised from ethyl alcohol in needles, m. p. 210° (Found: Br, 58.9.  $C_{14}H_9O_2NBr_4$  requires Br, 58.9%). The same product was obtained when 2:4:4':5'-tetrabromo-2'-nitrodiphenyl ether was reduced and the base acetylated in the usual manner.

CLII.—*Quinoline Compounds containing Arsenic.*  
*Part I. Synthesis of 6-Methoxyquinoline Derivatives of Aminophenylarsinic Acids.*

By ROBERT HENRY SLATER.

THE chemotherapeutic activity in malaria of certain 6-methoxyquinoline compounds, such as quinine and plasmoquine (compare Barger and Robinson, J., 1929, 2947), and of arsenic (particularly in chronic cases where quinine has only a slight curative action) would seem to indicate that a highly efficient anti-malarial might be produced by the combination of a 6-methoxyquinoline derivative with an arsenic compound.

For the synthesis of compounds of this type, 4-chloro-6-methoxy-2-methylquinoline, easily accessible (Conrad and Limpach, *Ber.*, 1888, 21, 1651) and containing labile halogen, appeared to be a suitable initial material. The first method investigated, namely, direct condensation with *o*- or *p*-aminophenylarsinic acid, was unsuccessful, whether the two substances were heated together (a) in the dry state, (b) in presence of quinoline, or (c) in boiling amyl alcohol to which anhydrous potassium carbonate and a trace of copper powder and cuprous iodide had been added (compare Burton and Gibson, J., 1926, 459; Wintersteiner and Lieb, *Ber.*, 1928, 61, 1126).

When, however, 4-chloro-6-methoxy-2-methylquinoline was heated with an excess of *p*-phenylenediamine, 4-*p*-aminoanilino-6-methoxy-2-methylquinoline (I) was produced. This base was converted into *p*-6'-methoxy-2'-methyl-4'-quinolylaminophenylarsinic acid (II) by means of the Bart reaction, uniform yields being obtained when the solid diazo-compound was employed.

By a similar series of reactions 4-*m*-aminoanilino-6-methoxy-2-methylquinoline and *m*-6'-methoxy-2'-methyl-4'-quinolylaminophenylarsinic acid were obtained.

4-Chloro-6-methoxy-2-methylquinoline and benzidine condensed readily when heated together, with formation of 4-benzidino-6-methoxy-2-methylquinoline (III). This base was readily converted

into 4'-6''-methoxy-2''-methyl-4''-quinolyldiaminodiphenylarsinic acid (IV) by means of the Bart reaction.

*pp'*-Diaminodiphenylmethane and 4-chloro-6-methoxy-2-methylquinoline condensed slowly when heated together. *pp'*-Di-6'-methoxy-2'-methyl-4'-quinolyldiaminodiphenylmethane (V) was the only product even when a large excess of *pp'*-diaminodiphenylmethane was present.

Monoquinolyl derivatives also have not yet been obtained from *o*-tolidine or *o*-dianisidine and 4-chloro-6-methoxy-2-methylquinoline. Attempts are being made to condense these bases and various aminophenylarsinic acids with 4-bromo-6-methoxy-2-methylquinoline (which contains a more reactive halogen atom).

Several of the substances now described exhibit a remarkable tendency to form gels when warm dilute aqueous solutions of their salts are cooled, and most of them give brilliant colorations, ranging from red to purple, when they are added under suitable conditions to a dilute aqueous solution of iodine in potassium iodide. These reactions will be more fully described elsewhere.

The above quinolyldiaminodiphenylmethane and some of the intermediate compounds are being tested by the Joint Committee on Chemotherapy formed by the Medical Research Council and the Department of Scientific and Industrial Research in respect of their chemotherapeutic actions. The results of these tests will be published later.

#### EXPERIMENTAL.

4-*p*-Aminoanilino-6-methoxy-2-methylquinoline (I).—A mixture of 4-chloro-6-methoxy-2-methylquinoline (10.4 g.) and *p*-phenylenediamine (9 g.), heated at 130–140°/15 mm. during 20 minutes, became dark brown and almost completely solid. A solution of the product in the minimum amount of hot dilute hydrochloric acid (5%) was filtered, cooled, and added to twice its volume of concentrated hydrochloric acid (*d* 1.19). From the pale green, crystalline hydrochloride (13.5 g.) which separated, the free base was

liberated by aqueous ammonia. It crystallised from aqueous alcohol (50%) in large, thick, light brown, rectangular plates, melting with loss of water at 215° (Found: C, 68.5; H, 6.2.  $C_{17}H_{17}ON_3 \cdot H_2O$  requires C, 68.7; H, 6.4%). The base is soluble in ethyl alcohol, methyl alcohol, and acetic acid, but much less soluble in benzene and light petroleum. A dilute alcoholic or acetic acid solution does not give a coloration with *N*/1000-iodine. The hydrochloride separates in fine, white, prismatic needles when hydrochloric acid is added to an alcoholic solution of the base.

The *acetyl* derivative, prepared by means of boiling acetic anhydride, crystallised from aqueous alcohol (20% alcohol) in large, pale yellow rhombohedra which contained water of crystallisation. After dehydration at 150° the compound has m. p. 240° (Found: C, 71.2; H, 5.7; N, 12.8.  $C_{19}H_{19}O_2N_3$  requires C, 71.0; H, 6.0; N, 13.1%). It is soluble in alcohol and acetic acid, but practically insoluble in benzene and light petroleum. A warm dilute acetic acid solution (2%) sets to a firm jelly on cooling. A dilute acetic acid solution gives with *N*/1000-iodine a brilliant blue coloration, which disappears on warming and reappears on cooling. A dilute alcoholic solution behaves similarly, but fresh iodine solution has to be added to the cooled solution in order to restore the blue colour. A blue coloration is also produced when a dilute aqueous solution of potassium iodide is added to a mixture of an acetic acid solution of the acetyl compound and bromine water. Hydrochloric acid precipitates the hydrochloride from an alcoholic solution in yellow feathery needles which are sparingly soluble in water.

*p*-6'-Methoxy-2'-methyl-4'-quinolylaminophenylarsinic Acid (II).—A mixture of 4-*p*-aminoanilino-6-methoxy-2-methylquinoline (5.6 g.) and hydrochloric acid (9 c.c.; *d* 1.19) was cooled to -5° and diazotised (sodium nitrite, 1.6 g.; water, 7 c.c.) below 0°. After an hour, the mixture was neutralised at 0° with 5*N*-sodium hydroxide, and sodium arsenite solution (a mixture of arsenious oxide, 3 g., in 5*N*-sodium hydroxide solution, 6 c.c.; sodium carbonate, 6 g., in water, 18 c.c.; and 10% copper sulphate solution, 0.6 c.c., to which was added sufficient aqueous ammonia to give the soluble complex salt) added. The whole was kept at room temperature for 16 hours and then warmed gently on the water-bath until evolution of nitrogen ceased. After filtration, the solid residue was extracted thrice with small quantities of aqueous sodium hydroxide (5%). The hydrogen-ion concentration of the combined filtrates was adjusted with hydrochloric acid to  $p_H$  7.5; the *arsinic acid* was then quantitatively precipitated as a white gelatinous solid. This was collected and repeatedly dissolved in dilute sodium

hydroxide solution and reprecipitated at its isoelectric point ( $p_H$  7.5) with nitric acid; the stellate clusters of fine, white, prismatic needles obtained were washed with water (yield, 0.5—3.2 g.). The acid was unmelted at  $307^\circ$  (Found: N, 7.6; As, 19.4.  $C_{17}H_{17}O_4N_2As$  requires N, 7.2; As 19.3%).

A more uniform yield was obtained by the following method. A well-stirred mixture of 4-*p*-aminoanilino-6-methoxy-2-methylquinoline (5.6 g.) and glacial acetic acid (30 c.c.) was cooled to  $10^\circ$ , sodium nitrite (1.6 g.) added gradually, and the clear reddish-brown solution poured into dry ether (150 c.c.). The solid orange diazonium compound, which separated, was collected, washed with dry ether, and added to the sodium arsenite mixture (as used above). After standing over-night, the reaction product was worked up and the arsinic acid isolated as in the last experiment (yield, 2.6 g.).

The arsinic acid is practically insoluble in water and the usual organic solvents. It dissolves readily in dilute sodium and ammonium hydroxide solutions and in moderately concentrated hydrochloric acid. No satisfactory explanation can be advanced of the curious phenomenon that the acid is precipitated from a solution of its sodium salt in a crystalline form by nitric acid (*vide supra*) and, under exactly similar conditions, in a gelatinous form by hydrochloric acid. A colloidal solution of the arsinic acid in dilute acetic acid gives a purple coloration with *N*/1000-iodine.

The sodium salt is precipitated in colourless plates when concentrated sodium hydroxide solution is added to a solution of the arsinic acid in dilute alkali. The following salts are precipitable from an aqueous solution of the ammonium salt: magnesium salt, white, gelatinous, insoluble in hot water; barium salt, white, gelatinous, soluble in hot water, crystallises on cooling in fine slender needles; calcium salt, white, gelatinous, less soluble in hot water; silver salt, pale yellow, curdy, insoluble in hot water; mercuric salt, white, curdy, insoluble in hot water.

**4-*m*-Aminoanilino-6-methoxy-2-methylquinoline.**—A mixture of 4-chloro-6-methoxy-2-methylquinoline (10.4 g.) and *m*-phenylenediamine (10 g.) was heated at  $140^\circ/20$  mm. for  $1\frac{1}{2}$  hours, the almost solid product dissolved in hot dilute hydrochloric acid (5%), and the filtered solution rendered alkaline with aqueous ammonia. The base obtained crystallised from aqueous alcohol (20% alcohol) in long, pale brown, rectangular, prismatic needles (10 g.), *m. p.*  $230$ — $231^\circ$  (Found: C, 73.4; H, 6.2; N, 14.7.  $C_{17}H_{17}ON_2$  requires C, 73.1; H, 6.1; N, 15.0%).

4-*m*-Aminoanilino-6-methoxy-2-methylquinoline is readily soluble in ethyl alcohol, methyl alcohol, and acetic acid, but sparingly soluble in benzene and light petroleum. A dilute alcoholic or acetic

acid solution gives with *N*/1000-iodine a faint red coloration, which slowly deepens. The addition of hydrochloric acid to an alcoholic solution of the base gives a white gelatinous precipitate of the hydrochloride.

The *acetyl* derivative crystallises from aqueous alcohol (10% alcohol) in stout, pale yellow, prismatic needles, m. p. 269° (Found : C, 71.0; H, 6.1; N, 12.7.  $C_{19}H_{19}O_2N_3$  requires C, 71.0; H, 6.0; N, 13.1%). It is slightly soluble in ethyl alcohol and acetic acid, but practically insoluble in benzene and light petroleum. A dilute alcoholic solution gives a deep blue coloration with *N*/1000-iodine and a dilute acetic acid solution gradually gives a brilliant purple coloration; these colours disappear on warming but reappear on cooling. The addition of water to a solution of the acetyl compound in concentrated hydrochloric acid produces a white gelatinous precipitate of the hydrochloride.

*m*-6'-Methoxy-2'-methyl-4'-quinolylaminophenylarsinic Acid.—This acid was obtained from 4-*m*-aminoanilino-6-methoxy-2-methylquinoline by the Bart reaction under practically the same conditions which were used in the first method of preparation of its *p*-isomeride (base, 5.6 g.; hydrochloric acid, 15 c.c. of *d* 1.14; sodium nitrite, 1.6 g., in water, 7 c.c.), but a slightly higher temperature (0—5°) was permitted. The reaction of the alkaline filtrate was adjusted with hydrochloric acid to *p*<sub>H</sub> 5 and the *arsinic acid*, then quantitatively precipitated as a white gelatinous solid, was purified by several reprecipitations from solution in dilute aqueous sodium hydroxide at the above isoelectric point (*p*<sub>H</sub> 5), washed with water, and dried (yield, 1.5 g.). It darkened at 280° but was unmelted at 300° (Found : As, 19.5.  $C_{17}H_{17}O_4N_2As$  requires As, 19.3%).

This *arsinic acid* resembles the *p*-isomeride in solubility, but it is not precipitated in a crystalline form when nitric acid is added to an aqueous solution of its sodium salt; also, the colloidal solution in dilute acetic acid does not give a coloration with *N*/1000-iodine.

The sodium salt of the *arsinic acid* is readily precipitated as a crystalline mass when concentrated sodium hydroxide solution is added to its dilute alkali solution. The following salts are insoluble in cold water: magnesium salt, white, gelatinous, slightly soluble in hot water; calcium salt, pale yellow, gelatinous, less soluble in hot water; barium salt, white, gelatinous, soluble in hot water, gelatinous precipitate on cooling; silver salt and mercuric salt, pale yellow, curdy, insoluble in hot water.

4-Benzidino-6-methoxy-2-methylquinoline (III).—A mixture of 4-chloro-6-methoxy-2-methylquinoline (5.2 g.) and benzidine (7 g.) was heated at 160° during 15 minutes and the almost solid product was digested with excess of hot dilute hydrochloric acid (5%),

which readily converted it into an insoluble yellow hydrochloride. This was extracted several times with small quantities of boiling dilute hydrochloric acid and then warmed with sodium hydroxide solution. The base (7.2 g.) liberated crystallised from toluene in fine, pale yellow, microscopic, rectangular prisms, m. p. 245° (Found: C, 77.8; H, 6.1; N, 11.5.  $C_{23}H_{21}ON_3$  requires C, 77.7; H, 6.0; N, 11.8%).

*4-Benzidino-6-methoxy-2-methylquinoline* is soluble in acetic acid and boiling toluene, but sparingly soluble in ethyl and methyl alcohols, benzene and light petroleum. Its solution in warm dilute acetic acid sets to a gel on cooling. A dilute acetic acid solution of this base gives with *N*/1000-iodine a deep purple coloration; this disappears on warming but does not reappear on cooling.

The *acetyl* derivative crystallises from aqueous alcohol in stellate clusters of fine, yellow, rectangular, prismatic needles, m. p. 159—160° (Found: N, 9.7.  $C_{25}H_{23}O_2N_3 \cdot 2H_2O$  requires N, 9.7%). It is readily soluble in ethyl and methyl alcohols and in acetic acid, but it is only slightly soluble in benzene and practically insoluble in light petroleum. A solution in warm dilute acetic acid sets to a gel on cooling. A dilute alcoholic or acetic acid solution gives with *N*/1000-iodine a brilliant purple coloration which disappears on warming and reappears on cooling. This coloration is also produced when a dilute potassium iodide solution is added to a mixture of the acetic acid solution of the *acetyl* compound and bromine water. The addition of hydrochloric acid to an alcoholic solution of the base precipitates a crystalline hydrochloride sparingly soluble in water.

*4'-6''-Methoxy-2''-methyl-4''-quinolylaminodiphenylarsinic Acid* (IV).—A well-stirred mixture of the preceding benzidino-compound (3.5 g.), hydrochloric acid (5.7 c.c. of *d* 1.19), and water (15 c.c.) was cooled to 5°, and a saturated solution of sodium nitrite (0.8 g.) added gradually below 8°. After 1 hour, the diazo-mixture was carefully neutralised at 5° with aqueous sodium hydroxide (5*N*), and sodium arsenite solution (a mixture of arsenious oxide, 2 g., in 5*N*-sodium hydroxide solution, 4 c.c.; sodium carbonate, 4 g., in water, 12 c.c.; and 10% copper sulphate solution, 0.4 c.c., to which was added sufficient aqueous ammonia to give the soluble complex salt) added. After remaining at room temperature over-night, the mixture was warmed gently on the water-bath until evolution of nitrogen ceased. After the addition of *N*-sodium hydroxide (10 c.c.) the liquid was filtered, and the residue extracted thrice with warm dilute sodium hydroxide solution. The reaction of the combined filtrates was adjusted with hydrochloric acid in the cold to *p*<sub>H</sub> 7; the *arsinic acid* then completely precipitated was purified by several precipitations (at *p*<sub>H</sub> 7) from its solution in dilute alkali

with hydrochloric acid and obtained in pale yellow needles (radially arranged) which, when washed free from sodium chloride, were converted into a gelatinous solid (yield, 2.2 g.). The acid darkened at 290° but was unmelted at 300° (Found: As, 16.0.  $C_{23}H_{21}O_4N_2As$  requires As, 16.15%).

This arsinic acid is practically insoluble in water and in the usual organic solvents, readily soluble in dilute sodium and ammonium hydroxide solutions, but only slightly soluble in hydrochloric acid. A colloidal solution in dilute acetic acid gives with *N*/1000-iodine a dark red coloration which changes to purple on the addition of hydrochloric acid. The crystalline sodium salt is readily produced in the usual way. The magnesium, calcium, and barium salts are white and gelatinous, the silver salt is pale yellow and gelatinous, and the mercuric salt pale yellow and curdy: all are insoluble in water.

*pp'*-Di-6'-methoxy-2'-methyl-4'-quinolyldiaminodiphenylmethane (V).—*pp'*-Diaminodiphenylmethane (7.5 g.) was heated to 130°, and to the melt were added 4-chloro-6-methoxy-2-methylquinoline (5.2 g.) and a trace of finely divided copper-bronze. After 3 hours' heating, the mixture, which had almost completely solidified, was digested with hot dilute hydrochloric acid (5%) and the residual, sparingly soluble, pale yellow hydrochloride (4.5 g.) was treated with warm aqueous sodium hydroxide solution. The base thus liberated crystallised from hot alcohol in small, pale brown, rectangular, prismatic needles, m. p. 144° (decomp.) (Found: C, 77.3; H, 6.0; N, 10.2.  $C_{35}H_{32}O_2N_4$  requires C, 77.7; H, 6.0; N, 10.4%). It is soluble in ethyl alcohol and acetic acid, but only sparingly soluble in benzene and light petroleum. A dilute alcoholic or acetic acid solution gives with *N*/1000-iodine a deep purple coloration, which disappears on warming but reappears on cooling. The addition of hydrochloric acid to an alcoholic solution of the base precipitates the hydrochloride in fine, yellow, rectangular, prismatic needles.

The author desires to express his thanks to the Trustees of the Carnegie Trust for the Universities of Scotland and to the Court of the Grocers' Company for a Fellowship and a Scholarship, respectively, which have enabled this work to be carried out. He is also indebted to Dr. W. O. Kermack for his interest in the investigation.

CLIII.—*Some Derivatives of m-Xylene.*

By ERNEST G. BOYCE, WILLIAM P. RANKINE, and ALEXANDER ROBERTSON.

*m-Xylorcinolcarboxylic Acid*.—The procedure adopted by one of us (A. R.) and Robinson (J., 1927, 2196) for the preparation of *p*-orsellinic acid has proved suitable for the preparation of *m*-xylorcinolcarboxylic acid (compare Kostanecki, *Ber.*, 1886, **19**, 2323). A mixture of *m*-xylorcinol (Robertson and Robinson, *loc. cit.*) (5 g.), potassium carbonate (10 g.), and glycerol (10 g.) was heated (oil-bath at 130°) for 5 hours in an atmosphere of carbon dioxide. Addition of 15% hydrochloric acid to the cooled reaction mixture precipitated *m*-xylorcinolcarboxylic acid (4 g.), which crystallised from dilute alcohol in colourless prismatic needles, m. p. 199–200° (decomp.) (Kostanecki, *loc. cit.*, gives m. p. 196°) (Found: C, 59.5; H, 5.7. Calc. for  $C_9H_{10}O_4$ : C, 59.4; H, 5.5%). The acid quickly decomposes in boiling water into *m*-xylorcinol and carbon dioxide. The ferric chloride reaction is green in alcohol and pure blue in water. This acid, unlike  $\beta$ -orcinolcarboxylic acid (Robertson and Stephenson, this vol., p. 313), is not esterified in boiling methyl or ethyl alcohol. If sodium bicarbonate is used in the preparation, the yield is halved.

*6-Methoxy-m-4-xylylidine*.—4-Nitro-*m*-6-xylene (1 mol.) was methylated with methyl sulphate (2 mols.) and 20% aqueous sodium hydroxide (2.5 mols.) (compare Pfaff, *Ber.*, 1883, **16**, 1136). The alkali-insoluble ether crystallised from alcohol in pale yellow needles, m. p. 56–57°. Iron powder (80 g.) was added in portions of 10 g. at intervals of 3 minutes to a boiling solution of the nitro-ether (60 g.) in alcohol (300 c.c.) and concentrated hydrochloric acid (20 c.c.), and the mixture was refluxed for 5 hours, a test then showing that reduction was complete. The filtered solution was concentrated to 100 c.c., cooled, saturated with hydrogen chloride, and kept in an ice-chest. After some hours, the hydrochloride was collected, and a further quantity was isolated from the mother-liquor by concentration to 50 c.c. and renewed saturation with hydrogen chloride. The salt crystallised in glistening prisms; total yield, 50 g. Agitation of a suspension of the salt in excess of bicarbonate solution gave the amine, m. p. 83° after crystallisation from benzene-ligroin and then from dilute alcohol (colourless needles). The *acetyl* derivative crystallised from water in needles, m. p. 160° (Found: C, 68.6; H, 7.5.  $C_{11}H_{15}O_2N$  requires C, 68.7; H, 7.4%).

*6-Methoxy-m-4-xyleneol*.—The foregoing hydrochloride (17 g.) was

dissolved in 10% sulphuric acid (200 c.c.) and crushed ice (200 g.) was added after sudden cooling and shaking to ensure the separation of small crystals. Sodium nitrite (6 g.), dissolved in water (50 c.c.), was then introduced, and the mixture stirred for 15 minutes. The filtered diazo-solution was gradually added to boiling 10% sulphuric acid (600 c.c.). On cooling, 6-methoxy-*m*-4-xylene separated in pale yellow crystals. Recrystallisation from ligroin gave the substance in colourless needles, m. p. 80° (Found: C, 70.9; H, 7.8.  $C_9H_{12}O_2$  requires C, 71.0; H, 8.0%). It is readily soluble in alcohol, ether, and benzene. The phenol does not give a ferric chloride reaction.

*2-Hydroxy-6-methoxy-3 : 5-dimethylbenzaldehyde*.—Condensation of the monomethyl ether of xylocinol and hydrogen cyanide in the presence of hydrogen chloride and zinc chloride after the method of Gattermann gave a compound which on solution in water reverted to the original ether. The aldehyde was subsequently obtained by partial methylation of *m*-xylocinylaldehyde (1 mol.) (Robertson and Robinson, *loc. cit.*) with methyl iodide (1.5 mols.) and excess of potassium carbonate in acetone under reflux on the steam-bath for 2 hours. After removal of the potassium salts the acetone was distilled under diminished pressure, and the alkali-soluble residue crystallised from dilute methyl alcohol. The aldehyde formed slender colourless needles, m. p. 52° (Found: C, 66.4; H, 6.3.  $C_{10}H_{12}O_3$  requires C, 66.7; H, 6.3%). The substance gives a dark green ferric chloride reaction almost identical with that given by *m*-xylocinylaldehyde. It is insoluble in water and readily soluble in alcohol, acetone, or ethyl acetate. Condensation of the aldehyde with  $\alpha$ -methoxyacetoveratrone (Pratt and Robinson, J., 1923, 123, 745) with hydrogen chloride in dry ethyl acetate by the method of Robinson gave 3 : 5 : 3' : 4'-tetramethoxy-6 : 8-dimethylflavylium chloride in red-brown prisms; the ferrichloride crystallised from acetic acid in elongated red-brown prisms, m. p. 177–178° (Found: C, 45.6; H, 4.3.  $C_{21}H_{23}O_5, FeCl_4$  requires C, 45.6; H, 4.2%).

*m*-Xylocinol does not condense with acetonitrile by the method of Hoesch.

We are indebted to the Chemical Society for a grant which has in part defrayed the cost of this investigation.

CLIV.—*The Formation of Phenoxazines.*

BY OSCAR L. BRADY and CECIL WALLER.

CERTAIN substituted 2-nitro-2'-hydroxydiphenylamines on treatment with alkali readily lose nitrous acid to give phenoxazines:

The reaction has been investigated by Turpin (J., 1891, 59, 720), Ullmann (*Annalen*, 1908, 366, 79), and Ullmann and Sané (*Ber.*, 1911, 44, 3730), but no satisfactory explanation has been suggested for the influence of other groups present in the molecule upon the reaction.

It was found by these workers that the phenoxazines are formed when the following compounds are treated with alkali: 2:4:6-trinitro-, 2:6-dinitro-, 2:4-dinitro-6-carboxy-, 2:6-dinitro-4-carboxy-, 2:6-dinitro-4-benzoyl-, 2:4-dinitro-6-sulpho-, 2:6-dinitro-4-sulpho-, 2:4-dinitro-6-methyl-, and 2:6-dinitro-4-chloro-2'-hydroxydiphenylamines. No reaction occurred, however, with 2:4-dinitro-2'-hydroxydiphenylamine. Thus in all cases where the phenoxazine was formed the 6-position was occupied, and Ullmann concluded that this was a necessary condition for the reaction to occur. In order to test this view more fully, a number of similar compounds have been investigated. In all the cases previously studied, with the exception of 2:4-dinitro-2'-hydroxy-6-methyldiphenylamine, a "negative" group occupied the 6-position. It did not seem likely that groups of such different character as NO<sub>2</sub> and CH<sub>3</sub> would activate the 2-nitro-group, but in order to test this point a group at the other end of the scale, namely, methoxyl, was tried and it was found that 2:4-dinitro-2'-hydroxy-3:6-dimethoxydiphenylamine readily gave the phenoxazine.

The presence of a methyl group in another position in the nitrated ring had no influence; 2:6-dinitro-5-methyl- and 2:6-dinitro-4-methyl-2'-hydroxydiphenylamines readily gave phenoxazines, but 2:4-dinitro-5-methyl-2'-hydroxydiphenylamine did not do so. A methyl group in the 6'-position was also without effect, 2:6-dinitro-2'-hydroxy-3:6'-dimethyldiphenylamine giving the phenoxazine and 2:4-dinitro-2'-hydroxy-6'-methyl- and 2:4-dinitro-2'-hydroxy-5:6'-dimethyl-diphenylamines failing to do so.

The lack of reactivity of, for example, 2:4-dinitro-2'-hydroxydiphenylamine might be due to chelation of the 2-nitro-group with

the imino-group (I) preventing its access to the hydroxyl group; the presence of another group in the 6-position which could itself

chelate (II) would negative this effect and most of the compounds investigated have such a group, but it is difficult to suppose that the methyl group would be effective in this respect. Attempts to prepare *N*-methyl derivatives in order to eliminate the possibility of chelation as in (I) were, however, unsuccessful.

The only explanation that can be suggested is a purely steric one : if the 6-position is free, for steric reasons the large nitro-group takes up a position remote from the hydroxyl group, thus bringing the

6-position near it (III). If there is a group in the 6-position, there is less reason for the compound to be oriented as (IV) than as (V). Experiments are in hand with the object of obtaining evidence of such orientation in compounds of this type.

#### EXPERIMENTAL.

*2:6-Dinitro-3-methyl-, 2:4-Dinitro-5-methyl-, and 2:6-Dinitro-4-methyl-2'-hydroxydiphenylamines.*—2:3:4-, 3:4:6-, or 3:4:5-Trinitrotoluene (4 g.), *o*-aminophenol (4 g.; 2 equivs.), and benzene (240 c.c.) were boiled for 4 hours under reflux, nitrous fumes being evolved; the mixture was then cooled and filtered. In the case of 2:3:4-trinitrotoluene the filtrate was evaporated to dryness, and the residue crystallised four times from dilute alcohol; 2:6-dinitro-2'-hydroxy-3-methyldiphenylamine was then obtained in reddish-purple needles (3 g.), m. p. 148° (Found: N, 14.7.  $C_{13}H_{11}O_5N_3$  requires N, 14.5%).

In the second case the filtrate was evaporated to small bulk and, while it was still hot, boiling light petroleum was added until precipitation commenced. On cooling, a brown solid separated which, crystallised from benzene and light petroleum, gave 2:4-dinitro-2'-hydroxy-5-methyldiphenylamine as a deep purple-brown, micro-crystalline powder (2.7 g.), m. p. 203° (Found: N, 14.8%).

Crystallised from methyl alcohol or from somewhat diluted acetic acid, this compound separated as an orange-red solid of the same m. p.

In the third case the tarry solid obtained on evaporation of the benzene was crystallised repeatedly from dilute alcohol; 2:6-dinitro-2'-hydroxy-4-methyldiphenylamine was then obtained in lustrous purple-brown needles, m. p. 152° (Found: N, 14.4%).

2-Chloro-6-nitro-2'-hydroxy-3-methyldiphenylamine.—A solution of 3:4-dinitro-*o*-chlorotoluene (2.3 g.) and *o*-aminophenol (5 g.) in alcohol (150 c.c.) was boiled under reflux for 20 hours, and cooled. Water and a little hydrochloric acid were then added and the precipitated tarry mass was extracted with boiling light petroleum; the precipitate obtained from the cooled extract was crystallised from the same solvent, 2-chloro-6-nitro-2'-hydroxy-3-methyldiphenylamine being obtained in purple-red needles (1 g.), m. p. 106° (Found: N, 10.2.  $C_{13}H_{11}O_3N_2Cl$  requires N, 10.0%).

2:4-Dinitro-2'-hydroxy-3:6-dimethoxydiphenylamine.—This was prepared from trinitroquinol dimethyl ether (2.6 g.) and *o*-aminophenol (2.1 g.) in benzene (100 c.c.) as before. The reaction mixture was cooled, the liquid filtered and heated to boiling, and boiling light petroleum (200 c.c.) added. The precipitate produced on cooling was crystallised from benzene and light petroleum, 2:4-dinitro-2'-hydroxy-3:6-dimethoxydiphenylamine being obtained in brown prisms (1.5 g.), m. p. 186° (Found: N, 12.6.  $C_{14}H_{13}O_7N_3$  requires N, 12.5%).

2:4-Dinitro-2'-hydroxy-5:6'-dimethyl-, 2:6-Dinitro-2'-hydroxy-4:6'-dimethyl-, and 2:4:6-Trinitro-2'-hydroxy-6'-methyldiphenylamines.—3:4:6- and 3:4:5-Trinitrotoluenes and picryl chloride were each heated with 2 equivalents of 2-amino-*m*-cresol in benzene under reflux for 4 hours, and the solutions cooled and filtered. In the first and second cases the filtrates were evaporated to dryness, and the residues crystallised repeatedly from dilute alcohol; there were then obtained 2:4-dinitro-2'-hydroxy-5:6'-dimethyldiphenylamine as brick-red prisms, m. p. 173° (Found: N, 14.1.  $C_{14}H_{13}O_5N_3$  requires N, 13.9%), and 2:6-dinitro-2'-hydroxy-4:6'-dimethyldiphenylamine as purple plates, m. p. 198° (decomp.) (Found: N, 14.0%). In the third case light petroleum was added to the filtered solution, and the precipitate crystallised from benzene and light petroleum; 2:4:6-trinitro-2'-hydroxy-6'-methyldiphenylamine was then obtained as a bright crimson, microcrystalline powder, m. p. 176° (Found: N, 16.7.  $C_{13}H_{10}O_7N_4$  requires N, 16.8%).

Formation of Phenoxazines.—The general method adopted was to dissolve the diphenylamine compound (1 g.) in 1% aqueous sodium

hydroxide (25 c.c.) and heat the solution on the water-bath for a time varying from a few minutes to 2 hours according to the nature of the compound undergoing reaction. The phenoxazine, if formed, was precipitated and the time necessary for reaction was indicated by the amount of precipitate. Nitrite, or in one case chloride, was detected in the solution after reaction. The yields were excellent.

2 : 6-Dinitro-2'-hydroxy-3-methyldiphenylamine gave 1-nitro-4-methylphenoxazine, which separated from somewhat diluted acetic acid as a dark violet powder, m. p. 169° (Found : N, 11.9.  $C_{13}H_{10}O_3N_2$  requires N, 11.6%). The same compound was obtained from 2-chloro-6-nitro-2'-hydroxy-3-methyldiphenylamine, this result showing which of the two nitro-groups in 2 : 6-dinitro-2'-hydroxy-3-methyldiphenylamine is the reactive one :

2 : 6-Dinitro-2'-hydroxy-4-methyldiphenylamine gave 1-nitro-3-methylphenoxazine, almost black needles, m. p. 165°, from light petroleum (Found : N, 11.8%). 2 : 4-Dinitro-2'-hydroxy-3 : 6-dimethoxydiphenylamine gave 3-nitro-1 : 4-dimethoxyphenoxazine, crimson needles, m. p. 173°, from benzene and light petroleum (Found : N, 9.5.  $C_{14}H_{12}O_5N_2$  requires N, 9.7%). 2 : 4 : 6-Trinitro-2'-hydroxy-6'-methyldiphenylamine gave 1 : 3-dinitro-9-methylphenoxazine, deep purple prisms, m. p. 224°, from benzene (Found : N, 14.7.  $C_{13}H_9O_5N_3$  requires N, 14.6%). 2 : 6-Dinitro-2'-hydroxy-4 : 6'-dimethyldiphenylamine gave 1-nitro-3 : 9-dimethylphenoxazine, a violet powder, m. p. 162°, from benzene (Found : N, 11.6.  $C_{14}H_{12}O_3N_2$  requires N, 11.4%). 2 : 4-Dinitro-2'-hydroxy-5-methyl-, 2 : 4-dinitro-2'-hydroxy-6'-methyl-, and 2 : 4-dinitro-2'-hydroxy-5 : 6'-dimethyl-diphenylamines were not converted into phenoxazines under the above conditions, no precipitate formed, and no nitrite was produced.

3-Bromo-4 : 6-dinitrotoluene.—A hot alcoholic solution of 4 : 6-dinitro-*m*-tolylhydrazine (5 g.) (Brady and Bowman, J., 1921, 119, 894) was treated with successive small quantities of cupric bromide (30 g.), the mixture was cooled, and the liquid filtered. The filtrate was heated with a little concentrated hydrochloric acid and hydrogen peroxide to oxidise any cuprous bromide and poured into water. The precipitate obtained, after crystallising from alcohol, gave 3-bromo-4 : 6-dinitrotoluene in pale yellow needles, m. p. 101° (Found : N, 10.5.  $C_7H_5O_4N_2Br$  requires N, 10.7%).

*2:4-Dinitro-2'-methoxy-N-methyldiphenylamine*.—This was prepared by heating *N*-methyl-*o*-anisidine (3 g.) and 2:4-dinitrochlorobenzene (5 g.) together with a little anhydrous zinc chloride for 6 hours in an oil-bath at 130–140°. The product was distilled in steam to remove unchanged dinitrochlorobenzene, the solid residue extracted with boiling dilute hydrochloric acid, and the insoluble matter crystallised from alcohol; 2:4-dinitro-2'-methoxy-*N*-methyldiphenylamine was then obtained in yellow needles, m. p. 169° (Found: N, 14.3.  $C_{14}H_{13}O_5N_3$  requires N, 13.9%). The methoxyl group could not be demethylated by treatment with an aqueous or glacial acetic acid solution of hydrogen bromide.

*N*-Methyl-*o*-aminophenol decomposes when heated above 80°. No reaction occurred when it was boiled for many hours in benzene with 2:4-dinitrochlorobenzene or 3-bromo-4:6-dinitrotoluene.

THE RALPH FORSTER LABORATORIES OF ORGANIC CHEMISTRY,

UNIVERSITY COLLEGE, LONDON.

[Received, March 25th, 1930.]

### CLV.—*The Preparation of Diphenyl Ethers.*

By (Miss) ROSALIND VENETIA HENLEY.

It has been shown by Groves, Turner, and Sharp (J., 1929, 512) that the use of copper-bronze in the preparation of 2-nitrodiphenyl ethers is unnecessary, since it does not increase the yield, and hampers manipulation. The following experiments have been done in order to try to determine the most favourable conditions for the preparation of such ethers, and if possible to eliminate the necessity of extensive purification, owing to the presence of much unchanged material. The effects of different proportions of halogenonitro-compound, phenol, and potassium hydroxide were studied, also the variation of time and temperature, and the use of copper, and the elimination of water, in the operations.

The method used in the condensations was as follows: the water was added to the potassium hydroxide, which was then fused. The phenol was added to the potassium hydroxide, and the two were heated until all the solid had dissolved. The halogenonitro-compound was then added, and the mixture was heated in a metal-bath, in a flask fitted with a short air-condenser. The mixture was then diluted with water, alkali was added, and the oil was extracted with carbon tetrachloride, washed with water, dried over sodium sulphate, and distilled in a vacuum, the purity of the product being determined by its constant boiling point.

*Series A.—Variation of the proportion of phenol and potassium hydroxide.*

	I.	II.	III.	IV.
<i>o</i> -Chloronitrobenzene ...	1 mol.	1 mol.	1 mol.	1 mol.
Phenol .....	1 mol.	1.5 mols.	1.75 mols.	3 mols.
Potassium hydroxide ...	1 mol.	1.25 mols.	1.33 mols.	2 mols.
Water .....	0.1 mol.	0.1 mol.	0.1 mol.	0.1 mol.
Yield, % .....	68	70	72.4	60.5

The condensation was effected at 160—180°, for 2 hours.

The most favourable conditions are those given in experiment III.

*Series B.—Variation of the time of condensation.*

*Experiment I.* The conditions used in experiment III of series A were repeated, the time of the experiment being varied. When the mixture was heated for  $\frac{1}{2}$  hour only, the reaction was incomplete, since the yield of 2-nitrodiphenyl ether was only 57%.

*Experiment II.* When the condensation was prolonged for 4 hours, the yield was 73%, showing that no improvement had been obtained.

*Series C.—Variation of the temperature of condensation.*

*Experiment I.* The conditions used in Experiment III, series A were repeated in the following experiments: When the mixture was heated at 200—210° for 1 hour, a yield of 95.5% of ether was obtained.

*Experiment II.* The same experiment was repeated, the condensation being allowed to occur for only  $\frac{1}{2}$  hour; an 84% yield was obtained, showing that the reaction was less complete.

*Experiment III.* A further experiment was done by heating the mixture at 240° for 1 hour, but the yield was only 90%, showing that no improvement had occurred.

The condensation was effected under the conditions of experiment III, series A, but with omission of the water (0.1 mol.); the yield was only 63%.

When experiment III, series A, was repeated in the presence of copper-bronze, the yield obtained was 72%, showing that no benefit is derived from its use, even when the more favourable proportions of phenol and potassium hydroxide are taken.

*Series D (a).*—In order to determine whether the conditions described in the previous experiments were generally applicable to diphenyl ethers, a series of experiments was performed with different phenols, *o*-chloronitrobenzene being the halogenonitro-compound. A control set of experiments was performed; equimolecular proportions of halogenonitro-compound, phenol, and potassium

hydroxide were used, the condensation being effected at 200—210° for 1 hour. The amount of water used was 0.1 mol.

Phenol ...	<i>o</i> -Chlorophenol	<i>p</i> -Chlorophenol	<i>o</i> -Cresol	<i>m</i> -Cresol	<i>p</i> -Cresol
Yield of ether, %	80	66	72	70	73

*Series D* (b).—The series was repeated under the conditions of experiment I, series C.

Phenol ...	<i>o</i> -Chlorophenol	<i>p</i> -Chlorophenol	<i>o</i> -Cresol	<i>m</i> -Cresol	<i>p</i> -Cresol
Yield of ether, %	91	86	85	87	87

Comparison of the two series shows that the yields are increased between 10—20% by using the increased proportions of phenol and potassium hydroxide.

The fifth experiment in series D (b) was repeated, 95 g. of *o*-chloronitrobenzene, 114 g. of *p*-cresol, and 45 g. of potassium hydroxide being used. At the end of the reaction, the condensation mixture was shaken with very dilute alkali solution until cold; a crystalline meal then separated. After being dried in the air, this weighed 129 g. (94% yield). As a result of the improved conditions worked out, it is possible to prepare ethers similar to the above, without extraction with a solvent, and subsequent vacuum distillation.

*Series E*.—The comparison of yields obtained by using different halogenonitro-compounds was also made.

*Experiment I*. 2:5-Dichloronitrobenzene was condensed with phenol, under the conditions described in the series of experiments D (a), and the yield of ether obtained was 74%. When the experiment was repeated under the conditions of experiments D (b), the yield was increased to 85%.

*Experiment II*. According to Fox and Turner (this vol., p. 1115), when 2:5-dibromonitrobenzene is condensed with phenol at 160—180° for 6 hours, 1 mol. of halogenonitro-compound, 1 mol. of phenol, 1 mol. of potassium hydroxide, and 0.1 mol. of water being used, the yield of 4-bromo-2-nitrodiphenyl ether is 48% of the theoretical. When the condensation was effected under the conditions of experiments D (b), the yield was increased to 85%.

It appears, therefore, that the best conditions for the preparation of substituted diphenyl ethers consist in having increased proportions of phenol and potassium hydroxide, and in working at a temperature not below 200°.

My thanks are due to Dr. E. E. Turner for much helpful advice during this work.

CLVI.—*The Preparation of Compounds analogous in Structure to Sulphinic Acids but containing p-Toluenesulphonimido-groups in Place of Oxygen Atoms. Phenyl- and Methyl-p-toluenesulphonimido-sulphine-p-toluenesulphonylimines:*

By SYDNEY GEORGE CLARKE, JOSEPH KENYON, and HENRY PHILLIPS.

THE resolution of *dl*-*m*-carboxyphenylmethylsulphine-*p*-toluenesulphonylimine (I) (Clarke, Kenyon, and Phillips, J., 1927, 188), corresponding to the *dl*-sulphoxide (II) resolved by Harrison, Kenyon, and Phillips (J., 1926, 2079), provided experimental evidence that the *p*-toluenesulphonimido-group could become linked

with sulphur in the same manner as the oxygen atom of a sulphoxide. It has now been found that compounds can be prepared analogous in structure to sulphinic acids but containing two *p*-toluenesulphonimido-groups in place of the two oxygen atoms of the sulphinic acid group. Two examples of this new class of compound have been

prepared in which R = C<sub>2</sub>H<sub>5</sub> and C<sub>6</sub>H<sub>5</sub> respectively. They can be obtained readily by the action of chloramine-T on solutions of sodium phenyl and ethyl mercaptides. The formation of these compounds, under the experimental conditions employed, provides evidence that in aqueous solution chloramine-T not only undergoes hydrolysis as in equation (a) but also dissociates to give a neutral *p*-toluenesulphonimido-radical as indicated in equation (b).

From a consideration of these equations it would be anticipated that, by the use of a suitable anhydrous solvent in which sodium chloride is insoluble, the production of the *p*-toluenesulphonimido-radical would be favoured and the hydrolysis of chloramine-T suppressed. This deduction receives support from the fact that

a greater yield of the phenyl compound is obtained from solutions of phenyl mercaptan in acetic acid or in pyridine than from solutions of the mercaptan (as sodium salt) in water. Even when a large excess of chloramine-T is employed in these reactions, the same two compounds are obtained, indicating that the sulphur atoms of the mercaptans show little or no tendency to combine with three *p*-toluenesulphonimido-groups to produce compounds analogous to sulphonic acids. The chemical properties of *phenyl-* and *ethyl-p-toluenesulphonimidodisulphine-p-toluenesulphonylimines* are also in agreement with the view that the large *p*-toluenesulphonimido-groups exert a protective influence on the central sulphur atoms and cause them to be far less reactive than the corresponding sulphur atoms of sulphinic acids. For example, sulphinic acids react readily with bromine to yield sulphonyl bromides and condense with formaldehyde, benzoquinone (Hinsberg, *Ber.*, 1884, **27**, 3359) and azobenzene (Hantzsch and Glogauer, *Ber.*, 1897, **30**, 2565), but, under the same experimental conditions, ethyl- and phenyl-*p*-toluenesulphonimidodisulphine-*p*-toluenesulphonylimines do not react with these reagents. A similar difference in behaviour exists between sulphilimines and sulfoxides; *m*-carboxyphenylmethylsulphine-*p*-toluenesulphonylimine (I) cannot be converted into a derivative of sexavalent sulphur, whereas the corresponding sulfoxide (II) readily forms a sulphone. When heated with concentrated hydrochloric acid, the new sulphonylimines slowly decompose, producing the corresponding disulphides, sulphonic acids, and *p*-toluenesulphonamide. The quantities of *p*-toluenesulphonamide obtained are in harmony with the view that two *p*-toluenesulphonimido-groups are present in each molecule.

It was not found possible to replace the imido hydrogen atoms in these compounds by methyl groups by the agency of either methyl sulphate or methyl iodide under various experimental conditions. During such attempted methylations, the compounds decomposed, *p*-toluenesulphon-monomethyl- and -dimethyl-amides being the chief products. From the decomposition products of the methylation of ethyl-*p*-toluenesulphonimidodisulphine-*p*-toluenesulphonylimine, *ethyl-p-toluenesulphonylsulphinamide* (IV) was isolated.

The sulphonylimines undergo oxidation much less readily than do the corresponding sulphinic acids. They are unaffected by perhydrol, but, in alkaline solution, they are converted by potassium permanganate into tribasic acids (V). These new acids yield

*p*-sulphonamidobenzoic acid on hydrolysis with concentrated acids, but the experimental evidence that they contain oxygen atoms linked to the central sulphur atoms is not conclusive.

Ethyl- and phenyl-*p*-toluenesulphonimidodisulphine-*p*-toluenesulphonylimines were also isolated from the products of the interaction of ethyl- and phenyl-thiolacetates with chloramine-T. The failure to obtain the sulphilimines of these salts by this means can be attributed either to the instability of these sulphilimines in the presence of water, or, alternatively, to the preferential formation

of the corresponding sulfoxides, which decompose in a similar manner (Pummerer, *Ber.*, 1909, **42**, 2282; 1910, **43**, 1404) :

The ethyl- and phenyl-*p*-toluenesulphonimidodisulphine-*p*-toluenesulphonylimines isolated from these reactions doubtless arise from the interaction of the chloramine-T with the mercaptans produced during the decomposition of either the sulphilimine or the sulfoxide or both these compounds, as indicated in the above equations.

#### EXPERIMENTAL.

*Ethyl-p-toluenesulphonimidodisulphine-p-toluenesulphonylimine* (III; R = Et).—(a) *From ethyl mercaptan.* Chloramine-T (58 g., 2 mols.) in warm water (150 c.c.) was added to a solution of ethyl mercaptan (6.2 g.) in sodium hydroxide (3*N*, 33 c.c.), and after an hour the solution was acidified with dilute sulphuric acid. The *ethyl-p-toluenesulphonimidodisulphine-p-toluenesulphonylimine* (20 g.) produced was extracted from the precipitate obtained by means of dilute sodium carbonate solution, in which the *p*-toluenesulphonamide (12.8 g.) simultaneously precipitated was insoluble. By acidification of the sodium carbonate extract, the new compound was precipitated. After crystallisation from ethyl alcohol, it had m. p. 189° (decomp.), either alone or when mixed with the *ethyl-p-toluenesulphonimidodisulphine-p-toluenesulphonylimine* prepared from ethylthiolacetic acid as described below.

(b) *From ethylthiolacetic acid.* A warm solution of chloramine-T (240 g.) in water (1000 c.c.) was added to an alkaline solution of ethylthiolacetic acid (48 g.) in sodium hydroxide (3*N*, 200 c.c.). After 3 days, the solid which had separated was removed by filtration, and, on acidification of the alkaline filtrate, *ethyl-p-toluene-*

sulphonimidodisulphine-*p*-toluenesulphonylimine was precipitated. It was purified as described above and then weighed 20.4 g. and had m. p. 189° (decomp.) [Found: C, 47.8; H, 5.0; N, 7.0; S, 23.7.  $C_{16}H_{20}O_4N_2S_3$  requires C, 48.0; H, 5.0; N, 7.0; S, 24.0%. 0.4000 G. required 0.0400 g. of sodium hydroxide for neutralisation to phenolphthalein: equiv., 400.  $(C_{16}H_{19}O_4N_2S_3)H$  requires equiv., 400. Found for the *silver* salt, after drying at 120–130°: Ag, 21.6.  $C_{16}H_{19}O_4N_2S_3Ag$  requires Ag, 21.3%].

The solid which was removed by filtration was triturated with chloroform (150 c.c.); *p*-toluenesulphonamide (83 g., m. p. 138°) remained undissolved. From the chloroform extract a neutral substance (3.1 g.) was isolated which, after crystallisation from ethyl alcohol, had m. p. 128° (decomp.). This neutral compound decomposed at its m. p., yielding an inflammable vapour, and left a residue (97% of the original) which, after crystallisation from ether and light petroleum, had m. p. 108–112°. On hydrolysis with hot concentrated hydrochloric acid, the neutral compound gave 15% of its weight of *p*-toluenesulphonamide (Found: C, 34.4; H, 3.7; N, 4.1; S, 18.2; Cl, 20.9%, corresponding fairly closely with the empirical composition  $C_{10}H_{12}O_4NCl_2S_2$ ).

*The Chemical Properties and Reactions of Ethyl-p-toluenesulphonimidodisulphine-p-toluenesulphonylimine.*—*Hydrolysis.* Dilute sulphuric acid was without action on the compound, but the clear solution obtained by heating it (1.0 g.) with 50% sulphuric acid deposited *p*-toluenesulphonamide (0.82 g.) on cooling [Theoretical quantity for  $C_2H_5S(C_7H_7O_2SN)_2$ , 0.86 g.]. A similar result was obtained by the use of concentrated hydrochloric acid.

*Oxidation.* Formation of 
$$Et \begin{array}{c} \diagup \\ O \end{array} S^{++} \begin{array}{c} \diagdown \\ \diagup \end{array} \begin{array}{l} NH \cdot SO_2 \cdot C_6H_4 \cdot CO_2H \\ N \cdot SO_2 \cdot C_6H_4 \cdot CO_2H \end{array}$$
 To ethyl-*p*-toluenesulphonimidodisulphine-*p*-toluenesulphonylimine (8 g.) dissolved in dilute aqueous sodium hydroxide, small quantities of a saturated solution of potassium permanganate (in all, 13.6 g.) were added during 3 hours. After the passage of sulphur dioxide to dissolve the manganese dioxide, the resulting solution was acidified with dilute sulphuric acid; the new compound (8.2 g., m. p. 260–262°) was then precipitated. After three recrystallisations from alcohol, it had m. p. 275–276° (decomp.), which was unchanged by reprecipitation of the compound from its solution in sodium hydroxide solution and further recrystallisation from alcohol [Found: S, 20.6%. 0.5000 G. neutralised 0.1204 g. of sodium hydroxide: equiv., 166.  $(C_{16}H_{13}O_9N_2S_3)H_3$  requires S, 20.2%; equiv., 159.  $(C_{16}H_{13}O_8N_2S_3)H_3$  requires S, 20.8%; equiv., 154]. This acid (1.0 g.) was heated under reflux with concentrated hydrochloric acid (25 c.c.) for 1.5 hours. . . . *p*-Sulphon-

amidobenzoic acid (0.68 g.), m. p. 284—285°, either alone or when mixed with an authentic specimen of that compound, was filtered from the cold reaction mixture (Found: S, 16.1. Calc. for  $C_7H_7O_4NS$ : S, 15.9%).

*Action of methylating agents. Formation of ethyl-p-toluenesulphonylsulphinamide*,  $Et\cdot SO\cdot NH\cdot SO_2\cdot C_6H_7$ . The sulphonylimine (8 g.), dissolved in *N*-sodium hydroxide (40 c.c.), was treated with methyl sulphate and sufficient sodium hydroxide to maintain the solution alkaline, until the oily precipitate which separated from the hot reaction mixture ceased to increase in amount. On cooling, this oily precipitate solidified; after crystallisation from alcohol, it was obtained (1.8 g.) with m. p. 78—79°, either alone or when mixed with *p*-toluenesulphondimethylamide prepared by the action of methyl sulphate on an alkaline solution of *p*-toluenesulphonamide (Found: S, 16.1.  $C_9H_{13}O_2NS$  requires S, 16.1%). The filtrate from this *p*-toluenesulphondimethylamide was concentrated, and, after several days, it deposited a crystalline sodium salt. On acidification of an aqueous solution of this salt, *ethyl-p-toluenesulphonylsulphinamide* (3.5 g.) was precipitated, and this, after crystallisation from alcohol, had m. p. 120° (Found: S, 25.6; N, 5.6.  $C_9H_{13}O_3NS_2$  requires S, 25.9; N, 5.6%).

By treatment of *ethyl-p-toluenesulphonimidodisulphine-p-toluenesulphonylimine* in boiling toluene containing anhydrous potassium carbonate with methyl sulphate, only a mixture of *p*-toluenesulphonmonomethyl- and -dimethyl-amides was obtained. Similarly, the silver salt of the sulphonylimine, when heated under reflux with methyl iodide, gave *p*-toluenesulphondimethylamide. Each of these methylation reactions yielded small quantities of other products which were not identified.

*Phenyl-p-toluenesulphonimidodisulphine-p-toluenesulphonylimine* (III; R = Ph).—(a) *From thiophenol*. (i) *In water*. To thiophenol (5.5 g., 1 mol.), dissolved in dilute aqueous sodium hydroxide, a warm aqueous solution of chloramine-T (28.3 g., 2 mols.) in water (100 c.c.) was added. The granular precipitate which was thrown down consisted mainly of *p*-toluenesulphonamide, but gave some diphenyl disulphide (5 g.), m. p. 61—62°, when extracted with benzene. The warm filtrate, on cooling, deposited the crystalline sodium salt of phenyl-*p*-toluenesulphonimidodisulphine-*p*-toluenesulphonylimine, m. p. 226° (Found: Na, 4.8.  $C_{20}H_{19}O_4N_2S_3Na$  requires Na, 4.9%). A warm aqueous solution of this salt gave, on acidification, phenyl-*p*-toluenesulphonimidodisulphine-*p*-toluenesulphonylimine which, after crystallisation from alcohol, had m. p. 152—153° [Found: C, 52.9; H, 4.6; N, 6.5; S, 21.3.  $C_{20}H_{20}O_4N_2S_3$  requires C, 53.1; H, 4.5; N, 6.3; S, 21.4%. 0.2000 G. neutralised

0.0176 g. of sodium hydroxide: equiv., 455. ( $C_{20}H_{19}O_4N_2S_3$ )H requires equiv., 448]. The *silver* salt was a white curdy precipitate obtained by vigorously stirring a solution of the sodium salt to which silver nitrate had been added [Found (after drying at  $110^\circ$ ): Ag, 19.9.  $C_{20}H_{19}O_4N_2S_3$ Ag requires Ag, 19.5%].

(ii) *In acetic acid*. Chloramine-T (280 g.) was shaken with a hot solution of thiophenol (55 g.) in glacial acetic acid (300 c.c.). After being heated on a steam-bath for 15 minutes, the mixture was poured into water. The solid material which separated was extracted with benzene to remove diphenyl disulphide, and then digested with hot dilute sulphuric acid. A heavy viscous oil remained which crystallised on cooling and, after recrystallisation, gave phenyl-*p*-toluenesulphonimidodisulphine-*p*-toluenesulphonylimine (40 g.), m. p.  $152-153^\circ$ . A further quantity of this compound (20 g.) was obtained by acidification of the filtrate from the solid material which separated when the reaction mixture was poured into water.

(iii) *In pyridine*. The reaction was carried out as described in (ii). When the reaction mixture was poured into water, only diphenyl disulphide separated. The sulphonylimine was precipitated by the addition of acid to the aqueous pyridine. Thiophenol (5 g.) gave 5 g. of the sulphonylimine.

(b) *From phenylthiolacetic acid*. Chloramine-T (85 g.) was shaken with a solution of the sodium salt of phenylthiolacetic acid (23.5 g.) in hot water. After being heated for 30 minutes on the steam-bath, the mixture was cooled and the water together with some crystalline material was decanted from the compact solid mass which had formed on the bottom of the flask. Diphenyl disulphide (12 g.), m. p.  $60-61^\circ$ , was extracted from this mass with benzene. The residual solid was recrystallised from alcohol and proved to be the sodium salt of phenyl-*p*-toluenesulphonimidodisulphine-*p*-toluenesulphonylimine (4 g.), m. p.  $227-228^\circ$ , either alone or when mixed with the sodium salt prepared directly from sodium thiophenoxide. The crystalline material, mentioned above, was dissolved in hot water and reprecipitated as an oil by the addition of acid. This oil solidified on cooling and proved to be the sulphonylimine, m. p.  $153^\circ$ , either alone or when mixed with the sulphonylimine prepared from sodium thiophenoxide.

*The Chemical Properties and Reactions of Phenyl-*p*-toluenesulphonimidodisulphine-*p*-toluenesulphonylimine.—Hydrolysis.* When heated on a steam-bath for 30 minutes with concentrated hydrochloric acid (100 c.c.), the sulphonylimine (3 g.) gradually lost its crystalline character and gave place to an oil. The hot acid, decanted from the oil, deposited *p*-toluenesulphonamide (1.4 g.) on cooling: on con-

centration, the filtrate from this sulphonamide deposited a further quantity (0.3 g.) of this substance. The filtrate from this second crop of sulphonamide was taken to dryness in a vacuum; the residue (benzenesulphonic acid) gave benzenesulphonamide, after successive treatment with phosphorus pentachloride and ammonium carbonate.

The oil, obtained as described above, solidified on cooling. After being freed from *p*-toluenesulphonamide by extraction with sodium hydroxide solution and recrystallised from light petroleum, it gave diphenyl disulphide (0.7 g.), m. p. and mixed m. p. 60–61°.

*Oxidation.* The preparation of  $\text{Ph-O-S}^{\text{++}}\begin{matrix} \text{NH}\cdot\text{SO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CO}_2\text{H} \\ \text{N}\cdot\text{SO}_2\cdot\text{C}_6\text{H}_4\cdot\text{CO}_2\text{H} \end{matrix}$ .

Perhydrol was without action on hot aqueous solutions of either phenyl-*p*-toluenesulphonimidodisulphine-*p*-toluenesulphonylimine or its sodium salt. The latter compound was, however, successfully oxidised with potassium permanganate. To a solution of the sodium salt (4.4 g.) in water (50 c.c.), heated on a steam-bath, a saturated aqueous solution of potassium permanganate was added during 3 hours. In all, 6.6 g. of permanganate (about 3 mols. oxygen) were added: a further small addition was not decolorised. After passage of sulphur dioxide to dissolve the manganese mud, hydrochloric acid was added; a colourless crystalline solid then separated. After three recrystallisations from alcohol, it (1.2 g.) was obtained with m. p. 201° (decomp.) (Found: N, 5.4; S, 17.9.  $\text{C}_{20}\text{H}_{16}\text{O}_9\text{N}_2\text{S}_3$  requires N, 5.3; S, 18.3%.  $\text{C}_{20}\text{H}_{16}\text{O}_8\text{N}_2\text{S}_3$  requires N, 5.5; S, 19.0%).

When a suspension of this compound (1.0 g.) in concentrated hydrochloric acid was heated under reflux for 1 hour, a silky crystalline compound was produced, m. p. 284–285°, either alone or when mixed with *p*-sulphonamidobenzoic acid.

*Action of methylating agents.* To a solution of the sulphonylimine (9 g.) in dilute aqueous sodium hydroxide heated to 90–95°, methyl sulphate (21 g., 9 mols.) was added gradually with vigorous shaking. During the addition an oil separated which solidified on cooling; after recrystallisation from alcohol, it had m. p. 79–80°, either alone or when mixed with *p*-toluenesulphonodimethylamide. The aqueous filtrate from this sulphonamide gave, on evaporation, a small quantity of a basic oil which was not identified.

The finely divided sulphonylimine (4.5 g.) and potassium carbonate (4.0 g.) were heated under reflux in toluene containing methyl sulphate (2 g.) for 7 hours. The toluene was removed and the portion of the residue insoluble in water was proved to consist of a mixture of *p*-toluenesulphon-monomethyl- and -dimethyl-amides, together with some diphenyl disulphide and unchanged sulphonyl-

imine. The only product which could be isolated from the products of the interaction of the silver salt of the sulphonylimine with methyl iodide was diphenyl disulphide.

The authors wish to thank the Government Grant Committee of the Royal Society and also Imperial Chemical Industries, Ltd., for grants which have defrayed much of the cost of this investigation.

[Received, April 3rd, 1930.]

## CLVII.—*Nor-dl*-ephedrine and *Nor-dl-ψ*-ephedrine.

By DONALD HOLROYDE HEY.

As previous attempts (this vol., p. 18) to obtain *nor-dl*-ephedrine and *nor-dl-ψ*-ephedrine (IV) from *isonitrosopropiophenone* (I) by direct reduction had proved unsatisfactory, attention was directed to the *oxime* of phenylacetylcarbinol (III): this on reduction with sodium amalgam in dilute acetic acid solution readily gave a viscous oil, which on treatment with hydrochloric acid gave *nor-dl*-ephedrine hydrochloride together with a small quantity of *nor-dl-ψ*-ephedrine hydrochloride. By introducing suitable modifications of the methods of obtaining phenylacetylcarbinol described in the literature the yield of this compound has been more than doubled, which therefore greatly improves the efficiency of this method of synthesis. A similar method, depending on the reduction of the oximes of ketonic alcohols of the type  $\text{OH}\cdot\text{CHPh}\cdot\text{COR}$ , has been recorded by Tiffeneau and Lévy (*Compt. rend.*, 1926, 183, 969).

In the reduction of *isonitrosopropiophenone* (I), as carried out by Rabe (*Ber.*, 1912, 45, 2166), in addition to a small quantity of the amino-alcohol (IV), a second compound was obtained, melting at 112°, which was described as the oxime of phenylacetylcarbinol (III). Hartung and Munch (*J. Amer. Chem. Soc.*, 1929, 51, 2262) also observed the formation of a second compound, but only when *isonitrosopropiophenone* was reduced catalytically in the absence of hydrochloric acid. This compound melted at 108–110° and was not identified. The results of the present investigation give further support to Rabe's contention that the compound isolated by him was the oxime of phenylacetylcarbinol, which agrees in all its

properties with those of the oxime here described. The compound isolated by Hartung and Munch has also now been identified as the oxime of phenylacetylcarbinol. A specimen, kindly submitted by Dr. Hartung, produced no depression of melting point when mixed with the oxime described in this communication, and further observations by Dr. Hartung confirm this view. While there are many examples of the reduction of  $\alpha$ -oximino-ketones to amino-ketones, their reduction to oximino-alcohols is apparently very rare. However, the formation of this oxime in the reduction of isonitroso-propiophenone, though unusual, would not necessarily signify that the oximino-group is less susceptible to the action of the reducing agent than the carbonyl group (compare Hartung and Munch, *loc. cit.*), since it is not improbable that, under the conditions employed, the oxime is formed by molecular rearrangement of an intermediate hydroxylamino-alcohol (II).

#### EXPERIMENTAL.

*dl*-Mandelamide was prepared in excellent yield by the method of McKenzie and Wren (J., 1908, 93, 310).

*Preparation of Phenylacetylcarbinol.*—By observing the following modifications in the methods of Wren (J., 1909, 95, 1592) and of Tiffeneau and Lévy (*Bull. Soc. chim.*, 1925, 37, 1247) the yields of phenylacetylcarbinol were increased to about 50% of the theoretical yield. Well-powdered *dl*-mandelamide (20 g.) was added very slowly to an excess of the Grignard reagent (7 mols.), well cooled in ice. The latter was prepared from 22 g. of magnesium, 140 g. of methyl iodide, and 250 c.c. of dry ether. When all the amide had been added, the mixture was kept at room temperature for 1 hour and then gently boiled under reflux for 12 hours. The solution, well cooled in ice, was decomposed by the gradual addition of ice and dilute sulphuric acid. No unchanged amide separated and the liberated phenylacetylcarbinol was extracted with ether and dried. It distilled as a pale yellow oil (9.5 g.) at 135–137°/24 mm. (Found: C, 71.8; H, 6.6. Calc. for  $C_9H_{10}O_2$ : C, 72.0; H, 6.7%). The semicarbazone, from boiling toluene, melted at 194°.

The 2:4-dinitrophenylhydrazone was prepared by warming an alcoholic solution of 2:4-dinitrophenylhydrazine and phenylacetylcarbinol. Orange needles separated on cooling, which after recrystallisation from alcohol melted at 170° (Found: N, 17.1.  $C_{15}H_{14}O_5N_4$  requires N, 17.0%).

The oxime of phenylacetylcarbinol was prepared by boiling under reflux for 2 hours a solution of 5 g. of the ketone, 2.6 g. of hydroxylamine hydrochloride, and 1.5 g. of sodium hydroxide in water with the addition of sufficient alcohol to make the solution homogeneous

at the temperature of boiling. When cold, the solution was acidified and the oxime was extracted repeatedly with ether and dried. Evaporation of the ether left an oily residue, which when kept in a vacuum deposited a crystalline solid (4 g.). Recrystallisation from hot water gave the oxime in white needles, m. p.  $112.5^{\circ}$  (Found: C, 65.55; H, 6.3; N, 8.4.  $C_9H_{11}O_2N$  requires C, 65.45; H, 6.7; N, 8.5%). A small quantity of a less soluble compound was also formed, which crystallised from alcohol in small white needles, m. p.  $231^{\circ}$ . This was in all probability phenylmethylglyoxime (Borsche, *Ber.*, 1907, 40, 740) (Found: N, 15.8. Calc. for  $C_9H_{10}O_2N_2$ : N, 15.7%).

*Reduction of Phenylacetylcarbinol Oxime.*—60 G. of 3% sodium amalgam were gradually added to a solution of the oxime (2 g.) in dilute acetic acid. After 6 hours, the mixture was made alkaline and extracted several times with ether. After drying over solid caustic potash, evaporation of the ether left a colourless viscous oil, which was dissolved in warm hydrochloric acid. The solid which separated on standing was recrystallised from absolute alcohol, nor-*dl*-ephedrine hydrochloride being obtained, m. p.  $192^{\circ}$  after a second recrystallisation (Found: Cl, 18.7. Calc. for  $C_9H_{13}ON, HCl$ : Cl, 18.9%). From the mother-liquor a small quantity of nor-*dl*- $\psi$ -ephedrine hydrochloride was obtained, which after several recrystallisations from absolute alcohol melted at  $169^{\circ}$  (Found: Cl, 18.9%) (compare Nagai and Kanao, *Annalen*, 1929, 470, 157).

### CLVIII.—*The Constitution of Sinactine (1-Tetrahydro-epiberberine).*

By KAKUJI GOTO and ZENJIRO KITASATO.

SINACTINE, the natural occurrence of which was prophesied by W. H. Perkin and his co-workers (Perkin, J., 1918, 113, 494; Haworth, Koepfli, and Perkin, J., 1927, 2261), is present in *Sinomenium acutum*, Reht and Wills, in minute quantities and has been isolated from the root as a sub-alkaloid of sinomenine by Goto and Sudzuki (*Bull. Chem. Soc. Japan*, 1929, 4, 220). These authors assigned to it the formula  $C_{19}H_{21}O_4N$  and suggested that it might contain the tetrahydropapaverine skeleton. We have now found that its formula is  $C_{20}H_{21}O_4N$  and that it contains the tetrahydroberberine skeleton.

Sinactine contains two methoxy-groups and one methylenedioxy-group. Its absorption spectra resemble closely those of tetra-

hydroberberine and tetrahydropapaverine (*loc. cit.*), an *M*/1000-alcoholic solution producing an absorption band at a frequency of about 3500: this similarity suggests a very close structural relation between these compounds (compare Dobbie and Lauder, J., 1903, 83, 614; Kitasato, *Acta Phytochim.*, 1927, 3, 229).

By the action of mild oxidising agents, such as iodine in alcoholic solution, on sinactine a base is produced which forms an intensely orange chloride,  $C_{20}H_{18}O_4NCl$ , corresponding to the berberinium salt. From this base, by reduction, *r*-sinactine is obtained. This melts at  $168^\circ$  and has properties very similar to those of tetrahydroepiberberine (III), m. p.  $169-170^\circ$  (Perkin, J., 1918, 113, 512; Haworth and Perkin, J., 1926, 1777): direct comparison of *r*-sinactine with a specimen of synthetic tetrahydroepiberberine, kindly sent to us by Dr. R. D. Haworth, and the melting point of a mixture of the two substances definitely established their identity.

From the foregoing, it appears that sinactine is *l*-tetrahydroepiberberine (III), that is, the positions of the methylenedioxy-group and the two methoxy-groups in sinactine are the reverse of their positions in tetrahydroberberine (I).

The relationship of the ten-membered ring alkaloids is still more clearly brought out when their formulæ are compared:

## EXPERIMENTAL.

The roots of *Sinomenium acutum* are digested three times with 0.5% hydrochloric acid at the ordinary temperature and the combined extracts are made alkaline with sodium carbonate and shaken thrice with chloroform. The chloroform solution is treated with dilute hydrochloric acid to remove alkaloids (sinomenine, etc.) other than sinactine. Sinactine hydrochloride accumulates in chloroform when this is repeatedly used in the extraction of the alkaloids without evaporation; it is so sparingly soluble in water (0.74%) that it can easily be purified from sinomenine.

Sinactine, m. p.  $175^{\circ}$ , is obtained in needles from a solution of its hydrochloride by means of ammonia or in colourless slender prisms by crystallisation from alcohol. It is sparingly soluble in cold methyl or ethyl alcohol, almost insoluble in water, and readily soluble in chloroform. The solution of a crystal in a drop of acetic acid gives at first no coloration on the addition of sulphuric acid, but gradually a violet tint develops [Found by microanalysis: C, 71.0, 70.5, 71.05; H, 6.4, 6.3, 6.3; N, 4.4; OMe, 18.9.  $C_{18}H_{15}O_2N(OMe)_2$  requires C, 70.8; H, 6.2; N, 4.2; OMe, 18.3%]. The alkaloid has  $[\alpha]_D - 312^{\circ}$  in chloroform ( $c = 1$ ;  $l = 1$ ). It contains a methylenedioxy-group, as it gives a copious precipitate on treatment with phloroglucinol-sulphuric acid; it has no phenolic hydroxyl group, since it does not react with ferric chloride, potassium ferricyanide, or a diazo-solution; and it has no methylimino-group, since after being heated for 2 hours at about  $300^{\circ}$  with hydriodic acid and ammonium iodide it gives no precipitate with silver nitrate.

The hydrochloride separates from water in colourless needles, m. p. about  $272^{\circ}$  (decomp.). The chloroplatinate forms crystals which begin to darken at  $240^{\circ}$  and melt at  $245-247^{\circ}$ .

*r-Sinactine*.—Sinactine (0.5 g.) is dissolved in boiling alcohol, and a 2% alcoholic solution of iodine added in portions. The colour of the iodine disappears rapidly and an orange crystalline precipitate separates (compare Perkin, J., 1918, 113, 514). After  $\frac{1}{2}$  hour's boiling, the precipitate is collected, treated with sulphurous acid to remove a trace of iodine, and recrystallised from boiling water; orange-yellow needles are obtained which darken at  $275^{\circ}$  and decompose at about  $300^{\circ}$ . This iodide is suspended in water and digested with freshly precipitated silver chloride for an hour. After removal of silver compounds, the filtrate and washings are concentrated considerably and treated with hydrochloric acid. The dehydrosinactine chloride that separates after a few hours is recrystallised from hot water by addition of hydrochloric acid:

the orange needles obtained have all the properties of *epiberberin*-ium chloride described by Perkin (*loc. cit.*, p. 516).

Dehydrosinactine chloride (1 g.) is reduced for 5 hours with glacial acetic acid (10 c.c.), 15% sulphuric acid (100 c.c.), and zinc dust. When sodium chloride is added to the filtered solution, a pale yellow precipitate separates: this is collected, washed with dilute sodium chloride solution, dissolved in boiling alcohol, and decomposed by very dilute aqueous ammonia. The base obtained is optically inactive and crystallises from much alcohol in colourless needles, m. p. 168° (Found: C, 71.0; H, 6.2. Calc.: C, 70.8; H, 6.2%). Mixed with synthetic tetrahydro*epiberberine* (m. p. 166–167°), it melts at 166°. Moreover, a solution of the base in glacial acetic acid, on addition of concentrated sulphuric acid, gives a colourless solution which gradually turns deep violet: tetrahydro*epiberberine* shows the same reaction. The hydrochloride of *r*-sinactine separates from much water in fine needles, which decompose at about 286°. The methosulphate, prepared in the same way as tetrahydro*epiberberine* methosulphate (Perkin, *loc. cit.*), crystallises from methyl alcohol in large colourless prisms, m. p. 257° (decomp.). The iodide melts at 275°.

## CLIX.—*Studies of Electrolytic Polarisation. Part IX.*

### *Complex Cyanides: (c) Zinc, Cadmium, and Mercury.*

By SAMUEL GLASSTONE.

FROM previous studies (J., 1929, 690, 702) it was concluded, in contrast to the views of Le Blanc and Schick (*Z. Elektrochem.*, 1903, 9, 636; *Z. physikal. Chem.*, 1903, 46, 213) and of Foerster (*Z. Elektrochem.*, 1907, 13, 561), that the cathode potential-*C.D.* curves and the current efficiency for metal deposition in the electrolysis of complex cyanides depend on (a) the variation of electrode potential with increasing ratio of cyanide to metal in the solution, and (b) the relation of the potential in the presence of excess of cyanide to that at which hydrogen evolution occurs. If the solution under examination is one in which an increase of the cyanide concentration causes an appreciable alteration of potential, *i.e.*, if it corresponds with a position on the metal ion-cyanide titration curve where there is a marked inflexion, polarisation should be appreciable. On the other hand, very little polarisation should result when the addition of cyanide has only a small influence on the electrode potential; this occurs when the solution already

contains an excess of cyanide. If the cathode potential remains below that requisite for the evolution of hydrogen, the efficiency for metal deposition is 100%; but if the *C.D.* exceeds a value at which the rate of deposition of metal is greater than the rate of diffusion of the appropriate ions to the electrode, the cathode potential rises rapidly, the efficiency for metal deposition falls off, and hydrogen evolution commences. If the hydrogen potential is attained before the limiting *C.D.* is reached, the current efficiency decreases at this point, but there is no rapid increase of cathode potential. Since all the polarisation observed in the electrolysis of complex cyanides is due ultimately to concentration changes, and not to the slowness of any chemical reaction, it can be decreased by vigorous stirring of the electrolyte.

The above views, based on observations on complex silver and copper cyanides, have now been tested and confirmed by similar experiments involving electrometric titrations of salts of zinc, cadmium, and mercury with sodium cyanide solutions, together with cathode-potential and current-efficiency measurements at various *C.D.*'s.

Zinc dissolves spontaneously in alkali cyanide solutions with the evolution of hydrogen, since the electrode potential  $\text{Zn}|\text{KCN}$  is about  $-1.25$  volts; hence the electrolytic behaviour of complex zinc cyanide solutions was expected to be similar to that of the cuprocyanides (J., 1929, 702). Cadmium and mercury are not attacked by potassium cyanide solution in the absence of air; on electrolysis their complex cyanides were, therefore, expected to give results similar to those obtained with argentocyanide solutions (J., 1929, 690). The limited observations made by Spitzer (*Z. Elektrochem.*, 1905, **11**, 345) and by Höing (*ibid.*, 1916, **22**, 286) on zinc, and by Efremov (*Ann. Inst. Polyt. Ural*, 1927, **6**, 111) on cadmium, were seen to support these conclusions.

#### EXPERIMENTAL.

The experimental methods were similar to those already used for the study of silver and copper complex cyanides. With zinc and cadmium the electrometric titrations were performed on the corresponding sulphates in *N/5*-solutions; the electrolysis solutions were made from the same salts by the addition of appropriate amounts of cyanide. Sodium cyanide was used almost exclusively throughout this work; independent experiments showed that potassium cyanide gave exactly similar results. For the observations with the mercury cathode, a pure specimen of mercuric cyanide was used; as this substance is almost a non-electrolyte, a small amount of sodium sulphate was added to the solution.

It is noteworthy that mercuric cyanide is stable in contact with metallic mercury, whereas under these conditions most other mercuric salts are unstable and tend to form mercurous salts. Mercurous cyanide, however, is unstable and decomposes immediately into mercuric cyanide and mercury (Abel, *Z. anorg. Chem.*, 1901, 26, 379). The explanation of this behaviour lies in the fact that mercuric cyanide yields only a very small concentration of mercuric ions in solution; from observations made in the course of the present work the mercuric-ion concentration (assumed equal to the activity) is about  $10^{-21}$  g.-ion per litre in  $N/5$ -solutions of the cyanide. According to Abel (*loc. cit.*, p. 375),  $[\text{Hg}_2^{++}]/[\text{Hg}^{++}]$  is equal to 120 when mercuric and mercurous ions are in equilibrium with metallic mercury; hence the concentration of mercurous ions in the mercury-mercuric cyanide system is about  $10^{-19}$  g.-ion per litre. Mercurous salts are generally more highly ionised than corresponding mercuric salts (compare Lowry, *Trans. Faraday Soc.*, 1928, 24, 1), and so only an extremely small concentration of mercurous cyanide can co-exist with mercuric cyanide and mercury. The latter salt is, therefore, stable and the former unstable.

Cathode-potential measurements were made by the methods described in previous papers of this series. Attempts were made to determine the current efficiencies for metal deposition, but only with cadmium was a systematic study possible. Zinc dissolves so readily in solutions containing the slightest excess of free cyanide that even at high *C.D.*'s there was a net loss in weight of the cathode. A rough indication of the efficiencies can, however, be obtained from the cathode-potential measurements. A satisfactory investigation of the current efficiency with a mercury cathode was prevented by experimental difficulties, but approximate determinations were made with an amalgamated copper electrode as well as with one of liquid mercury; the results indicated that the metal was discharged almost entirely as bivalent ions.

Unless otherwise stated, experiments were carried out at room temperature ( $15^\circ$ ). All electrode-potential measurements are expressed on the normal hydrogen scale.

### Results.

*Zinc.*—The electrometric titration curve of zinc sulphate solution with sodium cyanide, a zinc electrode being used as indicator, is shown in Fig. 1. The precipitate of zinc cyanide dissolves completely when the ratio  $\text{Zn} : \text{CN} = 1 : 4$ , in approximately  $N/10$ -solutions (see Treadwell, *Chem.-Ztg.*, 1914, 38, 1230; Corbet, J., 1926, 3190); this fact, together with the shape of the titration curve, suggests that  $\text{Zn}(\text{CN})_4^{--}$  is the chief complex ion present in solution. The

$p_H$  of the  $\text{Na}_2\text{Zn}(\text{CN})_4$  solution is about 10, and the reversible potential of a hydrogen electrode in it is  $-0.57$ ; the reversible zinc potential is  $-0.99$  volt. In the electrolysis of such a solution, therefore, hydrogen may be expected to be liberated at the cathode instead of metal, but the high overvoltage of hydrogen at a zinc cathode prevents this happening. Actually, it has been observed that hydrogen bubbles appear at a zinc electrode in a complex cyanide solution at a potential of  $-1.18$  volts; even at less negative potentials, however, some of the current will be utilised in the discharge of hydrogen ions, since the resulting atoms are removed by diffusion

FIG. 1.

or by depolarisation with air. It is clear, therefore, that 100% efficiency for zinc deposition is not to be expected from solutions containing cyanides.

The titration curve shows that cathodic polarisation cannot be as marked as with silver and copper, since the sudden rise of potential occurring when the ratio  $\text{CN}:\text{Zn}$  exceeds 4:1 is only from  $-0.99$  to  $-1.14$ ; beyond this, the zinc electrode potential rises gradually to  $-1.24$  volts, which is the value in a  $0.5N$ -sodium cyanide solution. Since the free evolution of hydrogen commences at  $-1.18$  volts, the subsequent change of potential of the zinc cathode should be similar to that in a simple cyanide solution in which hydrogen discharge is the only cathodic process (Table I, last column).

The actual cathode potentials (C.P.) and current efficiencies (C.E.) recorded in Table I are in agreement with the predictions

made from a study of the titration curve. Solution I was  $M/10$  with respect to  $\text{Na}_2\text{Zn}(\text{CN})_4$ , and Solution II contained in addition  $N/5$ -sodium cyanide. The current efficiencies, which are in any case very rough, could not be determined for Solution II for the reason given on p. 1239. Experiments were also made with Solution I stirred (500 r.p.m.) at  $15^\circ$ , and unstirred at  $70^\circ$ .

40	-1.39	26	-1.24	36	-1.28	36	-1.47	-1.50

It is to be noted that stirring the electrolyte and raising the temperature have not the same marked influence on the current efficiency for zinc deposition as for copper (*loc. cit.*); this is because the polarisation in the former case is smaller, and so stirring and raising the temperature, which tend to decrease polarisation, cannot be relatively so effective. Further, since the cathode potential for zinc deposition from cyanide solutions is always more negative than that required for the reversible discharge of hydrogen ions, the removal of accumulated hydrogen as a result of stirring will increase the proportion of current devoted to the discharge of these ions, and the efficiency of zinc deposition must decrease in consequence. Similarly, at high temperatures the overvoltage for hydrogen evolution is decreased, and a larger proportion of the current will be utilised in liberating hydrogen than for the same cathode potential at lower temperatures. All the observed results may, therefore, be explained without the necessity of assuming that the complex zincicyanide ion dissociates *slowly* into its constituents.

During the course of this work, it was noted that zinc sulphate solution dissolves appreciable amounts of zinc cyanide: 1 l. of  $M$ -solution dissolves about 0.003 g.-mol. at  $15^\circ$ , and 0.01 g.-mol. at  $70^\circ$ . This suggests, as in the case of silver (see Hellwig, *Z. anorg. Chem.*, 1901, 25, 157), that a complex zinc cyanide *kation*, possibly  $[\text{Zn}_2(\text{CN})_2]^{++}$ , is formed; these complex ions, rather than simple zinc ions, may be actually discharged at the cathode during the electrolysis of cyanide solutions (compare J., 1929, 700, 712).

*Cadmium.*—The electrode potential–titration curve for  $M/5$ -cadmium sulphate solution with sodium cyanide and a cadmium electrode, is shown in Fig. 2; the slight inflexion corresponding with the formation of  $\text{Cd}(\text{CN})_2$  indicates that this substance is comparatively soluble. The electrode potential of cadmium in the system containing cadmium and cyanide in the ratio 1 : 2 is  $-0.49$  volt; hence the solubility of cadmium cyanide in water is of the order of  $10^{-3}$  g.-mol. per litre. This is of a similar order to the solubility of zinc cyanide, but is appreciably greater than that of silver and copper cyanides. It is of interest that at least 1 c.c. of  $N$ -sodium cyanide solution

FIG. 2.

must be added to 10 c.c. of  $N$ -cadmium sulphate solution before a permanent precipitate of cadmium cyanide is formed; the latter is thus appreciably soluble in the sulphate solution, possibly as a result of the formation of a complex kation of the type  $[\text{Cd}_2(\text{CN})_2]^{++}$ . The shape of the titration curve when the ratio  $\text{CN} : \text{Cd}$  exceeds 2 : 1, and the fact that the precipitate of cadmium cyanide dissolves completely when the ratio is *ca.* 3.5 : 1 (see also Corbet, *loc. cit.*), suggests that at least two complex ions,  $\text{Cd}(\text{CN})_3^-$ , or perhaps  $[\text{Cd}(\text{CN})_3(\text{H}_2\text{O})]^-$ , and  $\text{Cd}(\text{CN})_4^{2-}$  are present in solution (see also Pines, *J. Czech. Chem. Comm.*, 1929, 1, 387).

During electrolysis, the cathodic polarisation of cadmium in a solution containing  $\text{Cd} : \text{CN} = 1 : 4$  should be of the same order as with zinc; a rapid rise of potential can occur only between  $-0.67$

and  $-0.82$  volt, and this will be followed by a more gradual rise to about  $-0.95$  volt, the potential of cadmium in  $N/2$ -sodium cyanide solution. There is, however, an important difference between cadmium and zinc as regards hydrogen evolution; it has been found that the gas commences to be evolved freely from a cadmium cathode in sodium cyanide solution at a potential of about  $-1.1$  volts, a value distinctly more negative than that of cadmium in the same solution. It is clear, therefore, that during the electrolysis of complex cadmicyanide solutions the metal should be deposited at almost 100% efficiency, unless the *C.D.* is such that the rate of deposition exceeds the rate of diffusion of cadmium compounds to the cathode. At this limiting *C.D.* the potential will rise and the current efficiency for metal deposition fall. It may be calculated by the method described in a previous paper (J., 1929, 697) that for an  $M/10$ -solution of a cadmium salt the limiting *C.D.* at which the rates of deposition and diffusion are equal is about  $0.0055$  amp./cm.<sup>2</sup>. This value, as in the case of argentocyanide solutions, should be independent of the amount of free cyanide present,\* but should depend on (a) the concentration of the cadmium salt, (b) the temperature of the solution, and (c) whether the solution is stirred or not. Raising the temperature or stirring the electrolyte should raise the limiting *C.D.* for 100% deposition, but dilution should bring about a decrease.

The results obtained in the investigations on the electrolysis of cadmium cyanide solutions are given in Table II. Solution I contained Cd and CN in the ratio of 1 to 4, and in Solution II the ratio was 1 to 6; the concentration of cadmium salt was  $M/10$  in each original electrolyte.

These results are in agreement with the views already expressed; the limiting *C.D.* for 100% efficiency of metal deposition is about  $0.006$  amp./cm.<sup>2</sup> in the  $M/10$ - and  $0.00055$  in the  $M/100$ -solutions. As in the work on silver, the effect of stirring at 500 r.p.m., or of raising the temperature to  $70^\circ$ , is to increase the limiting *C.D.* in the dilute solution four- or five-fold. It is of interest that the limiting *C.D.* for 100% efficiency of metal deposition in an  $M/10$ -cadmium sulphate solution is  $0.006$  amp./cm.<sup>2</sup>; this result indicates, in agreement with expectation, that the simple  $\text{Cd}^{++}$  and the complex  $\text{Cd}(\text{CN})_4^{--}$  ions diffuse at almost the same rate. The limiting *C.D.* is thus independent of the actual concentration of  $\text{Cd}^{++}$  ions, but depends primarily on the total cadmium concentration.

\* If the solution contains a large excess of free cyanide the efficiency may be somewhat lowered, since hydrogen ions may be discharged to replace the gas removed by diffusion and depolarisation.

**Mercury.**—Since mercuric salts, other than the cyanide, are unstable in the presence of mercury, an  $M/10$ -solution of the latter salt was used for the electrometric titration with sodium cyanide and a mercury indicator electrode; the variation of mercury electrode potential with varying  $Hg:CN$  ratios is shown in Fig. 3. The shape of the curve indicates that  $Hg(CN)_4^{--}$  is the main ion formed when alkali cyanide is added to mercuric cyanide, but the absence of any marked horizontal portion between the  $Hg:CN$  ratios 1:2 and 1:4 (i.e., between 0 and 2 added equivs.) suggests that the ion  $Hg(CN)_3^-$  is also formed to some extent. Since mercuric cyanide is soluble in water, it is not possible to verify this conclusion by observations on the solubility in the presence of alkali cyanide. From the titration curve, it may be seen also that on electrolysis the cathode potential of mercury in a solution of mercuric cyanide should alter with increasing polarising  $C.D.$  at first rapidly from 0.18 to 0.03, more slowly to -0.15, rapidly again to -0.25, and finally more gradually to about -0.35 volt. In a solution of  $Na_2Hg(CN)_4$ , the polarisation should be marked at low  $C.D.$ 's, since the mercury potential rises from -0.15 to -0.25 for quite small changes in the  $Hg:CN$  ratio. If the electrolyte contains excess of

free cyanide there should be very little polarisation even at appreciable *C.D.*'s.

As the rate of diffusion of the mercuricyanide ion is probably similar to that of other ions (diffusion coefficient, 1.2 approx.), the limiting *C.D.* for 100% efficiency of mercury deposition should be about 0.006 amp./cm.<sup>2</sup>; above this *C.D.* some of the current must be utilised in the discharge of hydrogen ions. Since the overvoltage for hydrogen evolution at a mercury electrode is more than 0.7, the cathode potential for the liberation of this gas from cyanide

FIG. 3.

solutions will be about -1.3 volts. Hence, in the electrolysis of mercuricyanide solutions, the potential beyond the limiting *C.D.* must rise rapidly from -0.35 to -1.3 volts, and at the same time the current efficiency should fall. The actual results obtained were in agreement with these anticipations. Cathode-potential measurements made by means of the commutator were trustworthy only up to the limiting *C.D.*, for above this point the rate of fall of potential on switching off the current—as might be anticipated from the factors already mentioned—was too great to allow of accurate extrapolation being made. The potentials in Table III are therefore only for *C.D.*'s at which there is no tendency for hydrogen

evolution to occur; the highest *C.D.* quoted for any particular electrolyte may be regarded as the limiting value for 100% efficiency of mercury deposition in that solution. On account of the difficulties of working with a mercury cathode, only a limited number of current-efficiency measurements were made; these, as well as others with an amalgamated copper electrode, indicated that at all *C.D.*'s given in Table III the metal-deposition efficiency was about 100%. Solution I was *M*/10-mercuric cyanide containing some sodium sulphate to increase the conductance; Solution II was *M*/10- $\text{Na}_2\text{Hg}(\text{CN})_4$ , and Solution III contained in addition 0.4*N*-sodium cyanide solution.

TABLE III.  
*Cathode potentials.*

<i>C.D.</i> $\times 10^4$ (amps./cm. <sup>2</sup> ).	Solution I.			Solution II.		
	I.	Diluted 5-fold.	Diluted, at 70°.	II.	Diluted 10-fold.	Solution III.
—	0.18	0.18	0.19	—0.15	—0.13	—0.33
2.0	0.08	0.02	0.09	—0.21	—0.19	—0.36
4.0	—	—0.03	0.04	—0.24	—0.24	—0.37
5.0	—	—0.05	—	—	—0.27	—
6.0	0.01	—0.07	—	—0.27	—0.29	—0.39
8.0	—	—0.15	—	—0.28	—	—
12	—0.02	—0.31	—0.03	—	—	—
20	—0.04	—	—0.06	—0.30	—	—0.41
30	—0.06	—	—0.16	—0.33	—	—0.42
50	—0.19	—	—0.21	—0.34	—	—
60	—0.32	—	—0.32	—0.35	—	—0.43

These results are in harmony with the anticipations based on the general principles applicable to the electrolysis of complex cyanide solutions. As in previous cases, dilution decreases the limiting *C.D.* to an extent proportional to the reduction of concentration, whereas raising the temperature (and stirring) increases this *C.D.* The extent of cathodic polarisation is a function of the variation of the mercury potential with changes in the Hg:CN ratio; although the mercuricyanide ion probably dissociates rapidly into its constituents, there must be some polarisation in Solution II, but less in Solution III.

#### *Summary.*

(1) Cathode-potential and current-efficiency measurements have been made in solutions containing complex cyanides of zinc, cadmium, and mercury.

(2) The main factors influencing the results are (a) the variation of electrode potential with increasing ratio of cyanide to metal, (b) the potential for hydrogen evolution at the given metal, and (c) the concentration of the electrolyte.

(3) There is no reason to believe that any of the complex cyanides studied hitherto dissociate slowly.

(4) Electrometric-titration curves indicate the presence of  $\text{Zn}(\text{CN})_4^{--}$  ions in zinc solutions,  $\text{Cd}(\text{CN})_3^-$  and  $\text{Cd}(\text{CN})_4^{--}$  ions in cadmium solutions, and  $\text{Hg}(\text{CN})_3^-$  and  $\text{Hg}(\text{CN})_4^{--}$  ions in mercuric solutions.

### CLX.—*The Acetates of Ruthenium.*

By (the late) ALFRED WILLIAM MOND.

THE ruthenium salts of the acids of the acetic series appear to be unknown. In this paper the preparation of several of the *acetates* is described. They are all of the complex basic type, as is to be expected from the position of the metal in the periodic table (compare chromium and especially iron). Though the great solubility of most of these compounds makes their purification very difficult, the analytical results indicate that definite chemical individuals were obtained.

They were made by the action of the acid on the hydroxide formed by treating ruthenium trichloride,  $\text{RuCl}_3$ , with alkali. This is generally regarded as the hydrated trioxide  $\text{Ru}_2\text{O}_3 \cdot x\text{H}_2\text{O}$ ; but Howe (*J. Amer. Chem. Soc.*, 1927, **49**, 2381) maintains that it contains quadrivalent ruthenium, and that its formula should be written  $\text{RuO}_2 \cdot x\text{H}_2\text{O}$ , whilst Crowell and Yost (*ibid.*, 1928, **50**, 374) and Remy and Lührs (*Ber.*, 1928, **61**, 917; 1929, **62**, 200) consider that in the hydroxide, and in the more or less hydrolysed solutions of the chloride in water, the metal is partly trivalent and partly quadrivalent. This leads to a difficulty in formulating some of the acetates. Most of them are derived from a complex salt which should be written  $\text{Ru}_2(\text{C}_2\text{H}_3\text{O}_2)_4(\text{OH})_4$  if the metal is quadrivalent, and  $\text{Ru}_2(\text{C}_2\text{H}_3\text{O}_2)_4(\text{OH})_2(\text{OH}_2)_2$  if it is trivalent. The difference in composition for the metal and the carbon lies within the errors of analysis; but the values for the hydrogen, though rather uncertain owing to the difficulty of ensuring complete removal of the water without decomposition, agree best with the assumption that the metal is trivalent. Two of the acetates must contain trivalent ruthenium.

The first product (A) of the action of glacial acetic acid on the trioxide is  $\text{Ru}_2(\text{C}_2\text{H}_3\text{O}_2)_4(\text{OH})_2(\text{OH}_2)_2$ . This on hydrolysis yields (B)  $\text{Ru}_2(\text{C}_2\text{H}_3\text{O}_2)_3(\text{OH})_3(\text{OH}_2)_2$  and (C)  $\text{Ru}_2(\text{C}_2\text{H}_3\text{O}_2)(\text{OH})_5(\text{OH}_2)_2$ . (It seems simpler to distinguish the compounds by letters, rather

than by lengthy systematic names.) These three obviously belong to one type. Two others of a different type were obtained: (D)  $\text{Ru}_2(\text{C}_2\text{H}_3\text{O}_2)_4(\text{OH})_2$ , formed along with (B) in the hydrolysis of (A), and (E)  $\text{Ru}_2(\text{C}_2\text{H}_3\text{O}_2)_5(\text{OH})$ . These differed in properties from the first three, being excessively hygroscopic, and less easily reduced to the metal on ignition.

#### EXPERIMENTAL.

Pure ruthenium sponge, kindly lent by the Mond Nickel Company, was converted through the tetroxide into the trichloride, and thence by precipitation in aqueous solution with alkali into the hydroxide, which was washed, dried, and used in the subsequent work.

*Methods of Analysis.*—For the estimation of ruthenium, a weighed quantity of the compound was heated in a porcelain crucible, and then ignited strongly in a stream of hydrogen (introduced by a silica tube passing through the lid) until the weight was constant. For the two compounds (D) and (E) it was necessary, in order to prevent reaction with the crucible in the earlier stages, to wrap the sample in filter paper and heat it at first gently and then more strongly until the paper was burnt away; the subsequent reduction in hydrogen was then carried out as before.

The carbon and hydrogen were determined by combustion.

(A).  $\text{Ru}_2(\text{C}_2\text{H}_3\text{O}_2)_4(\text{OH})_2(\text{OH}_2)_2$ .—Freshly prepared hydroxide was boiled for 2 hours with glacial acetic acid. The dark green, almost black, solution was filtered and concentrated on a water-bath. On cooling, a solid separated, which was filtered off and, after removal of as much as possible of the mother-liquor by pressing between filter papers, was dried in a desiccator over sulphuric acid. It formed a black crystalline powder, readily and completely soluble in water or alcohol to a deep green solution (Found: Ru, 40.0; C, 18.71; H, 3.18.  $\text{C}_8\text{H}_{18}\text{O}_{12}\text{Ru}_2$  requires Ru, 39.93; C, 18.85; H, 3.53%). A further but less pure yield was obtained from the mother-liquor.

(B).  $\text{Ru}_2(\text{C}_2\text{H}_3\text{O}_2)_3(\text{OH})_3(\text{OH}_2)_2$ .—A strong solution of the previous compound in water was boiled for about 20 minutes. It became acid, turned brown, and deposited a black precipitate. This was filtered off and dried at  $80^\circ$ . It was insoluble in water (Found: Ru, 43.9; C, 15.45; H, 3.32.  $\text{C}_6\text{H}_{16}\text{O}_{11}\text{Ru}_2$  requires Ru, 43.51; C, 15.40; H, 3.42%).

(D).  $\text{Ru}_2(\text{C}_2\text{H}_3\text{O}_2)_4(\text{OH})_2$ .—The brownish filtrate from (B) was evaporated on a water-bath. It gave no signs of crystallising, but left a black powder, very hygroscopic and readily soluble in alcohol, from which it was precipitated unchanged by ether. A drop of the concentrated aqueous solution, when evaporated on a warmed microscope slide, formed a network of brownish-black crystals

(Found: Ru, 43.08; C, 19.62; H, 3.34.  $C_8H_{14}O_{10}Ru_2$  requires Ru, 42.96; C, 20.28; H, 2.96%).

(C).  $Ru_2(C_2H_3O_2)(OH)_5(OH_2)_2$ .—On prolonged treatment with water, the tetra-acetate (A) undergoes further hydrolysis; after 24 hours' treatment with dilute acetic acid at  $100^\circ$ , the solution on evaporation left a residue of a black powder, completely soluble in water or alcohol to a brownish-green solution, and approximating in composition to  $Ru_2(C_2H_3O_2)_2(OH)_4(OH_2)_2$ . When this was boiled with water, nearly all the ruthenium was precipitated as a black powder of the composition of (C) (Found: Ru, 53.30; C, 6.10; H, 3.01.  $C_2H_{12}O_9Ru_2$  requires Ru, 53.05; C, 6.26; H, 3.13%).

(E).  $Ru_2(C_2H_3O_2)_5OH$ .—Freshly prepared ruthenium hydroxide was dissolved in 50% acetic acid, and the deep green solution filtered and evaporated to dryness. A black, very hygroscopic residue remained, which gave a deep green solution in water or alcohol, and was precipitated from the latter as a black powder (Found: Ru, 39.5; C, 23.41; H, 3.5.  $C_{10}H_{16}O_{11}Ru_2$  requires Ru, 39.47; C, 23.28; H, 3.10%).

*Ruthenium Formates*.—Ruthenium hydroxide dissolves readily in 50% formic acid, and the deep green solution on evaporation leaves a black crystalline residue very soluble in water, but, unlike the acetates, insoluble in alcohol. The composition of this approximates to the formula  $Ru_3(HCO_2)_7(OH)_2 \cdot 5H_2O$  (Found: Ru, 41.0; C, 11.2; H, 1.96.  $C_7H_{19}O_{21}Ru_3$  requires Ru, 41.00; C, 11.29; H, 2.55%). Belloni (*Arch. Pharm.*, 1909, 247, 123) obtained in the same way from ferric hydroxide a formate of the similar formula  $Fe_3(HCO_2)_7(OH)_2 \cdot 7H_2O$ .

On prolonged heating with water, the *ruthenium formate* is partially hydrolysed, with the production of a series of yellow, brown, and black products, some soluble in water and some in alcohol, which were not further examined.

## CLXI.—*Physicochemical Studies of Complex Acids.* *Part I. Tungstic Acid.*

By HUBERT THOMAS STANLEY BRITTON and WILLIAM LESLIE  
GERMAN.

IN a previous communication (Britton, J., 1927, 147) it was shown that in solution tungstic acid reacts with sodium hydroxide as a dibasic acid, but that in all other respects its behaviour is abnormal. The present paper deals with potentiometric and conductometric

experiments which have been carried out to gain some insight into its nature. For this purpose, it was possible to use the quinhydrone electrode successfully in acid solutions.

When a concentrated solution of sodium tungstate is treated with an excess of hydrochloric acid, tungstic acid is usually precipitated. If, however, dilute solutions are employed, no separation occurs, the solution remaining perfectly clear. This is a surprising fact in view of the insolubility of tungstic acid in dilute acid solutions, though the freshly precipitated oxide may often be peptised by concentrated acid solutions. It might be inferred, from the approxi-

FIG. 1.

mate  $p_H$  curve given in the earlier paper, that the comparatively high concentration of hydrogen ions set up in the solution immediately after the amount of added hydrochloric acid exceeded 1.5 mols. per mol. of sodium tungstate, was caused by the liberation of tungstic acid in an ionised form, the tungstic acid hitherto produced having combined with the undecomposed sodium tungstate in the form of polytungstates. Contrary to expectation, the following work indicates that the enhanced hydrogen-ion concentration is due to free hydrochloric acid, which, on the basis of the equation  $\text{Na}_2\text{WO}_4 + 2\text{HCl} \rightarrow 2\text{NaCl} + \text{WO}_3 \cdot \text{H}_2\text{O}$ , would not

be expected to exist until 2 mols. are added, unless an inert sodium polytungstate (which could resist the attack of hydrochloric acid) were produced in the course of the reaction.

#### EXPERIMENTAL.

Quinhydrone yielded reproducible *E.M.F.*'s in all solutions of tungstates, the contact electrode being bright platinum foil attached to a platinum wire fused into the end of a glass tube containing mercury. The solutions undergoing examination were placed in beakers, to which about 0.05 g. of quinhydrone had been added. They were connected, through a salt bridge containing a saturated solution of potassium chloride, the ends of which were

plugged loosely with filter paper, to a normal calomel electrode. Before any potentials were measured, the solution was vigorously shaken mechanically. These measurements were made at room temperature, and the  $p_H$  values were calculated by using the appropriate normal reduction potential of quinone-quinol obtained from Biilmann and Krarup's formula (J., 1924, 125, 1954).

The conductometric titrations were performed in a thermostat, carefully regulated to  $25.0^\circ \pm 0.05^\circ$ , a specially designed cell being used in which efficient mechanical stirring was possible without moving the cell or disturbing the electrodes (see Fig. 1) The cell has a capacity of 150 c.c.; it is provided with a tightly fitting

FIG. 2.

ebonite cap, through which pass two glass tubes supporting the square platinum electrodes and, in the centre, a short copper tube in which the rod of the glass paddle rotates. The latter, which operates below the electrodes, is prevented from coming into contact with them by means of the rubber band placed just below the copper tube. The paddle rod is supported in the aluminium pulley wheel by means of a tightly fitting rubber bung in which it is fitted. The electrodes were platinised in the usual manner. The water used in the solutions had a specific conductivity of  $4 \times 10^{-6}$  mho.

*Reaction between Sodium Tungstate and Hydrochloric Acid.*—

(a) *Potentiometric method.* This reaction has been investigated electrometrically in solutions of various concentrations, but as the type of curve obtained in all cases is the same, reference will be made only to those relating to the more dilute solutions. In Fig. 2

are given the quinhydrone curves illustrating the course taken by the hydrogen-ion concentration when 50 c.c. of 0.05*M*-sodium tungstate were titrated with 0.1095*M*-hydrochloric acid. Curve A represents the change occurring during a titration in which about 3 minutes elapsed between each addition of acid. Curve B was constructed from  $p_H$  measurements made on solutions corresponding with various stages of the titration after they had been allowed to stand for one week. Curve C refers to data obtained from solutions corresponding with different stages of the titration after 5 minutes' boiling followed by immediate cooling to room temperature. The  $p_H$  values at different stages of the titration under these conditions are recorded in Table I. Two inflexions appear in Curve A, one of which was obscured in the curve given in the earlier paper on account of difficulties introduced by the electrodes then used. The first occurs between  $p_H$  6.3 and 3.8, the corresponding polytungstate formed varying from about 2.3 to 4.0 mols. of  $WO_3$  per mol. of  $Na_2O$ . These limits happen to be those associated with the so-called paratungstate and the metatungstate respectively. This inflexion disappears (as shown Curves B and C) when the solutions concerned are boiled or allowed to stand. The second inflexion indicates that after the metatungstate has been formed the solution rapidly acquires an acid reaction of a magnitude similar to that which would be caused by free hydrochloric acid. Curve D represents the course which would have been taken by the hydrogen-ion concentration if the hydrochloric acid had reacted with the sodium tungstate in accordance with the equation  $Na_2WO_4 + 2HCl \longrightarrow 2NaCl + WO_3 \cdot H_2O$ , on the assumptions (1) that, after the stoichiometrical

75.0	"	1.61	1.61*	1.60*

\* Some precipitation had taken place.

amount of acid has been added, the hydrogen ions are due only to the excess of hydrochloric acid, and (2) that the tungstic acid liberated has no effect. Such an assumption seemed justifiable in view of the observations of Kargin (*Kolloid-Z.*, 1929, 49, 281), who found that tungstic acid sols had  $p_H$  values of 3.69–3.68.

Curve D was obtained with the quinhydrone electrode, and relates to the addition of 0.1095*N*-hydrochloric acid to a volume (*viz.*, 95.6 c.c.) of solution equal to that of the solution in the original titration when exactly 2 mols. (45.6 c.c.) of hydrochloric acid had been added, and which contained the exact weight of sodium chloride that would have been formed if the reaction shown above had at that point been just completed. Typical data are given in Table II. Ageing and boiling had no great effect on the  $p_H$  values of the very acid solutions, in spite of the fact that the solutions to which more than 50 c.c. of hydrochloric acid had been added underwent partial precipitation of tungstic oxide.

TABLE II.

HCl, c.c.	Corresponding vol. of HCl for Curve A, c.c.	$p_H$ .		Difference, 100 [H <sup>+</sup> ].
		NaCl + HCl.	Curve A.	
4.4	50	2.44	2.00	0.64
14.4	60	2.00	1.77	0.70
24.4	70	1.77	1.67	0.44
34.4	80	1.67	1.58	0.49

Increasing the concentrations of the reactants had little effect on the reaction as indicated by  $p_H$  data. One significant difference, however, occurred in the appearance of solutions containing more than 1.5 mols. of hydrochloric acid on boiling or ageing. Thus, when 0.55*N*-hydrochloric acid and 0.250*M*-sodium tungstate were used, the solution became opalescent with 1.5 mols. and increased with more acid until coagulation ensued at  $p_H$  1.9 on ageing and at  $p_H$  1.3 after boiling. The tungstic acid formed in these experiments, therefore, first exists in a perfectly clear solution, but on being boiled or kept, it undergoes very gradual precipitation. The surprising facts are that this precipitation has very little influence on the hydrogen-ion concentration, and further, that this concentration is greater than that which can be attributed to the excess of hydrochloric acid. It was suggested in the previous paper that the tungstic acid might possibly exist in the clear acid solution in a sub-colloidal form peptised by the hydrochloric acid. Were this the case, it would appear that a little hydrochloric acid would be either adsorbed by or chemically combined with the tungstic acid, and consequently the hydrogen-ion concentration of the acid solution would be slightly reduced. This is contrary to the facts. Nevertheless, the precipitation of the tungstic acid on standing suggests that it is colloidal; so also does the fact that if an electrolyte, such as potassium chloride, be included in the sodium tungstate solution, precipitation occurs much more readily on addition of hydrochloric acid.

A series of electrometric titrations was made of solutions to which 25 c.c. of *N*-potassium chloride had been added. The curves obtained were identical with A in Fig. 2, but the solutions began to become cloudy at the stage corresponding approximately with the formation of sodium metatungstate. Table III (col. 2) shows the  $p_H$  values relating to various additions of 0.535*N*-hydrochloric acid to a mixture of 50 c.c. of 0.1*M*-sodium tungstate and 25 c.c. of *N*-potassium chloride: since the amount of acid required for double decomposition is 18.7 c.c., the acid is in excess in every case. The third column, referring to the  $p_H$  values of solutions containing the

same amounts of potassium chloride, sodium chloride, and hydrochloric acid, again shows that the tungstic acid solutions possessed enhanced hydrogen-ion concentrations. It should be emphasised that any possible influence caused by the potassium chloride was eliminated by the inclusion of this salt in all these solutions.

(b) *Conductometric method.* The two conductometric titrations detailed in Tables IV and V illustrate the nature of the reaction taking place between sodium tungstate and hydrochloric acid in solutions of different concentrations.

The curve illustrating Table IV is given in Fig. 3, and is seen to be in harmony with the potentiometric curves given in the previous paper and in Fig. 2 of the present paper. The sharp break at 1.93 c.c. corresponds with the neutralisation of the free alkali. Afterwards the conductivity does not begin to change appreciably until sufficient acid has been added to form the paratungstate in solution, whereupon a somewhat gradual increase occurs until 4.35 c.c. of acid have been added. At this point a sharp rectilinear increase in conductivity begins, and passes through the theoretical end-point at 5.01 c.c., *i.e.*, when the additional 3.08 c.c. calculated for the conversion of the sodium tungstate into sodium chloride have been added. The data in Table V give a similar curve.

An attempt has been made to analyse these conductometric-titration curves on the assumption that the observed specific conductivity of a solution at any point in a titration is equal to the sum of the specific conductivities of the solutes at the dilutions in which they are present. For the purpose of calculation, the reaction between sodium tungstate and hydrochloric acid was regarded as taking place according to the equation on p. 1250, and the liberated tungstic oxide was assumed to contribute no conductivity to the solution. The data for sodium tungstate were extrapolated from the records of Walden (*Z. physikal. Chem.*, 1887, 1, 529), and those for sodium chloride and hydrochloric acid from the data given in Landolt-Bornstein's "Tabellen." Tables IV and V give the calculated values of the specific conductivities so obtained. Table IV shows a satisfactory agreement between the calculated and observed values over the range of 2—4 c.c. of added acid; thereafter the observed values are considerably higher than those calculated on the assumption that free hydrochloric acid was present in the solution only after 5.01 c.c. had reacted. The character of the curve in Fig. 3 indicates that the free acid must have existed before that point, actually from 4.35 c.c. If this were so, it would appear that the sodium polytungstate formed at this stage behaved as if it were the salt of a strong acid and therefore was not decomposed by hydrochloric acid. Such a possibility is not easily reconciled with the  $p_H$  values of tungstic acid sols. Similar conclusions may be drawn from

Table V, although it will be observed that, corresponding with additions of acid up to 2.0 c.c., the differences between the observed and calculated specific conductivities of these more concentrated solutions are somewhat greater than in Table IV. Although the theoretical end-point in this case is at 3.08 c.c., the considerable discrepancies appeared at 2.5 c.c.

It may be argued, that, in the first stages of these titrations, the tungstic acid immediately combines with the undecomposed sodium tungstate to form a polytungstate. This appears to be the case, at

FIG. 3.

any rate until the solute has acquired the composition of sodium metatungstate ( $\text{Na}_2\text{O}_4\text{WO}_3$ ), as may be seen from Table VI. This table gives the specific conductivities ( $\kappa \times 10^3$ ) of solutions of sodium tungstate, paratungstate, and metatungstate at various dilutions as calculated from the data of Walden (*loc. cit.*), Rosenheim (*Z. anorg. Chem.*, 1916, **96**, 139), and Soboleff (*ibid.*, 1896, **12**, 16) respectively. The dilutions refer to the volumes in litres containing 1 g.-atom of sodium.

TABLE VI.

Dilution.	32.	64.	128.	256.	512.	1024.
Normal tungstate .....	2.80	1.49	0.78	0.40	0.21	0.11
Paratungstate .....	2.14	1.25	0.70	0.39	0.21	0.12
Metatungstate .....	2.80	1.54	0.84	0.46	0.24	0.13

These figures reveal that the introduction of tungstic acid into a solution of sodium tungstate results in a comparatively small change in conductivity, probably owing to the ionisation of the polytungstates being similar to that of the normal tungstate, thus:  $\text{Na}_2[\text{O}(\text{WO}_3)_x] \rightleftharpoons 2\text{Na}^+ + [\text{O}(\text{WO}_3)_x]^-$ . It appears probable, in view of inflexions in the potentiometric and conductometric curves occurring when approximately 1.5 mols. of hydrochloric acid have been added to 1 mol. of sodium tungstate, in which case  $x = 4$ , that a polytungstate is formed very soon afterwards which behaves as a salt of a strong acid, and therefore resists reaction with further hydrochloric acid and thus remains in solution as such, imparting increased hydrogen-ion concentration and specific conductivity to the solution. Such a view seems feasible when it is remembered that tungstic acid sols, prepared by the prolonged dialysis of solutions of sodium tungstate to which an excess of hydrochloric acid has been added, contain an appreciable amount of sodium oxide (compare Graham, *Proc. Roy. Soc.*, 1864, **13**, 340; Sabanéeff, *Z. anorg. Chem.*, 1897, **14**, 354; Biltz and Vegesack, *Z. physikal. Chem.*, 1910, **68**, 376). If it be assumed that such a sodium polytungstate is formed in these conductometric titrations at the points at which the sudden increases in conductivity begin, viz., at 4.35 c.c. in the first titration and 2.42 c.c. in the second, and that the conductivities then prevailing remain constant as far as the complex tungstate and sodium chloride in the solution are concerned, then the increases in conductivity caused by subsequent additions of hydrochloric acid will be due entirely to the added acid. It happens that in both cases the complex tungstate formed at this stage corresponds with  $\text{Na}_2\text{O}, 5\text{WO}_3$ . It will be seen from Fig. 3 that the specific conductivity due to it and the sodium chloride is  $17.4 \times 10^{-4}$  mho. To test this view, the specific conductivities of the supposed excesses of hydrochloric acid in the various dilutions were calculated and added to the observed conductivity at the point when the limiting complex tungstate was considered to be formed. Table VII, giving

TABLE VII.

Titration.	HCl, c.c.	Dilution of HCl (litres).	Specific conductivity $\times 10^3$ ,	
			obs.	calc.
I	5.0	521	2.51	2.61
	5.5	296	3.07	3.20
	6.0	207	3.61	3.78
	6.5	160	4.22	4.35
	7.5	110	5.09	5.48
II	3.4	35.4	20.0	20.5
	3.8	24.6	24.3	25.0
	4.2	18.9	28.6	29.4
	4.4	16.9	31.2	31.5

the observed and calculated conductivities of the acid solutions in the two titrations, supports this hypothesis.

It was decided to test whether this idea would account for the increased acidity of solutions of sodium tungstate to which an excess of hydrochloric acid had been added. If the complex  $\text{Na}_2\text{O}_5\text{WO}_3$  were formed in the course of the potentiometric titration (Fig. 2), then the amount of acid added in excess of 36.5 c.c. would determine the hydrogen-ion concentration. The following table has been compiled on this basis, it being assumed that the hydrochloric was completely ionised.

HCl, c.c. ....	40.0	50.0	60.0	70.0	80.0
$p_{\text{H}}$ , obs. ....	2.49	2.00	1.77	1.67	1.58
$p_{\text{H}}$ , calc. ....	2.37	1.83	1.63	1.51	1.44

The agreement is not entirely satisfactory, although comparison with the data given in the third column of Table II shows that the hypothesis accounts for much of the increased hydrogen-ion concentration. It also explains the difference in  $p_{\text{H}}$  found in the potassium chloride experiments (see Table III).

Boiling and ageing of acid tungstate solutions had no effect on their specific conductivity, but had slight effects on those solutions in which insufficient acid had been added to form the complex. This is in accordance with the  $p_{\text{H}}$  observations.

*Reaction between Sodium Tungstate and Weak Acids.*—As typical acids, phenylacetic and acetic were chosen, but since the published values of the dissociation constant of the former acid had been obtained from conductivity data, it was considered advisable to redetermine its value at 18° by means of the hydrogen electrode.

NaOH, c.c. ...	7.5	12.5	15.0	20.0	23.0	25.0	27.5
$p_{\text{H}}$ .....	3.73	4.04	4.18	4.45	4.68	4.78	4.95
$K_a \times 10^5$ .....	5.51	5.48	5.44	5.34	5.38	5.54	5.30

Mean  $K_a = 5.4 \times 10^{-5}$ .

The following  $p_{\text{H}}$  values of various points on the titration curve of 50 c.c. of 0.0667*N*-phenylacetic acid with 0.0980*N*-sodium hydroxide were confirmed by the *E.M.F.* obtained with the quinhydrone electrode. Previous values at 25° range from 5.0—5.45  $\times 10^{-5}$  (Ostwald, *Z. physikal. Chem.*, 1889, 3, 369; Dittrich, *J. pr. Chem.*, 1896, 53, 368; White and Jones, *J. Amer. Chem. Soc.*, 1910, 44, 197).

Fig. 4 gives the titration curves of 50 c.c. of 0.05*M*-sodium tungstate solution with 0.0667*N*-phenylacetic acid and with 0.0936*N*-acetic acid solution. The upper curves represent the  $p_{\text{H}}$  values which would have been established if the sodium tungstate had been entirely converted into the sodium salts of the weak acids

when the stoichiometric amount of the respective acids had been added, and if, thereafter, the curves represented the  $p_H$  values of weak acid solutions buffered by the sodium salts, it being assumed as before that the tungstic acid set free had no effect on their hydrogen-ion concentrations. It is seen that the initial parts of the curves indicate a buffered action in the same  $p_H$  zone as when hydrochloric acid was used. The lower  $p_H$  values assumed by the two solutions soon after 1 equiv. of acid had reacted prove that, some time before the 2 mols. of weak acid had been added, a sodium polytungstate must have been formed which behaved as the salt of strong acid

FIG. 4.

and was in consequence undecomposable by weak acids. If it be considered that this particular sodium polytungstate is formed very soon after the inflexions have occurred, say at 50 c.c. ( $\equiv 1.33$  equivs.) of phenylacetic acid, and 35.6 c.c. ( $\equiv 1.33$  equivs.) of acetic acid, then it is easy to calculate what  $p_H$  values would be set up by the added acids in the presence of the amounts of salts of the respective weak acids formed in the production of the complex tungstate. Tables VIII and IX give (1) the  $p_H$  values of the acid solutions in the two titrations, (2) those which would have been set up if the sodium tungstate had been completely decomposed, liberating tungstic oxide, and (3) those calculated on the basis that the polytungstate formed which resisted the attack of these acids was  $\text{Na}_2\text{O}, 3\text{WO}_3$ .

TABLE VIII.

70	4.59	—	4.67
80	4.46	5.49	4.49
90	4.35	4.97	4.36
100	4.26	4.74	4.27
110	4.20	4.59	4.19
120	4.11	4.48	4.12

TABLE IX.

Acetic acid;  $K_a=1.8 \times 10^{-5}$ .

Acid, c.c.	$p_H$ (1).	$p_H$ (2).	$p_H$ (3).
50	5.11	—	5.14
60	4.91	5.65	4.91
70	4.79	5.25	4.76
80	4.68	5.05	4.65
90	4.65	4.91	4.56
100	4.56	4.80	4.49

In both tables the figures given in the second and fourth columns are in remarkably good agreement. It is fairly certain, therefore, that the cause of the non-precipitation of tungstic oxide from dilute acid solutions is to be traced to the existence of sodium polytungstate, probably in the form of a colloidal electrolyte, *e.g.*,  $2Na^+ + [O(WO_3)_x]^{x-}$ , in which the anion contains much tungstic oxide that is perhaps in a molecularly polymerised form, or, more probably, in a negatively charged colloidal micelle. One difference between the action of a strong and a weak acid lies in the extent to which the normal tungstate is decomposed before it can exist in a solution containing an excess of an acid. When hydrochloric acid was used, the polytungstate shown to be present in acid solution had approximately the composition  $Na_2O, 5WO_3$ , whereas that present in solutions of the weak acids corresponded to  $Na_2O, 3WO_3$ . Much less decomposition had thus occurred.

These observations throw much light on the methods which have been adopted to prepare various polytungstates. Thus, Lefort (*Compt. rend.*, 1876, 82, 1182; *Ann. Chim. Phys.*, 1876, 9, 98) prepared  $Na_2O, 3WO_3, 4H_2O$  by crystallising an aqueous solution of the precipitate obtained by pouring a solution of sodium tungstate into one of boiling acetic acid. Wells (*J. Amer. Chem. Soc.*, 1907, 29, 112) and Gibbs (*Proc. Amer. Acad.*, 1880, 15, 1) both obtained  $Na_2O, 2.5WO_3$  from cold acetic acid solutions of sodium tungstate. By the use of solutions of strong acids (hydrochloric and nitric), substances considerably richer in tungstic oxide have been prepared. According to Ullik (*Sitzungsber. Wien Akad.*, 1867, 56, 157; *J. pr. Chem.*, 1868, 103, 147) and Leontowitsch (*J. Russ. Phys. Chem. Soc.*, 1905, 37, 130) respectively,  $Na_2O, 8WO_3, 12H_2O$  and  $Na_2O, 6WO_3, 15H_2O$  may thus be prepared. The fact that these polytungstates may be obtained from acid solutions furnishes remarkable support to the conclusions drawn from the foregoing experiments.

It was suggested on p. 1257 that the sodium polytungstates containing more tungstic oxide than the metatungstate behaved as if they were the salts of a strong acid, in that they were not easily decomposed by hydrochloric acid. The mode of ionisation of such

an acid cannot be confirmed by direct experiment on account of the insolubility of tungstic oxide. Dumanski, Buntin, Dijatschkovski, and Kniga (*Kolloid-Z.*, 1926, **38**, 208) studied the reaction between sodium tungstate and hydrochloric acid by means of conductivity and cryoscopic measurements. They considered that the rapid increase in conductivity and the abnormal depression of the freezing points (greater than would have been expected if colloidal tungstic acid had been liberated), which occurred after approximately 1.4 equivs. of hydrochloric acid had been added, indicated that tungstic acid was being set free as an ionised semi-colloid. Although this interpretation at first sight may appear to be convincing, it is felt that the hypothesis now advanced is the true one, especially as it affords an explanation of the methods adopted to prepare various polytungstates having high acid content.

The  $p_H$  values of Kargin's (*loc. cit.*) tungstic acid hydrosols do not give any indication of dissociation of the order that would be necessary to impart to the solution the conductivity observed. It appears probable, on the basis of observations described in this paper, coupled with those of Sabanéeff (*loc. cit.*) and Biltz and Vege-sack (*loc. cit.*), that dialysis, even when prolonged, does not cause all the sodium to be removed from the colloidal solution, that Kargin's tungstic acid hydrosols contained a little sodium, and that this sodium was positively charged and the tungstic acid was present as a negatively charged micelle. If the structure and stability of tungstic acid sols, prepared by dialysis of acidified solutions of sodium tungstate, can thus be accounted for, then it appears that the  $p_H$  values of such sols are caused by the hydrogen-ion concentration of the sodium polytungstate they contain.

The authors take this opportunity to thank the Chemical Society for a grant from its Research Fund, and one of us (W. L. G.) thanks the Devon County Education Committee for a Major Exhibition and the Department of Scientific and Industrial Research for a grant which made this collaboration possible.

## CLXII.—*Physicochemical Studies of Complex Acids.* *Part II. Vanadic Acid.*

By HUBERT THOMAS STANLEY BRITTON and ROBERT ANTHONY ROBINSON.

A NUMBER of alkali-metal vanadates have been described and have generally been prepared either by fusion of carbonates with vanadium pentoxide or by crystallisation of solutions containing various

amounts of acid or alkali. Vanadates are said to exist having the general formula  $n\text{Na}_2\text{O} \cdot \text{V}_2\text{O}_5 \cdot x\text{H}_2\text{O}$ , where  $n = 3, 2, 1, \frac{5}{8}, \frac{4}{7}, \frac{3}{5}, \frac{3}{7}, \frac{2}{5}, \frac{1}{5}$ , etc. Nevertheless, little work has been done on the constitution of alkali vanadates in solution, the most comprehensive investigation being that of Düllberg (*Z. physikal. Chem.*, 1903, 45, 129), who studied the conductometric titration of sodium orthovanadate solutions with hydrochloric acid under various conditions, determined the freezing-point depressions of different vanadate solutions, and postulated the existence in solution of a hexavanadic acid,  $\text{H}_4\text{V}_6\text{O}_{17}$ .

Since the addition of the slightest quantity of acid to a sodium orthovanadate solution produces a yellow coloration, it is interesting to note that while the ortho-, pyro-, and meta-salts are white or a faint yellow, the higher vanadates are orange or red. Thus,  $\text{Na}_2\text{O} \cdot 2\text{V}_2\text{O}_5 \cdot 9\text{H}_2\text{O}$  has been obtained in orange-red crystals (von Hauer, *Sitzungsber. Akad. Wien*, 1856, 21, 337; 1860, 39, 455), and on being heated on the water-bath gives the metavanadate and  $\text{Na}_2\text{O} \cdot 3\text{V}_2\text{O}_5$  (Norblad, *Acta Lund Univ.*, 1874, 2, 1). Norblad also isolated orange-red crystals of  $2\text{Na}_2\text{O} \cdot 3\text{V}_2\text{O}_5 \cdot 10\text{H}_2\text{O}$ , which Rammelsberg (*Wied. Ann.*, 1883, 20, 938) obtained with  $16\text{H}_2\text{O}$ .

Conductometric and potentiometric titrations of sodium vanadates and vanadic acid are now described, and the results are explained on the hypothesis that vanadium tends to form a heavy molecule, on the border-line between a true solute and a colloidal micelle, and corresponding to  $\text{Na}_2\text{O} \cdot 2\text{V}_2\text{O}_5$  or  $\text{Na}_2\text{O} \cdot 3\text{V}_2\text{O}_5$ .

## EXPERIMENTAL.

*Nomenclature.*—There is considerable confusion as to a suitable nomenclature for the large number of compounds of the alkali oxides with vanadium pentoxide. The use of the prefixes "ortho," "pyro," and "meta" for three of the vanadates stresses a false analogy between them and the phosphates and, moreover, tends to single out three of the vanadates from others of equal or greater importance. We therefore propose in this and succeeding communications to designate an alkali vanadate by a prefix denoting the ratio of  $\text{M}_2\text{O}$  to  $\text{V}_2\text{O}_5$  ( $\text{M}$  = alkali metal); thus sodium orthovanadate becomes the 3:1-vanadate, the pyro-salt becomes the 2:1-vanadate, and the compound  $\text{Na}_2\text{O} \cdot 2\text{V}_2\text{O}_5$  will be called the 1:2-vanadate.

### A. Conductometric Titrations.

1. *Direct Titration of Sodium 3:1-Vanadate.*—Vanadium pentoxide dissolves slowly in cold sodium hydroxide solution giving a clear yellow solution, whose colour disappears on standing for some time. If, however, the pentoxide be dissolved in boiling sodium

hydroxide solution, a clear colourless solution is immediately obtained. Such a solution may also be prepared by treating ammonium metavanadate with hot sodium hydroxide solution. In view of the different appearance of the solutions obtained by various methods of preparation, it was of interest to see if the behaviour of the vanadate solutions towards hydrochloric acid could be in any way correlated with their method of preparation.

For this purpose solutions of the sodium 3:1-vanadate were prepared in the following ways and titrated conductometrically with hydrochloric acid at 25°: (1) Ammonium metavanadate,  $\text{NH}_4\text{VO}_3$ , was boiled with the stoichiometrical quantity of sodium hydroxide solution, a current of carbon dioxide-free air being drawn through the solution. (2) Vanadium pentoxide was boiled with the calculated amount of sodium hydroxide solution. Both these solutions were colourless. (3) Vanadium pentoxide was dissolved in the same amount of cold sodium hydroxide solution; this solution was yellow. (4) Solution (3) was kept for 48 hours, and had then become colourless. In all cases, the solutions were 0.005*M* with respect to  $\text{Na}_3\text{VO}_4$ . Solutions (1) and (2) were titrated directly with 0.1*N*-, and (3) and (4) with 0.0933*N*-hydrochloric acid, the liberation of the vanadic acid according to the equation  $2\text{Na}_3\text{VO}_4 + 6\text{HCl} \rightarrow \text{V}_2\text{O}_5 \cdot 3\text{H}_2\text{O} + 6\text{NaCl}$  corresponding to 15.0 c.c. in the first two cases and to 16.1 c.c. in the last two. The specific conductivities,  $\kappa$ , at different titres are given in Table I.

TABLE I.

*Specific conductivities ( $\kappa \times 10^3$ ) of 100 c.c. of 0.005*M*- $\text{Na}_3\text{VO}_4$  prepared in different ways and titrated directly with HCl.*

	$\text{Na}_2\text{O} : \text{V}_2\text{O}_5 =$	3:1	2.5:1	2:1	1.5:1	1:1	0.5:1	0.25:1	0:1
Soln. 1 .....		2.14	1.92	1.72	1.58	1.54	1.58	1.73	1.98
„ 2 .....		2.13	1.92	1.73	1.57	1.53	1.58	1.73	2.01
„ 3 .....		2.14	1.93	1.74	1.56	1.52	1.61	1.78	2.06
„ 4 .....		2.09	1.88	1.68	1.53	1.49	1.54	1.75	2.00

*Continuation of titration of Solution 2 beyond liberation of vanadic acid at 15 c.c. of HCl:*

HCl, c.c. ...	15	16	17	18	19	20	21	22	23	24	25
$\kappa \times 10^3$ .....	2.01	2.20	2.46	2.74	2.97	3.19	3.45	3.68	3.91	4.14	4.34

Table I indicates that all the vanadate solutions reacted with hydrochloric acid in the same way, irrespective of the manner in which they were prepared. The small differences between the conductivities of Solutions 3 and 4 may perhaps be ascribed to the disappearance of the yellow colour on ageing. When the results

are plotted, curves are obtained very similar to Curve C (Fig. 1), which will be discussed later.

2. *Effects of Ageing and Boiling.*—In view of the remarkable observation of Düllberg (*loc. cit.*), that the conductivity of solutions of sodium 3:1-vanadate, to which varying quantities of hydrochloric acid had been added, underwent a change on standing, we

FIG. 1.

have repeated and confirmed his experiments. In addition, we have investigated the effect of boiling such solutions. Three series of experiments were performed; a series of solutions, 100 c.c. in volume and 0.005*M* with respect to  $\text{Na}_3\text{VO}_4$ , were prepared containing 0.1*N*-hydrochloric acid in various quantities from 0 to 15 c.c., and their conductivities were measured (a) immediately, and (b) after they had stood for six days; a similar series of solutions was boiled and the conductivity then measured (c) at 25°.

In all cases, the addition of even the slightest amount of acid to a colourless vanadate solution produced a yellow coloration, which increased in intensity with addition of hydrochloric acid until about half the amount required to liberate  $\text{H}_3\text{VO}_4$  had been added, *i.e.*, 7 or 8 c.c. Boiling the coloured solutions decolorised those containing 10 c.c. of hydrochloric acid or less, and ageing decolorised those containing 8 c.c. or less. The results of these experiments are given in Table II and shown graphically in Fig. 1.

TABLE II.

*Specific conductivities of 100 c.c. of 0.005M- $\text{Na}_3\text{VO}_4$  containing x c.c. of 0.1N-HCl, (a) immediately, (b) after standing for 6 days, (c) boiling, after addition of acid.*

x .....	0	1	2	3	4	5	6	7
$\text{Na}_2\text{O}/\text{V}_2\text{O}_5$ .....	3	2.8	2.6	2.4	2.2	2	1.8	1.6
$\kappa \times 10^8$ (a) .....	2.15	2.08	1.97	1.87	1.79	1.70	1.62	1.58
(b) .....	2.15	2.03	1.93	1.83	—	1.65	1.65	1.65
(c) .....	2.09	2.00	—	1.76	—	—	—	1.64
x .....	8	9	10	11	12	13	14	15
$\text{Na}_2\text{O}/\text{V}_2\text{O}_5$ .....	1.4	1.2	1	0.8	0.6	0.4	0.2	0
$\kappa \times 10^8$ (a) .....	1.60	1.61	1.62	1.67	1.71	—	1.91	2.23
(b) .....	1.68	1.70	1.71	1.73	1.78	1.80	2.01	2.31
(c) .....	—	1.70	1.70	—	1.75	1.78	—	2.30

The results of the first experiment (Curve C) are almost identical with the direct titrations described above, the small difference being due to the dilution of the solution in the course of the former titration. No break appears in the curve corresponding to a 2 : 1- or a 1 : 1-vanadate. The effect of ageing is shown in Curve D. The effect of boiling is almost identical, as will be seen from the data in Table II. A break occurs at a point corresponding with the 2 : 1-vanadate, and another which approximates to the 1 : 3-vanadate. These breaks are shown more clearly by Curve G, constructed by subtracting from the total conductivity of the solution that due to the sodium chloride formed. Thus, Curve G represents the conductivity of the solution due to the vanadate at different points. For comparison, the titration curves of a potassium chromate (A) and a sodium phosphate (B) solution are shown on the same graph, but the scale of the conductivity axis has been moved. Breaks are found in these curves corresponding with  $\text{KHCrO}_4$ ,  $\text{Na}_2\text{HPO}_4$ , and  $\text{NaH}_2\text{PO}_4$ , and it is evident that the vanadate curves are anomalous.

3. *Titration of the Sodium 1 : 1-Vanadate.*—Curves C and D of Fig. 1 show that the variation of conductivity during titration with hydrochloric acid of a solution corresponding in composition with the 3 : 1-vanadate depends on whether the measurement is made immediately, or after boiling or ageing, after each addition of acid.

In order to study this matter further, a solution was prepared of the 1:1-vanadate by boiling the pentoxide with the calculated amount of sodium hydroxide solution. The vanadium content was the same as in the previous experiments. 100 C.c. of the solution were then titrated directly with 0.1*N*-hydrochloric acid; the conductivities found were as follows, the corresponding curve being F (Fig. 1), which starts at 10 c.c.:

HCl, c.c. ....	0	1	2	3	4	5	6	7
$\kappa \times 10^3$ .....	0.544	0.550	0.562	0.573	0.657	0.925	1.38	1.61

Since the initial conductivity of this solution is due entirely to the 1:1-vanadate, we should expect it to agree with the conductivity of the corresponding solution in Curve D, after correction has been made for the sodium chloride in the latter. Satisfactory agreement is obtained. Moreover, if from Curve F we subtract the conductivity of the sodium chloride formed during the reaction, a curve is obtained identical with the latter part of Curve G.

4. *Titration of the Sodium 2:1-Vanadate.*—In a similar manner, 100 c.c. of a 0.005*M*-solution corresponding in composition with the 2:1-vanadate ( $\text{Na}_2\text{HVO}_4$ ) were prepared and titrated with 0.1*N*-hydrochloric acid (see Curve E, Fig. 1, starting at 5 c.c.):

FIG. 2.

Again, satisfactory agreement was obtained between the initial conductivity of this solution and that of the solution in Curve D corresponding with 5 c.c. of hydrochloric acid when corrected for the conductivity of its sodium chloride. Also, if correction is made in Curve E for the sodium chloride formed, giving Curve H, the resulting conductivities are only slightly lower than those in Curve G.

Since Curves E and F relate to a direct titration of the 2 : 1- and 1 : 1-vanadate solutions respectively, it would appear that no influence of boiling or ageing on the solutions of Curves D and C should appear beyond the point relating to 5 c.c. of hydrochloric acid. To check this deduction, a solution of 100 c.c. of 0.005*M*- $\text{Na}_3\text{VO}_4$  was treated with sufficient hydrochloric acid to form the 2 : 1-vanadate, and boiled. It was then titrated directly with 0.0933*N*-acid without further boiling on addition of acid. A curve was obtained almost identical with that portion of Curve D beyond 5 c.c. of added acid.

We also showed that a solution of the 2 : 1-vanadate, prepared by dissolving the pentoxide in *cold* sodium hydroxide solution, and titrated directly with hydrochloric acid, gave a curve only slightly lower than Curve E in Fig. 1 and identical with it in form, although, unlike the above, this solution was yellow in colour.

It is therefore concluded that boiling or ageing effects are only to be obtained with solutions less acid than the 2 : 1-vanadate, although the effect of omitting the boiling or ageing operation with such solutions may be apparent in the subsequent titration after the 2 : 1-vanadate stage is passed.

5. *Effects of Boiling on Solutions between the 3 : 1- and the 2 : 1-Vanadate.*—Since boiling or ageing has little or no influence on solutions of the 2 : 1-vanadate, but considerable effect on the 3 : 1-vanadate, an experiment was carried out with solutions intermediate between these two vanadates. To four portions of a solution of the 3 : 1-vanadate,  $x$  c.c. of 0.0933*N*-hydrochloric acid were added, where  $x = 0, 1, 3.25, \text{ and } 5.40$  c.c. respectively. Each solution was boiled, diluted to 100 c.c. and 0.005*M* with respect to the vanadium content, and titrated directly, without any subsequent boiling, with acid of the same concentration.

The conductivities found are shown in Table III and plotted in Fig. 2. The initial broken-line curve corresponds to the boiling effect shown in Curve D in Fig. 1. This experiment shows that initial boiling of solutions between the 3 : 1- and the 2 : 1-vanadate lowers their conductivity, but on direct titration they tend to revert to a curve of the type C of Fig. 1. Initial boiling of a solution corresponding with the 2 : 1-vanadate leads, however, on titration with

TABLE III.

Specific conductivities of 100 c.c. of (a) 3:1-, (b) 2.8:1-, (c) 2.35:1-, (d) 2:1-vanadate, boiled initially and titrated directly with 0.0933N-HCl.

6. *Titration of Vanadic Acid with Alkalis.*—The effect of hydrochloric acid on vanadate solutions having been determined, the reverse titration of vanadic acid with alkalis was investigated. 0.005M Vanadic acid ( $\text{H}_3\text{VO}_4$ ) was formed by the addition of hydro-

chloric acid to the 3 : 1-vanadate and 100 c.c. were titrated with (a) 0.1*N*-sodium hydroxide, (b) 0.1023*N*-ammonia, and (c) 0.0487 *N*-baryta. Also (d) 100 c.c. of a solution corresponding with the minimum conductivity in Curve G of Fig. 1 (*i.e.*, prepared by diluting a mixture of 13 c.c. of 0.1*N*-hydrochloric acid and 25 c.c. of 0.02*M*- $\text{Na}_3\text{VO}_4$ ) were titrated with 0.1*N*-sodium hydroxide. The conductivities are given above and are plotted in Fig. 3, the Curve D starting from 2 c.c., because 13 c.c. of 0.1*N*-acid were used in making up this solution, whereas 15 c.c. would have been required to give  $\text{H}_3\text{VO}_4$  (see Fig. 1).

The first part of the curve, in all three cases, consists of a sharp drop, corresponding with the neutralisation of some excess acid; in the sodium hydroxide titration, the curve then rises regularly, showing no break which could be attributed to the 1 : 1-, 2 : 1-, or 3 : 1-vanadates.

The slow fall in the ammonium hydroxide curve is to be explained by the gradual dilution of the solution, which is more than sufficient to counterbalance the conductivity due to the ammonium hydroxide added; moreover, the ammonium chloride exerts a buffering effect. The baryta curve resembles that for sodium hydroxide, and a similar explanation applies, although here there is the added complication of a precipitation of a barium vanadate, which appears slowly during the course of the titration.

### B. Potentiometric Titrations.

An attempt has been made to follow the course of the titration of sodium 3 : 1-vanadate with hydrochloric acid potentiometrically. In a 0.005*M*- $\text{Na}_3\text{VO}_4$  solution, the hydrogen electrode was found to give steady, reproducible potentials, the *E.M.F.* in eight determinations varying only between -0.948 and -0.950, measured against the normal calomel electrode. This corresponds to  $p_{\text{H}}$  11.65 and  $[\text{OH}'] = 0.0045*N*$ , indicating 30% hydrolysis. The cell used was  $\text{H}_2(\text{Pt})|0.005*M*-\text{Na}_3\text{VO}_4|\text{sat. KCl}|1.0*N*-\text{KCl}, \text{Hg}_2\text{Cl}_2|\text{Hg}$ . On titration of the solution with 0.1*N*-hydrochloric acid, the electrode ceased to give satisfactory results: it showed a slight but steady fall in potential up to 13 c.c., but then became very erratic, the *E.M.F.* falling rapidly. A typical titration is illustrated in Fig. 4. That reduction was proceeding, at any rate in the more acid solutions, was evident from their blue colour after hydrogen had been passing for a short time.

Titration with the oxygen electrode also yielded unsatisfactory results. As is well known, this electrode does not give reproducible readings even under favourable conditions; it was therefore calibrated against the value of -0.950 volt, obtained for the hydrogen

electrode in  $0.005M\text{-Na}_3\text{VO}_4$  solution, and then afforded qualitative results, as may be seen from a typical curve in Fig. 4; in agreement with the hydrogen electrode, there is no sharp fall, but a considerable lowering of the  $p_H$  of the solution in the region of the 1:2-, 1:3-, and 1:4-vanadates.

Attempts were made to use the quinhydrone electrode in the titration of vanadic acid solutions with alkali. Its behaviour was very erratic, however, a fact which is not surprising in view of the closeness of the normal reduction potential of quinone-quinol to that of quinquevalent-quadrivalent vanadium.

FIG. 4.

### Discussion.

The foregoing experiments may be summarised as follows: The sodium 3:1-vanadate, when titrated directly with hydrochloric acid, shows but little analogy with the formally similar phosphate (compare Curves B and C, Fig. 1): while the phosphate shows breaks corresponding with the primary and secondary salts, the vanadate has a continuously varying conductivity, although, when allowance is made for the conductivity due to the sodium chloride in the solution, a break appears at a point corresponding with 13/15ths decomposition. If these solutions are boiled or aged after each addition of acid in the course of the titration, the nature of the curve changes, a break being obtained at the 2:1-vanadate and, according to Düllberg (*loc. cit.*), in the more concentrated solutions, at the 1:1-vanadate. The main divergence from the phosphate analogy, however, lies in the break at 13/15ths decomposition, which appears in all the titrations. These boiling (or ageing)

effects are not operative in all vanadate solutions. Solutions of the 3:1-vanadate, when titrated directly with acid, follow what we may term the "abnormal" smooth curve, typified by C in Fig. 1. If these solutions are boiled after every addition of acid until the 2:1-vanadate is reached, another type of curve, exemplified by D in Fig. 1, which we will call the "normal" type, is obtained. Boiling a solution corresponding to the 2:1-vanadate, or a more acid vanadate, produces no change in its titration with hydrochloric acid. Omission of the boiling operation at any stage previous to the 2:1-vanadate, however, results in the solution reverting to the "abnormal" curve on further titration.

Direct titration by alkali of a solution corresponding with vanadic acid shows no evidence of salt formation corresponding to the 1:1-, 2:1-, or 3:1-vanadates.

Potentiometric titration of the 3:1-vanadate with hydrochloric acid, using the hydrogen electrode, indicates that there is a steady fall in  $p_H$  from 11.65 in the 3:1-vanadate solution to about 8.4 when 13/15ths of the decomposition is complete, after which the solution rapidly becomes acid.

Düllberg explained his titration curves by postulating a hexavanadic acid,  $H_4V_6O_{17}$  (i.e.,  $3V_2O_5 \cdot 2H_2O$ ). At the point corresponding to 12.5/15ths of the decomposition, he supposed that the monohydrogen salt of this acid was formed, viz.,  $HN_3V_6O_{17}$  or  $Na_2O \cdot 2V_2O_5 \cdot \frac{1}{3}H_2O$ , and that the ion  $HV_6O_{17}'''$  did not readily dissociate. In this way he accounted for the decomposition apparently ceasing at 5/6ths of the expected titration.

Against this hypothesis it must be urged that only a small number of vanadates can be derived by simple substitution of hexavanadic acid. Moreover, our figures tend to show that the break occurs somewhat beyond 5/6ths of the decomposition.

By subtracting the conductivity of the sodium chloride from that of the sodium vanadate-sodium chloride mixtures, as in Curves G and H of Fig. 1, an estimate can be made of the minimum conductivity; averaging these values from eight experiments, we estimate this conductivity to be 0.00029 mho, the minimum value occurring at 12.83/15ths of the acid required to liberate vanadic acid; in all cases the solution was 0.005M with respect to vanadium. This is a surprisingly low conductivity, indicating a very heavy molecule, i.e., polymerisation.

A more feasible, and at the same time a more fruitful, hypothesis is to postulate the existence of a complex with a high  $V_2O_5 : Na_2O$  ratio, corresponding with 12.85 c.c. of hydrochloric acid. Such a complex would have the approximate composition  $Na_2O \cdot 2V_2O_5$  or

$\text{Na}_2\text{O}, 3\text{V}_2\text{O}_5$ , but as we shall show that this can only exist in a polymerised form, it would appear to be on the border line between a true solute and a colloidal micelle, and consequently a simple ratio between  $\text{Na}_2\text{O}$  and  $\text{V}_2\text{O}_5$  is not to be expected.

Such a complex could easily give rise to a series of salts by addition of small amounts of acids and evaporation, especially as it is by no means certain that many of these more complex vanadates are of definite chemical composition.

Now, Düllberg has shown that a solution, 0.1*M* with respect to vanadium, and corresponding with 12.5 c.c. of hydrochloric acid in our graph (Fig. 2), has a freezing point of  $-0.0751^\circ$ . For a solution of 0.1*M*- $\frac{1}{4}(\text{Na}_2\text{O}, 2\text{V}_2\text{O}_5)$  we should expect a depression of  $-0.186^\circ$  if the solution were un-ionised; for a doubly polymerised molecule we should expect  $-0.093^\circ$ , and for a trebly polymerised molecule  $-0.0465^\circ$ . The last figure would be somewhat higher if the molecule were ionised, and if it be assumed that our complex contains three atoms of vanadium, the freezing point would indicate about 21% dissociation. Moreover, Düllberg has demonstrated that the 1:1-vanadate is probably trebly polymerised, showing that condensation of molecules is occurring even at this stage of the titration.

In one case (Soln. 2 in Section 1), the conductometric titration of a 0.005*M*-3:1-vanadate solution with hydrochloric acid was carried beyond the liberation of vanadic acid at 15 c.c. of 0.1*N*-acid. The latter portion of this titration, from 15 to 25 c.c. of acid, is shown in Fig. 2, where it is contrasted with the calculated conductivity of the added hydrochloric acid, assumed present as free acid. The observed conductivities at titres of 15 and 25 c.c. were 0.00201 and 0.00434 mho, respectively, a difference of 0.00233 mho. The conductivity due to the addition of 10 c.c. of 0.1*N*-acid is calculated as 0.00320 mho, or, after allowing for the decrease in the conductivity of the sodium chloride on dilution from 115 to 125 c.c., which is approximately 0.00016 mho, the calculated difference becomes 0.00304. The observed increase in conductivity is therefore about 23% less than the calculated, showing that the complex is not entirely resistant to the action of acids, but that some replacement of sodium by hydrogen occurs.

Similar conclusions are to be drawn from the alkali titration of vanadic acid. In Fig. 3 the titration of 0.005*M*-vanadic acid with 0.1*N*-sodium hydroxide is contrasted with the calculated increase in conductivity due to the sodium hydroxide calculated as free alkali. Between the titres of 3 c.c. and 20 c.c. of caustic soda the conductivity increased by 0.00289 mho. The addition of 17 c.c.

of 0.1*N*-sodium hydroxide would give a calculated increase of 0.00333 mho, or 0.00305 mho after 0.00028 mho is allowed for the decrease in conductivity owing to the dilution of the solution from 103 to 120 c.c. The observed increase is, therefore, 5% less than the calculated increase in conductivity, showing that there is a small interaction between the complex and the sodium hydroxide.

The decomposition of sodium 3 : 1-vanadate, when the solution is boiled or aged after each addition of acid, would appear to proceed as follows : The 3 : 1-vanadate is hydrolysed almost completely into sodium hydroxide and the 2 : 1-vanadate; addition of hydrochloric acid neutralises the hydroxide, and at one-third decomposition the solution consists, therefore, of sodium chloride and the 2 : 1-vanadate. The first reaction may be represented as  $\text{NaOH} + \text{Na}_2\text{HVO}_4 \longrightarrow \text{NaCl} + \text{Na}_2\text{HVO}_4$ . Now in Expt. B of Section 2 we found that the conductivity at one-third decomposition was 0.00165 mho, of which 0.000585 mho was due to sodium chloride. Thus the conductivity of the 2 : 1-vanadate is 0.001065 mho, and, adding to this the conductivity of an equimolecular amount of sodium hydroxide, *viz.*, 0.001175 mho, we get 0.00224 mho for the calculated value of the conductivity of the 3 : 1-vanadate, compared with 0.00215 mho for the observed. The discrepancy is probably due in the first place to the hydrolysis of the 3 : 1-vanadate being not quite complete, and secondly, to the 2 : 1-vanadate being itself hydrolysed to some extent.

The next stage, between one-third and two-thirds decomposition, consists of the formation of a condensed 1 : 1-vanadate :  $3\text{Na}_2\text{HVO}_4 + 3\text{HCl} \longrightarrow \text{Na}_3\text{V}_3\text{O}_9 + 3\text{NaCl} + 3\text{H}_2\text{O}$ . Further addition of acid results in an abstraction of soda from this heavy 1 : 1-vanadate molecule until a ratio of Na : V between 1 : 2 and 1 : 3 is reached, whereupon the molecule becomes sufficiently stable, and the residual soda is so closely bound in the complex that further addition of the acid causes no change, or only a very gradual and partial replacement. No break appears at two-thirds neutralisation, where the 1 : 1-vanadate begins to be converted into the complex, but this is marked by the fact that solutions containing the complex cannot be decolorised by boiling.

In the case of direct titration of the 2 : 1- or 1 : 1-vanadates, the same sequence of changes occurs.

The potentiometric curves given in Fig. 4, though by no means satisfactory, explain why Rosenheim and Yang (*Z. anorg. Chem.*, 1923, **129**, 181) found that, on titration of solutions of the 3 : 1-vanadate with sulphuric acid, phenolphthalein became decolorised when approximately 2 equivs. of acid had been added. The curves

show that the solutions are buffered at this stage so that the change-point could not possibly be sharp.

The same problem has been approached in another direction by Dumanski (*J. Russ. Phys. Chem. Soc.*, 1924, 54, 703), who prepared vanadium pentoxide sols by the method of Biltz (*Ber.*, 1904, 37, 1095), *i.e.*, grinding ammonium metavanadate with hydrochloric acid, filtering off the residue, and shaking it with water. On dilution of the red solution, a yellow solution was obtained, having a higher electrical conductivity and having no particles visible in the ultra-microscope. On coagulation with barium chloride, a small amount of barium was absorbed, increasing to a constant value after several hours' standing, whereupon the solid approximated to the composition  $\text{BaH}_2\text{V}_6\text{O}_{17}$ . The conductivity of the solution increased at the same time, consistent with a replacement of barium ions by hydrogen ions. From the amount absorbed in the first stage, the formula  $[\text{H}_2\text{V}_6\text{O}_{17}(\text{V}_2\text{O}_5)_6]'' + 2\text{H}^+$  was deduced.

The authors wish to thank the Chemical Society for a grant from the Research Fund.

## NOTES.

*The Supposed Mandelonitrile.* By WILSON BAKER and RANDAL GEORGE ARTHUR NEW.

WOOD and LILLEY (J., 1925, 127, 95) have described the spontaneous transformation of mandelonitrile to a "yellow solid," m. p.  $196^\circ$  (corr.), stated to be mandelonitrile. They claim to have confirmed the isonitrile structure by determinations of the molecular weight and of the percentage of nitrogen, by reduction to the base  $\text{CHPh}(\text{OH})\cdot\text{NH}\cdot\text{CH}_3$  (I) (yellowish-grey solid, m. p.  $180^\circ$  decomp.), and also by acid hydrolysis giving benzaldehyde, formic acid, tarry matter and mandelic acid. It is very unlikely that the change nitrile  $\rightarrow$  isonitrile should occur, and the high melting points of Wood and Lilley's products are not consistent with the structures given. Further the base (I) spontaneously loses water, giving the Schiff's base  $\text{CHPh}\cdot\text{N}\cdot\text{CH}_3$  (Zaunschirm, *Annalen*, 1888, 245, 281). We have found that the pure substance, crystallised twice from alcohol and twice from benzene, melts at  $198^\circ$  and has the formula  $\text{C}_{23}\text{H}_{18}\text{O}_2\text{N}_2$  (Found: C, 77.7; H, 5.1; N, 7.6; *M*, by Rast's method, 372. Calc.: C, 78.0; H, 5.1; N, 7.9%; *M*, 354), and that it is rapidly and completely hydrolysed by dilute acids, giving

benzaldehyde (1 mol.), mandelic acid (2 mols.), and ammonia (2 mols.).

Examination of the literature showed that this substance,  $C_{23}H_{18}O_2N_2$ , was first obtained from bitter-almond oil and described by Laurent in 1835 under the name "benzimide" (*Ann. Chim. Phys.*, [2], 59, 398; see also Laurent, *ibid.*, 1835, [2], 60, 218; *Annalen*, 1836, 17, 89; *Ann. Chim. Phys.*, 1837, [2], 66, 194; *Berzelius' Jahresber.*, 1837, 16, 246). Zinin in 1840 (*Annalen*, 34, 188; see also *Berzelius' Jahresber.*, 1842, 21, 356) and Gregory in 1845 (*Annalen*, 54, 372) prepared it from bitter-almond oil and potassium cyanide, and both assigned to it the correct molecular formula. It is clear that Gregory prepared it as early as 1834, but did not examine it till later. Laurent and Gerhardt (*Jahresber.*, 1850, 488) realised the identity of "benzimide" with Zinin and Gregory's product. Later Zinin showed (*J. Russ. Chem. Soc.*, 1869, 1, 213; see *Ber.*, 1869, 2, 509, 552) that the substance could be hydrolysed by acid to benzaldehyde, mandelic acid, and ammonia. The compound was first recognised as the acetal of benzaldehyde and mandelonitrile — di-( $\alpha$ -cyanobenzyloxy)phenylmethane,  $CHPh[O\cdot CH(CN)Ph]_2$ —by Schiff in 1870 (*Annalen*, 154, 346). The same conclusion was reached as the result of careful work and rational syntheses by Stollé (*Ber.*, 1902, 35, 1590) and later by Savelsberg (*J. pr. Chem.*, 1916, 93, 271), the latter having acknowledged Stollé's priority (*ibid.*, 1917, 96, 186). A correction of Wood and Lilley's work (Stollé, *Ber.*, 1925, 58, 975) appears to have been overlooked (see, for example, "Organic Syntheses," Vol. 6, 60) and we desire to record our complete agreement with the work of Stollé and Savelsberg.—THE DYSON PERRINS LABORATORY, OXFORD. [Received, April 5th, 1930.]

*Syntheses of 1-Methylanthraquinones.* By ARTHUR FAIRBOURNE  
and GRAHAM EDWARD FOSTER.

IN an attempt to obtain a sample of 1:2-dimethylantraquinone, by a process which should ensure its being free from the difficultly separable 2:3-isomeride (J., 1921, 119, 1573), 4-hydroxy-1:2-dimethylantraquinone was prepared (J., 1923, 123, 1137). The intermediate 2-*o*-hydroxyxyloylbenzoic acid, with acetic anhydride and sodium acetate, has yielded colourless plates, m. p. 195° (Found: C, 67.5; H, 5.1; *M*, 360.  $C_{20}H_{18}O_6$  requires C, 67.8; H, 5.1%; *M*, 354). Since it was stable towards hot water, this *diacetate* presumably has the structure (I) (compare Gleason and Dougherty, *J. Amer. Chem. Soc.*, 1929, 51, 310). The *hydroxyanthraquinone* has similarly been acetylated to yield 4-acetoxy-1:2-dimethylantraquinone, yellow

needles from alcohol, m. p.  $154^{\circ}$  (Found : C, 73.5; H, 4.9.  $C_{18}H_{14}O_4$  requires C, 73.5; H, 4.8%), but could not successfully be reduced in either acid or alkaline media (compare Elbs, *J. pr. Chem.*, 1890, **41**, 1; Braun and Bayer, *Ber.*, 1926, **59**, 914); distillation over zinc dust produced a colourless crystalline sublimate, m. p.  $200^{\circ}$ , which cannot have been the unknown 1:2-dimethylantracene since it was oxidisable to a product melting at  $280^{\circ}$  (compare Birukoff, *Ber.*, 1887, **20**, 2068; Fischer and Sapper, *J. pr. Chem.*, 1911, **83**, 201).

The proposed method of Pickles and Weizmann (P., 1904, **20**, 201) for synthesising anthraquinones of proved structures from the corresponding Grignard reagents and phthalic anhydride is likely to be particularly applicable when 1-methylantraquinones are required, but appears never to have been adopted for that purpose, owing to a fear that simultaneous formation of diarylphthalides (as II) would render it unsuitable. Opportunity for synthesising 1:2-dimethylantraquinone from magnesium *o*-3-xylyl bromide has not occurred, but the method has been tested in the similar case of magnesium *o*-tolyl bromide, under conditions maintaining a continuous excess of the anhydride to minimise further reaction of 2-*o*-toluoylbenzoic acid. The latter crystallised from alcohol in colourless needles, m. p. above  $120^{\circ}$  (Found : equiv. by titration with *N*/10-baryta, 236.  $C_{15}H_{12}O_3$  requires equiv., 240), and was converted into 1-methylantraquinone, m. p.  $173^{\circ}$ , agreeing with the description of Fischer and Sapper (*loc. cit.*) of a specimen synthesised in a different manner (Found : C, 81.0; H, 4.4. Calc. : C, 81.1; H, 4.5%). The method thus renders possible reaction (c) (J., 1921, **119**, 1574) which could not previously be realised.

The authors are indebted to the Chemical Society for a grant which has partly met the expenses incurred in this work, and also to the Department of Scientific and Industrial Research for a maintenance grant to one of them.—KING'S COLLEGE, LONDON. [Received, November 7th, 1929.]

CLXIII.—*A Revision of the Atomic Weight of Tantalum. Determination of the Ratios  $\text{TaBr}_5 : 5\text{Ag} : 5\text{AgBr}$  and  $\text{TaCl}_5 : 5\text{Ag} : 5\text{AgCl}$ .*

By KOLAR RAMAKRISHNAIYER KRISHNASWAMI.

THE accepted value for the atomic weight of tantalum is based on results which are not in satisfactory agreement. Marignac (*Arch. Sci. phys. nat.*, 1866, 26, 89), who was the first to employ purified materials, used the double fluorides of tantalum with potassium and with ammonium,  $\text{R}_2\text{TaF}_7$ , to determine the ratios  $2\text{K}_2\text{TaF}_7 : \text{Ta}_2\text{O}_5$ ,  $\text{K}_2\text{TaF}_7 : \text{K}_2\text{SO}_4$ ,  $\text{K}_2\text{SO}_4 : \text{Ta}_2\text{O}_5$ , and  $2(\text{NH}_4)_2\text{TaF}_7 : \text{Ta}_2\text{O}_5$ , and calculated therefrom values which ranged from 182.66 to 183.55, giving as a mean,  $\text{Ta} = 182.98$ . Hinrichson and Sahlbom (*Ber.*, 1906, 39, 2600) carried out five determinations of the ratio  $2\text{Ta} : \text{Ta}_2\text{O}_5$  by observing the gain in weight of known amounts of the metal when heated in a stream of oxygen; values ranging from 180.60 to 181.72 were obtained for Ta, the mean being  $181.02 \pm 0.09$ . Van Haagen (Thesis, University of Pennsylvania, 1909) sought to fix the ratio  $2\text{TaBr}_5 : \text{Ta}_2\text{O}_5$  by weighing the pentoxide formed from the hydrolysis of a known weight of the pentabromide; eight determinations gave values ranging from 183.10 to 183.42, the mean being  $183.28 \pm 0.09$ . Chapin and Smith (*J. Amer. Chem. Soc.*, 1911, 33, 1497) redetermined the ratio  $2\text{TaBr}_5 : \text{Ta}_2\text{O}_5$ , and calculated  $\text{Ta} = 181.69$ — $181.94$ ; mean  $181.82 \pm 0.04$ . Balke (*ibid.*, 1910, 32, 1127) conducted eight determinations of the ratio  $2\text{TaCl}_5 : \text{Ta}_2\text{O}_5$ , finding  $\text{Ta} = 181.45$ — $181.60$ ; mean  $181.52 \pm 0.02$ . Later, Sears and Balke (*ibid.*, 1915, 37, 833) concluded that determinations of the ratio  $2\text{TaCl}_5 : \text{Ta}_2\text{O}_5$  were untrustworthy owing to serious sources of error. They therefore attempted to find the ratio  $\text{TaCl}_5 : 5\text{Ag}$ , and from three series of determinations found  $\text{Ta} = 181.77$ ,  $181.31$ , and  $181.03$ , which gave on combination the general mean  $181.29 \pm 0.20$ . The poor agreement between the three series of results was later explained by Balke (*ibid.*, 1917, 39, 1852) as being due to uncertainty arising out of the analytical procedure employed, and he concluded that tantalum pentachloride was unsuitable for use in atomic-weight determinations (see p. 1289).

All the figures given above are on the basis of the recalculated data published by F. W. Clarke ("A Recalculation of the Atomic Weights," 1920), who summarised the situation thus: "So far as present evidence goes it seems probable that the atomic weight of tantalum is somewhere near 181 with an uncertainty of at least half a unit." This remark is equally applicable now, for no fresh

evidence has appeared. In 1912, the International Committee on Atomic Weights gave the value of tantalum as 181.5, which is still used by the German (*Ber.*, 1930, **63**, 1) and American (*J. Amer. Chem. Soc.*, 1929, **51**, 653) Chemical Societies, but in 1929 the Chemical Society (*J.*, 216) changed it to 181.3, the value deduced by Clarke (*op. cit.*) from the results of Sears and Balke (*loc. cit.*).

### *Purification of Materials.*

**Water.**—The distilled water of the laboratory was redistilled from a faintly alkaline, dilute permanganate solution and then redistilled in an all-silica still and condenser. The purified water was found by nephelometric test to be halogen-free and was collected and stored in stoppered Pyrex flasks.

**Nitric Acid.**—Merck's "pure" acid was redistilled in an all-silica still and condenser, and the middle fraction, which was found to be halogen-free, was collected and similarly stored.

**Oxalic Acid.**—"A.R." Material supplied by the British Drug Houses, Ltd., was used directly, since it dissolved completely in water and was also free from iron as well as halogens.

**Chlorine.**—The source of this gas was a cylinder of the liquid supplied by the Imperial Chemical Industries, Ltd., and stated to contain only a trace of bromine. The gas was passed through an all-glass apparatus in which it was first dried by sulphuric acid contained in four wash-bottles, then freed from possible traces of hydrogen chloride by passage through two tubes containing ignited lime, as recommended by Hönigschmid (*Z. anorg. Chem.*, 1927, **163**, 315), and finally dried by passage through two tubes containing phosphoric oxide.

**Bromine.**—This had been prepared free from chlorine and iodine by Willard and McAlpine's method (*J. Amer. Chem. Soc.*, 1921, **43**, 799) and was from a stock prepared for an earlier work. Removal of traces of hydrobromic acid was effected by keeping it over calcium oxide as recommended by Hönigschmid and Zintl (*Annalen*, 1923, **433**, 217).

**Argon.**—The gas from a steel cylinder of compressed argon was purified in an all-glass apparatus by bubbling through sulphuric acid and passing successively over soda-lime, hot copper and copper oxide, hot magnesium ribbon, and finally again over hot copper oxide and copper; it was then stored in galvanised-iron holders. As it was not considered necessary for this work to free it completely from nitrogen, it was passed through the purification train only once.

**Sodium Chloride.**—Kahlbaum's "pure" salt was reprecipitated twice from a filtered aqueous solution by passage of hydrogen

chloride, and the product was recrystallised from water and fused in a platinum basin.

*Potassium Bromide.*—Kahlbaum's "pure" salt was recrystallised twice from water, the crystals being drained centrifugally and fused in platinum.

*Silver.*—This was obtained from a stock prepared for an earlier work by following the method of Richards and Wells (*J. Amer. Chem. Soc.*, 1905, 27, 472), and fused on a magnesia support in a vacuum.

*Preparation of Tantalum.*—Although tantalum of a high degree of purity is commercially available, no details are to be found in the literature regarding the conditions governing its preparation in a pure state. Von Bolton (*Z. Elektrochem.*, 1905, 11, 45), who achieved a purity of 99%, merely mentions that he used a "modification" of the process by which Berzelius (*Pogg. Annalen*, 1825, 4, 10) and Rose (*ibid.*, 1856, 99, 60) had been unable to obtain metal of more than 58% purity; he effected further purification by fusing the compressed powdery material in a vacuum arc furnace. Spitzin and Kaschtanoff (*Z. anorg. Chem.*, 1929, 182, 207) state that their attempts by an improved Berzelius-Rose method yielded metal of only 95% purity. Since it appears that very pure tantalum cannot be prepared by other methods of reduction (e.g., Moissan, *Compt. rend.*, 1902, 134, 211; Goldschmidt, *Z. angew. Chem.*, 1898, 11, 823; Ruff and Thomas, *Z. anorg. Chem.*, 1925, 148, 18; Muthmann, Weiss, and others, *Annalen*, 1904, 337, 387; 1907, 355, 62), and as it was not considered feasible to study electrolytic methods (e.g., Bouhard, French Patent, 1907, 377931; Weintraub, U.S.P. 1910, 947983), it was decided to investigate the Berzelius-Rose method under improved conditions which included those indicated by Balke (*Chem. Met. Eng.*, 1922, 27, 1272; 28, 560). Briefly, it consisted in the preparation of the metal by the fusion of potassium tantalifluoride with sodium under conditions which minimised the formation of oxides of tantalum and sodium tantalate.

The starting material was the double fluoride obtained from Merck as well as Kahlbaum. Both the specimens contained nearly 1% of silica and small traces of iron, manganese, titanium, and niobium. Removal of silica was effected by treatment with sulphuric acid as described by Balke (*J. Amer. Chem. Soc.*, 1905, 27, 1142). The silica-free preparation was purified according to Meimberg and Winzer's method (*Z. angew. Chem.*, 1913, 26, 157), and finally recrystallised by cooling from its saturated solution at 100° in 5% hydrofluoric acid, all the crystallisations being done in platinum basins. The crystals were transferred to a stout gutta-percha suction funnel and freed as far as possible from mother-

liquor, after which they were centrifuged in a cylinder of platinum gauze. They were dried over caustic potash in a vacuum desiccator and preserved in small cardboard boxes lined with filter paper.

*The reduction process.* This had to be carried out in the absence of air and moisture; otherwise, oxides of tantalum and sodium tantalate would be formed in considerable quantities, and the removal of even small traces of oxide from the metal can be accomplished only by heating at a very high temperature—probably above  $1500^{\circ}$ —in a high vacuum. The bomb employed for the process is shown diagrammatically in Fig. 1. It consisted of a thick

FIG. 1.

steel cylinder (A) open at the top and having a recess at the bottom to take the solid steel piece (C), the top of which was turned to fit accurately a conical taper in the hollow steel vessel (B). A trace of oil on the taper was enough to secure good fitting when the bolts (N, N) were tightened. The clearance between A and B was about 1 mm., so that they could be welded together in case the tapering joint proved unsatisfactory. The reaction vessel D, made from a sheet of the purest commercial molybdenum, seemed to resist attack during the reaction.

The actual manipulation during an experiment was as follows. The shell A containing the block C and the reaction vessel D was

dried by being heated whilst a stream of argon passed through it. Pure freshly dried potassium tantalifluoride (50 g.) and Merck's sodium (18 g.), freshly cut into small pieces under dry benzene, were alternately transferred in small quantities to the reaction vessel while a stream of argon was circulating in the shell. The reaction vessel was then covered with its lid, the vessel B kept in position, and the bolts tightened. The bomb was now heated by burners and kept at a dull red heat for about an hour; its lower portion was then cooled quickly by a jet of water while two tubes were delivering argon near its top. After cooling to room temperature, the bomb was opened and the contents of the reaction vessel, which still contained some free sodium, were transferred in small quantities to

water (300 c.c.) contained in a large platinum basin, whereupon most of it disintegrated to a black powder, the few lumps remaining being crushed with a clean steel rod.

*Purification of the crude metal.* The powdery material in the dish was washed five or six times by decantation with cold water and then several times with dilute alcohol (25%), as recommended by Rose (*loc. cit.*), until the removal of soluble salts was practically complete. It was then digested with three successive portions of hot nitric acid (*d* 1.20), well washed with water, digested twice with hot hydrochloric acid (1 : 1), again washed with water, and finally dried in a stream of argon at about 300°. The dried powdery material was found to contain 97.9% of free tantalum. The powder was compressed into pellets, each weighing nearly 5 g., in a nickel-steel die at pressures ranging from 20,000 to 30,000 lb. per sq. in. and the pellets were freed from gas by 10 hours' heating at about 1000° in a vacuum of  $10^{-4}$ — $10^{-5}$  mm. They were then heated inductively in a vacuum furnace in a crucible of pure thoria, a current of 180 amps. at 7000 volts and 490,000 cycles being used. The vacuum maintained was about  $10^{-5}$  mm., and temperatures of 1700—1800° were reached. After this treatment the pellets were found to have sintered to a hard mass with a platinum-grey lustre, and oxidation experiments showed them to contain 99.2% of free tantalum. The remaining 0.8% was deemed to be tantalum oxide, since a spectrographic study of the metal did not reveal the presence of foreign metals.

#### *The Method of the Determinations.*

The method consisted in the preparation of the chloride and the bromide of tantalum by direct union, their purification by distillation and sublimation in a vacuum, and collection in sampling bulbs which were evacuated and then sealed for analysis. The bulb containing the halide was weighed and then broken under a dilute solution of ammonia whereby all the halogen was converted into the ammonium halide, which could be transferred to another vessel for halogen estimation. The insoluble tantalic acid, formed by the hydrolysis of the sample, and the glass fragments resulting from the breaking of the bulb were then digested with a hot solution of oxalic acid, whereupon all the tantalic acid went into solution. The glass pieces that remained were weighed in order to obtain the weight of the sample originally in the bulb. The estimation of halogen was carried out both nephelometrically and gravimetrically by the method of Richards as adopted by Hönigschmid. The ratios  $\text{TaBr}_5 : 5\text{Ag} : 5\text{AgBr}$  and  $\text{TaCl}_5 : 5\text{Ag} : 5\text{AgCl}$  so obtained enabled the calculation of the atomic weight of tantalum on the

assumption that the values for silver, bromine, and chlorine were 107.880, 79.915, and 35.457 respectively.

The analytical part of this work, including weighings, was carried out in special rooms which were free from acid fumes and were illuminated only by ruby light.

*Balance and Weighing.*—The weights were standardised by the method of Richards (*J. Amer. Chem. Soc.*, 1900, 22, 144), and the weighings performed in a room which was maintained by electrical heaters at a constant temperature of  $20^{\circ} \pm 0.1^{\circ}$ . The balance employed was of the special type made by Oertling with a beam of invar-steel which was protected by an aluminium partition and provided with a prism and mirror device to enable movements of the beam to be noted with a lamp and scale fixed at a distance of 2 m. from it. The weighings were done by the method of counterpoise and substitution, and the weights so obtained were corrected for errors due to inequality of weights and reduced to vacuum. Successive weighings of the same object usually agreed to 0.01 mg. and never differed by more than 0.02 mg.

*The Distillation Apparatus.*—This resembled the apparatus devised by Willard and McAlpine (*loc. cit.*) and is shown diagrammatically in Fig. 2. It consisted of a bubbler (*A*) into which bromine could be introduced through a side tube and separating funnel, a tube (*B*) in which powdered tantalum could be kept heated, the distillation bulbs (*C* and *D*), and the system of sampling bulbs (*E*). The three-way tap  $T_3$  served to introduce either argon or chlorine into the apparatus. Argon entered from a gas-holder through the tap  $T_1$ , and passed over copper gauze kept at  $500\text{--}550^{\circ}$  in *X*, through sulphuric acid in *Y*, and phosphoric oxide in *Z*; whereas chlorine entered through the tap  $T_2$  and, after bubbling through a strong solution of potassium permanganate in *P* and sulphuric acid in *Q*, passed over ignited lime in *R* and phosphoric oxide in *S*. A continuous flow of either gas through the apparatus could be maintained by keeping open  $T_1$  or  $T_2$  and also  $T_3$ ,  $T_5$ , and  $T_6$  while the other taps were kept closed. With taps  $T_7$  and  $T_8$  open and all the others closed, the apparatus could be evacuated by a mercury-vapour pump working in conjunction with a "Hyvac" pump. The trap *F*, which was cooled in liquid air, served not only to freeze bromine or chlorine, which would otherwise pass into the pumps, but also to minimise diffusion of mercury vapour into the apparatus. All the taps in the apparatus were lubricated with metaphosphoric acid.

*The Preparation of Tantalum Bromide.*—The parts *A* to *E* of the apparatus were kept at  $300\text{--}350^{\circ}$  and thoroughly dried and freed from air by alternate evacuation and filling with argon, the process

being repeated 5 or 6 times. Then, with a stream of argon flowing through the apparatus, the tip of the side tube attached to *B* was broken to introduce 7–8 g. of finely powdered tantalum, which had been previously dried in a current of argon. The tube was now sealed off and the apparatus evacuated and refilled with argon, thus ensuring the total absence of air and moisture from the system. Through some phosphoric oxide, which was kept in the separating funnel, somewhat more than twice the quantity of bromine necessary to react with the tantalum taken was run into the bubbler *A*, entry of air being prevented by closing the tap of the funnel while

FIG. 2.

there was still about 1 c.c. of bromine in it. The constriction  $c_1$  was then sealed. The furnace surrounding the tube *B* being kept at 650–700°, a beaker of water at about 55° was placed under the bubbler, and a slow stream of argon bubbled through, carrying bromine vapour to the hot tantalum in *B*. The initial formation of the bromide was immediate, although it continued slowly, much bromine escaping combination. By suitably warming the tube connecting *B* and *C*, and keeping *C* and *D* cool, most of the bromide was collected in *C*; some of it, however, went into *D*, and a small quantity was carried still farther in a thin cloud by the gas stream. At the same time, some drops of bromine collected in *C* and *D* and

also in some parts of the system *E*. When enough of the bromide had been prepared, the argon supply was stopped and the preparation tube *B* allowed to cool. The apparatus was then sealed at the constriction  $c_2$ , heated at 100–110°, and evacuated so as to remove all free bromine. The constriction  $c_3$  was now sealed and the tube *B* removed. With the pump in continuous operation, the bulb *C* was kept at about 300° in order to drive most of the bromide into the bulb *D*, which was kept cool. The constriction (not shown in the diagram) in the tube connecting *C* and *D* was then sealed. The sublimation of the bromide from *D* into the bulbs *E* was effected by suitable movement of the furnace, which was maintained at about 300°. With the vacuum pump in continuous operation the bulbs were finally sealed for analysis.

The bromide in the bulbs consisted of fine needles as well as some thin, lemon-yellow leaflets.

*Preparation of Tantalum Pentachloride.*—The chloride was prepared in an apparatus which was exactly like the foregoing except that it had no bubbler, the tube *B* being directly joined to the three-way tap by a tube having a constriction. The subsequent procedure was similar to that employed for the bromide, a slow stream of dry chlorine being passed over the powdered metal at 550–600°.

The chloride was perfectly snow-white during the earlier stages of the distillation, but later acquired a pale creamy colour, probably owing to prolonged heating.

*Spectrographic Studies of the Purity of the Tantalum Preparations.*—The instrument employed was a quartz Littrow spectrograph made by A. Hilger. The principle of the method consisted in the identification of the impurity lines in the spectrum of the tantalum compounds examined, by measurement as well as by superposition on the spectra of the probable impurities. The first step was the preparation of photographs of the ultra-violet and visible arc spectra of the tantalum compounds between copper poles, and also corresponding photographs of the copper arc. A series of photographs was prepared of the spectra of silica, iron, manganese, niobium, titanium, and molybdenum in the copper arc, each on a separate plate. The persistent lines of these elements were identified by measurement and suitably marked on the plates. By bringing each of these impurity spectra into juxtaposition with the tantalum spectrum, it was easy to note if any of the impurity lines were present in the latter, but as none of these could be traced it was decided to make an exhaustive examination for all the possible impurities by the R.U. (raies ultimes) powder method advocated by A. Hilger. Since the R.U. powder contains only small traces of nearly all the metals in a suitable diluent, its arc spectrum, although

Fig. 3.

consisting of only a limited number of lines, includes all the strongest lines of all the elements in it. Therefore, by photographing the R.U. spectrum in juxtaposition with that of the specimen to be examined, it is a relatively simple matter to ascertain the impurities present; moreover, it is possible, within certain limits, to estimate quantitatively the impurities according to the order of sensitivity of the lines observed. An examination of the spectrum photographs (Fig. 3) will make this matter clear. Niobium, for instance, is present in the R.U. powder to the extent of about 0.05%, but it gives about 15 lines, some of which are marked on the plate. Since not even one of these can be traced in the tantalum spectrum, it is concluded that niobium is absent. Similarly with most of the other elements. The results, however, are not so definite in the case of silica. It will be seen from the plate that the group of lines marked Si (2506.9—2528.5 Å.U.), which are strong in the R.U., are present in the tantalum spectrum also, though with a smaller intensity. Since, however, this group of lines is present in the spectrum of the poles themselves and with an intensity approximately equal to that in the tantalum spectrum, it can be deduced that the tantalum is practically free from silica. The other metals regarding which there is similar uncertainty are calcium and magnesium. The quantity in which they are present must, however, be very small. Dr. J. W. Ryde and Mr. H. G. Jenkins, of the Research Laboratories of the General Electric Co., Ltd., who developed the R.U. method, kindly undertook a confirmatory examination of these specimens and reported that spectroscopically they were unable to find impurities. There is, however, the possibility that silica, calcium, and magnesium may be present to a total extent of about 0.05%.

*Determination of the Ratios TaBr<sub>5</sub> : 5Ag : 5AgBr.*—The bulb containing the bromide was cleaned and dried as usual (compare Baxter, *Proc. Amer. Acad. Arts Sci.*, 1924—25, 60, 228), and its weight in air determined. It was then weighed in water by suspending it with a thin platinum wire, and from the observed loss of weight the vacuum correction was calculated in the usual manner. It was then placed on the bottom of a thick-walled conical Pyrex flask containing about 400 c.c. of a ca. 3% solution of ammonia, and broken by a blunt glass rod, which was quickly rinsed and removed. The flask was immediately stoppered, left for about 2 hours, and then rotated so as to disturb the flocculent precipitate which had settled, this operation being repeated 4 or 5 times at intervals of about an hour. After standing over-night, the clear supernatant liquid was poured through a Jena-glass Gooch crucible having a sintered-glass filter, and the filtrate caught directly in a large conical precipitation flask, made of Pyrex glass and kept inside an evacuated

bell-jar. The material remaining in the original flask, viz., the precipitate of tantalic acid and the glass fragments of the bulb, was washed by decantation 10—12 times with 70—80 c.c. portions of a hot (60°) 1% aqueous solution of ammonium nitrate, as recommended by Biltz and Voigt (*Z. anorg. Chem.*, 1922, **120**, 171), with the modification that it contained nearly 2% of free nitric acid in addition. The clear wash-liquids were passed through the Gooch crucible in each case, and the filtrates added to the first filtrate, which thus increased to about 1200 c.c. and was preserved for halogen estimation. The washing process was effective because the tantalic acid settled easily in the wash-liquid and so facilitated the decantation. It is shown later (p. 1291) that the washed residue was halogen-free and that practically none of it (either tantalic acid or glass) was transferred from the flask during washing.

To dissolve out the tantalic acid in order that the glass pieces might be weighed, the residue in the flask was digested on a boiling water-bath for about 2 hours with some 50 c.c. of a saturated solution of oxalic acid. The liquid in the flask was then diluted with about 300 c.c. of water, whereupon the solution became quite clear and was free from any particles of tantalic acid. The glass fragments appeared quite clean and transparent. The clear liquid was poured through a weighed silica Gooch crucible with a sintered-silica filter. The glass pieces were washed by decantation 10—12 times with 50 c.c. portions of warm water, then transferred with a jet of water to the crucible, dried, and weighed. (The washings from the above operations were discarded.) The glass pieces were dried slowly by being kept at 90—110° for about 2 hours and then at 400—420° for about 8 hours; and their weight was corrected to vacuum and subtracted from the corrected weight of the bromide bulb in order to obtain the weight of the bromide originally in the bulb. This was, however, corrected for a small error (0.03 mg.) which appeared to be incidental to the collection and weighing of the glass fragments (see p. 1291).

The estimation of halogen in the bromide solution, which contained only nitric acid and ammonium bromide and nitrate, was carried out according to the Harvard methods as developed by Hönigschmid. The standard solutions of silver nitrate and potassium bromide required to make up for the deficiency of either silver or bromide ions in the analytical solution, and for the generation of opalescence in the test mixtures, were all made up with the concentrations recommended by the author mentioned above. On the assumption that  $Ta = 181.37$ , which was calculated from the mean of two gravimetric determinations of the ratio  $TaBr_5 : 5AgBr$ , a quantity of silver was weighed out which was insufficient by about

0.1—0.2 mg. to precipitate quantitatively the bromide ion in the analytical solution. The silver was dissolved in about 50 c.c. of nitric acid ( $d$  1.20) in a conical Pyrex flask having a four-bulbed tube ground into its neck. After being gently boiled for a few minutes, the solution was diluted to about 0.1*N* and then transferred quantitatively to the flask containing the bromide solution, which was then stoppered, and shaken at frequent intervals. After standing for about 48 hours, the precipitate was found to have settled completely, leaving the supernatant liquid perfectly clear. Two 25-c.c. portions of the clear liquid were withdrawn and tested for excess of bromide or silver by addition of 1 c.c. of silver solution (1 in 1000) to one and 1 c.c. of an equivalent bromide solution to the other. The test solutions were allowed to stand for 4 hours with frequent stirring with glass rods, and then examined in a nephelometer of the Kober type with a Klett top-reader. According as the tests indicated excess of bromide or silver, standard solution of silver (0.1 in 1000) or equivalent bromide solution was added to the analytical solution until a nephelometric test indicated that the two ions were in exact equivalence as revealed by the equality of the intensity of opalescence developed when equal portions of the solution were treated with equivalent quantities of either silver or bromide test solution. After the end-point had been reached, excess of one of the standard solutions was added, and the end-point again obtained by back-titration in the nephelometer. The quantity of silver (in the standard solution) introduced in order to reach the point of equivalence was added to the weight of silver originally added in bulk to the analytical solution, and the ratio  $\text{TaBr}_5 : 5\text{Ag}$  calculated. The results of the determinations are given in Table I (a).

After completion of the nephelometric titration, 25 c.c. of *N*/10-silver nitrate solution were added to the contents of the flask in order to precipitate all the dissolved silver bromide. The flask was stoppered and occasionally shaken during the next 24 hours, and the precipitate then allowed to settle. The clear liquid was poured through a weighed Jena-glass Gooch crucible with a sintered-glass filter. The silver bromide in the flask was washed ten times by decantation with about 60 c.c. portions of 0.5% nitric acid, transferred to the crucible, dried for about 18 hours at 300—320°, and weighed. Most of the silver bromide was transferred to a porcelain crucible and fused in an electric furnace maintained at 500—520°; it was then seen to be transparent and free from dark patches—a clear indication of its purity. In two experiments in which the silver bromide was weighed both before and after fusion, the loss (due to expulsion of the last traces of moisture) was not more

than 0.02 mg. Since this result is in agreement with the long experience of Hönigschmid that silver bromide dried at  $300^{\circ}$  does not retain an appreciable amount of moisture, no attempts were made to determine the loss on fusion in every experiment. Confirmatory evidence regarding the purity of the silver bromide precipitate was obtained from determinations of the ratio  $\text{AgBr} : \text{AgCl}$  (see p. 1292).

The weight of the silver bromide obtained by weighing the dried precipitate was corrected for the quantity which escaped weighing owing to solution in the nitric acid washings, and also for the small amount which was retained by the walls of the precipitation flask. The estimation of these two sources of error was carried out jointly as recommended by Hönigschmid (*Z. anorg. Chem.*, 1924, **136**, 278; *Annalen*, 1923, **433**, 201), i.e., by dissolving out the traces of the silver bromide in the precipitation flask by the addition of ammonia, adding this solution to the nitric acid washings\* of the silver bromide, diluting the combined solution to a known volume, and comparing it nephelometrically with solutions containing known amounts of silver bromide. The quantity of silver bromide so estimated was added to the weight of the precipitate, and the ratio  $\text{TaBr}_5 : 5\text{AgBr}$  calculated. Table I (b) gives the results of the determinations.

*Determination of the Ratios  $\text{TaCl}_5 : 5\text{Ag} : 5\text{AgCl}$ .*—The sealed bulbs containing the chloride were weighed in air and in water, and then broken under a solution of ammonia. The subsequent procedure was exactly as in the case of the bromide, except that sodium chloride was substituted for potassium bromide in the solutions employed during the nephelometric determinations. The silver chloride precipitate was dried at  $300\text{--}320^{\circ}$  for about 18 hours before weighing. It always fused to a transparent, light amber-coloured mass, free from any dark patches: this was considered to be a definite indication of its purity. The results of the various determinations are given in Table II, all the weights being reduced to vacuum. The atomic weights of silver, bromine, and chlorine were assumed to be as on p. 1282.

The individual values for the atomic weight given in Table I(a) show an extreme variation of 0.03 unit (1.7 parts per 10,000). Their mean variation is 0.008 unit (0.5 part per 10,000) from the mean value 181.36, the probable error of which is found to be  $\pm 0.003$  unit.

\* These washings were collected separately from the mother-liquor from which the precipitation was made. The mother-liquor was discarded, as the quantity of silver bromide in it must have been negligible owing to the excess of silver nitrate present.

TABLE I.

No.	TaBr <sub>5</sub> , g.	(a) Ratio TaBr <sub>5</sub> :5Ag.			(b) Ratio TaBr <sub>5</sub> :5AgCl.

Total	16.90621	25.42856	0.66485	181.34	33.78278	0.50044	181.37

The individual values for the atomic weight given in Table II(a) show an extreme variation of 0.06 unit (3.3 parts per 10,000). Their mean variation is 0.019 unit (1.0 part per 10,000) from the mean value 181.34, the probable error of which is found to be  $\pm 0.007$  unit.

The corresponding data for Table II (b) are 0.04 and 0.015 unit, the mean atomic weight being  $181.37 \pm 0.004$ .

*Summary of Results.*—The mean values obtained from the four series of determinations are collected in the following table, from which it will be seen that the most probable value for the atomic weight of tantalum is 181.36.

Ratio.	No. of expts.	Mean value for at. wt. of Ta.	Probable error.
TaBr <sub>5</sub> :5Ag .....	6	181.36	$\pm 0.003$
TaBr <sub>5</sub> :5AgBr .....	8	181.35	0.004

TaCl <sub>5</sub> :5AgCl .....	5	181.37	0.004
General mean		181.357	0.0002

#### *Investigation of Some Possible Sources of Error.*

Sears (*loc. cit.*) found that, although tantalum pentachloride exists as a stable compound in an atmosphere of dry nitrogen and does not occlude chlorine, it is unsuitable for use in work where a high

degree of accuracy in its analysis is desired. This conclusion was based on the following observations: (a) Broken glass cannot be filtered off from the hydrolysed tantalum chloride because of the insoluble tantalic acid formed; (b) tantalum pentachloride cannot be weighed accurately in a vessel with a ground joint owing to hydrolysis caused by moist air diffusing in through the joint; (c) volatility of glass during fusion prevents an accurate estimate of the weight of tantalum pentachloride contained in a sealed glass tube of known weight; (d) when tantalum chloride is sealed in a glass bulb, some of it gets melted into the glass at the point of sealing.

The present work seems to be free from any of the above-mentioned sources of complication. The first did not arise because the tantalic acid could be completely dissolved out and so permitted the determination of the weight of the glass pieces. The second and third sources of error were avoided in the method employed for determining the weight of the sample: volatility of glass during fusion is a negligible factor, for Briscoe and Little (J., 1914, 105, 1315) and Weatherill (*J. Amer. Chem. Soc.*, 1924, 46, 2437) experienced no difficulty from that source. The last objection seems to be due to the tantalum pentoxide formed by hydrolysis of the chloride owing to the presence of moisture in the system. The tantalum chloride and also the tantalum bromide bulbs prepared in the earlier experiments had the appearance of frosted glass close to the point of sealing. The bulbs prepared in the later experiments and used for analysis were, however, free from this defect.

As spectrographic investigation afforded definite evidence that the tantalum halides prepared for analysis were almost entirely free from foreign metals, and as contamination from oxygenated compounds was obviated by carrying out the preparation and weighing in the absence of oxygen, air, and moisture, little uncertainty could be entertained regarding their purity. The method of analysis, however, involved several steps which demanded scrutiny.

A study was made of the process employed for washing the tantalic acid and glass fragments in order to extract all the halide present. As in every experiment the clear liquid was filtered through a Gooch crucible, it was easy to test whether any solid material was conveyed to it, by weighing the crucible before and after the filtration. Three experiments were performed with two different crucibles and the observed variations in weight were  $+0.02$ ,  $0.00$ , and  $+0.03$  mg., respectively, giving an average increase in weight of  $0.02$  mg. If this increase is due solely to tantalic acid, it is of no significance, since the crucibles employed

for this process were never used for the collection of either glass fragments or silver bromide precipitate; if it is due entirely to fine particles of glass, this would be a source of error, for this amount of glass would escape weighing and the apparent weight of the tantalum halide would be too high to this extent. Since, however, 0.02 mg. is within the limit of error of the determinations, the precise cause is immaterial.

The next point tested was whether any portion of the glass fragments was lost owing to solution, either colloidal or otherwise, in the wash-liquid. Bulbs similar to those employed for collecting the tantalum halides were fused on to a vacuum line and then sealed after evacuation. They were weighed in air and in water so as to obtain their weight in vacuum. They were then broken under a solution of 3% ammonia contained in a conical Pyrex-glass flask, and subjected to exactly the same treatment as the glass fragments in the actual determinations, *viz.*, washing with ammonium nitrate, decantation of the clear liquid, digestion with hot saturated solution of oxalic acid, and washing with water. They were then collected in a weighed Gooch crucible, dried as usual, and weighed. This weight was reduced to vacuum and compared with the weight of the bulb as determined at the beginning of the experiments; the results were as follows:

Bulb, g. ....	1.81427	1.70330	1.74959	1.68884
Glass pieces, g. ....	1.81425	1.70325	1.74958	1.68880
Difference, mg. ....	0.02	0.05	0.01	0.04

They indicate a definite average loss of 0.03 mg. This quantity was therefore added to the weight of glass as actually determined.

The next point to be tested was whether the process of washing removed the bromide quantitatively and left the residue of tantalic acid and glass fragments bromide-free. Although aqueous extracts of the residue failed to give any test for halogen, it was feared that adsorption of bromide ions might have proceeded in such a way as to escape detection in this manner. The material was therefore heated with sulphuric acid and tested for formation of hydrogen bromide. This was done by introducing the tantalic acid (and glass pieces) into a bulb (50 c.c.) through a side tube with a ground joint to accommodate a separating funnel. The condensing tube, which was fused to the bulb, was bent at right angles. With the end of the condensing tube dipping in 25 c.c. of 0.1*N*-silver nitrate solution, 10–15 c.c. of sulphuric acid ( $d$  1.84) were introduced into the bulb through the separating funnel, the tap of which was afterwards closed. The bulb was then heated in a bath at 120–125°. The silver nitrate solution remained clear without developing any opalescence. The distilling bulb was then allowed to cool, 0.05 mg.

of ammonium bromide (0.5 c.c. of 0.1 in 1000 solution) introduced into it, and the bulb reheated. The silver nitrate solution became strongly opalescent in less than 5 minutes. As the above test is very delicate, and as three lots of washed tantalic acid did not respond to it, it was concluded that the extraction of the halide was quite satisfactory.

The purity of the silver bromide precipitate was indicated by its appearance on fusion as already stated, and was confirmed by its conversion into silver chloride as follows. A portion of the dried silver bromide was transferred to a weighed porcelain crucible and fused in an electric furnace. The weight of the fused silver bromide was ascertained by reweighing the crucible. The crucible was then suitably supported in the centre of the furnace, which was maintained at about  $500^{\circ}$  while a stream of chlorine passed through it. After 5–6 hours, the chlorine supply was replaced by argon for about 2 hours in order to expel all the free chlorine. The crucible was then taken out of the furnace, cooled, and weighed. The results of three such experiments were :

AgBr, g. ....	4.16021	6.30116	5.99453
AgCl, g. ....	3.17510	4.80924	4.57492
AgBr/AgCl .....	1.31026	1.31022	1.31030

The mean of the three determinations ( $\text{AgBr/AgCl} = 1.31026$ ) is in tolerable agreement with the value obtained by Baxter (*Proc. Amer. Acad. Arts Sci.*, 1905, **41**, 82; 1906, **42**, 201), viz., 1.31017, thereby showing that the silver bromide formed in these experiments was adequately pure.

#### *Summary.*

Pure tantalum, prepared by a modified Berzelius–Rose method, was employed for the preparation of its bromide and chloride by direct union with the elements in an inert atmosphere. The halides were purified by distillation and sublimation in a vacuum, and collected in sampling bulbs for analysis. Spectrographic examination gave satisfactory evidence regarding their purity. They were analysed both nephelometrically and gravimetrically by the Harvard method as developed by Hönigschmid. Twenty-four closely-agreeing results pointed to the value 181.36 for the atomic weight of tantalum.

In conclusion, I wish to express my gratitude to Professor F. G. Donnan, F.R.S., for having provided every facility and for kind encouragement throughout the course of this work. My best thanks are due to Messrs. S. Barratt, B.A., and J. M. Walter, B.Sc., for valuable suggestions relating to the spectroscopic methods

employed. My warmest thanks are also due to Dr. C. Sykes of the Research Laboratories of the Metropolitan Vickers Electrical Co., Ltd., Manchester, for assistance with the high-frequency furnace, and to Dr. J. W. Ryde and Mr. H. G. Jenkins of the Research Laboratories of the General Electric Co., Ltd., Wembley, for carrying out a confirmatory analysis of the tantalum specimens. My hearty thanks are due to Mr. Henry Terrey, M.Sc., for assistance in the preparation of this paper.

#### CLXIV.—4-Sulpho-3-hydroxybenzoic Acid.

By MADHAVLAL SUKHLAL SHAH.

THE sulpho-*m*-hydroxybenzoic acid which is obtained by the sulphonation of *m*-hydroxybenzoic acid has now been prepared by a more convenient method than those described by Barth (*Annalen*, 1868, **148**, 38), Senhofer (*ibid.*, 1869, **152**, 102), and Remsen (*Z. Chem.*, 1871, 295): it consists in heating a mixture of *m*-hydroxybenzoic acid and sulphuric acid at 90° for 2 hours; the sulpho-*m*-hydroxybenzoic acid crystallises in large yield on cooling and there is no sign of any other product. The acid, when recrystallised from water, separates as  $C_7H_6O_6S \cdot 2\frac{1}{2}H_2O$ , m. p. 206°. Barth and Senhofer describe the acid, m. p. 208°, crystallising with  $1\frac{1}{2}$  molecules of water.

The author has confirmed Barth's observation (*loc. cit.*; *Annalen*, 1871, **159**, 230; contrast Remsen, *loc. cit.*) that no organic acid other than protocatechuic acid, m. p. 199°, is produced by fusion of the sulpho-*m*-hydroxybenzoic acid with alkali. Hence the sulphonic acid appears to be 4-sulpho-3-hydroxybenzoic acid.

In order to obtain further evidence the author studied the methyl ether of this acid, comparing it with the oxidation products of isomeric 3-methoxytoluenesulphonic acids described by Haworth and Lapworth (*J.*, 1923, **123**, 2982; 1924, **125**, 1299). The sulphonic acid methyl ether (I) crystallised as  $C_8H_8O_6S \cdot 2H_2O$  and gave characteristic *barium* and *potassium hydrogen* salts. The latter on trituration with phosphorus pentachloride produced a chlorosulphonyl-3-methoxybenzoyl chloride, m. p. 87°, which gave on treatment (a) with water, a chlorosulphonyl-3-methoxybenzoic acid, m. p. 214°, and (b) with ammonia, a sulphonamido-3-methoxybenzamide, m. p. 255°. The former when digested with ammonia

and the latter when hydrolysed with hydrochloric acid yielded the same sulphonamido-3-methoxybenzoic acid (II), m. p. 290° (decomp.).

Haworth and Lapworth (*loc. cit.*) state that their potassium hydrogen 4-sulpho-3-methoxybenzoate obtained from 3-methoxytoluene-4-sulphonic acid yielded 4-sulphonamido-3-methoxybenzoic acid, m. p. 255°, by the action of ammonia on the sulphonyl chloride, which was not isolated. From the author's results the substance, m. p. 255°, which Haworth and Lapworth describe under the name of sulphonamido-3-methoxybenzoic acid appears to be 4-sulphonamido-3-methoxybenzamide, m. p. 255°. In order to clear up this matter the experimental work of Haworth and Lapworth was repeated.

3-Methoxytoluene-4-sulphinic acid (III), prepared from 4-nitro-*m*-cresol via 4-nitro- and 4-amino-3-methoxytoluenes, was oxidised and 3-methoxytoluene-4-sulphonic acid and 4-sulpho-3-methoxybenzoic acid (I) were obtained. The latter gave, on treatment similar to that described above, 4-chlorosulphonyl-3-methoxybenzoyl chloride, m. p. 87°, 4-chlorosulphonyl-3-methoxybenzoic acid, m. p. 214°, 4-sulphonamido-3-methoxybenzamide, m. p. 255°, and 4-sulphonamido-3-methoxybenzoic acid (II), m. p. 290° (decomp.), identical with those obtained from the author's sulpho-*m*-hydroxybenzoic acid methyl ether, the conclusions being confirmed in each case by the mixed melting point test.

Haworth and Lapworth also state that their sulphonamido-3-methoxybenzoic acid, m. p. 255°, was produced when 3-methoxytoluene-4-sulphonamide (IV) was oxidised with alkaline permanganate. The author, however, obtained only 4-sulphonamido-3-methoxybenzoic acid, m. p. 290° (decomp.).

For full information the author converted (A) 4-sulpho-3-methoxybenzoic acid (I) and (B) 3-methoxytoluene-4-sulphinic acid (III), which yields 4-sulpho-3-methoxybenzoic acid as shown above, into 3-methoxybenzoic acid 4-methylsulphone (V).

(A) 4-Chlorosulphonyl-3-methoxybenzoic acid, m. p. 214°, prepared from sulpho-*m*-hydroxybenzoic acid methyl ether (I), was reduced by Gattermann's method (*Ber.*, 1899, **32**, 1136) and the 4-thiol-3-methoxybenzoic acid (monothiovanillic acid), m. p. 180°, which was obtained was converted on methylation into 4-methylthiol-3-methoxybenzoic acid (monothioveratric acid), m. p. 193°. The latter on oxidation gave 3-methoxybenzoic acid 4-methylsulphone (V), m. p. 227°.

(B) When 3-methoxytoluene-4-sulphinic acid (III) was similarly reduced, 4-thiol-3-methoxytoluene, b. p. 254°, was produced. This passed on methylation into 4-methylthiol-3-methoxytoluene, b. p. 269—270°. When the latter was oxidised with alkaline perman-

ganate, the same 3-methoxybenzoic acid 4-methylsulphone (V), m. p. 227°, as described in (A) was produced : a mixture of the two showed no depression in melting point. This proves that sulpho-*m*-methoxybenzoic acid (I) corresponds to 3-methoxytoluene-4-sulphinic acid (III) and that the sulpho-*m*-hydroxybenzoic acid is 4-sulpho-3-hydroxybenzoic acid.

The sulpho-*m*-hydroxybenzoic acid methyl ether (I) was also fused with sodium hydroxide and with potassium hydroxide with a view to get vanillic acid, but the product was protocatechuic acid. Partial fusion at a low temperature gave sulpho-*m*-hydroxybenzoic acid together with protocatechuic acid, which indicates that in alkali fusion 4-sulpho-3-methoxybenzoic acid (I) is first demethylated and then converted into 3:4-dihydroxybenzoic acid, *i.e.*, protocatechuic acid. Vanillic, *isovanillic*, and *veratric* acids have been found to be similarly demethylated and to yield protocatechuic acid.

#### EXPERIMENTAL.

*Sulpho-m-hydroxybenzoic Acid.*—*m*-Hydroxybenzoic acid (40 g.) was mixed with sulphuric acid containing 3% of sulphur trioxide (60 c.c.) and heated at 90° for 2 hours. The brown solution obtained solidified on cooling to a hard crystalline mass; this was crushed, washed with dilute sulphuric acid, and pressed and dried on porous tile. The crude substance crystallised from water (charcoal) in greenish-yellow needles or truncated prisms containing  $2\frac{1}{2}\text{H}_2\text{O}$ , m. p. 206° (yield, 61 g.). The substance effloresced on exposure to air and developed an intense violet fluorescence in dilute alkaline solutions (Found: equiv., 264, 263. Calc. for  $\text{C}_7\text{H}_6\text{O}_6\text{S}, 2\frac{1}{2}\text{H}_2\text{O}$ : equiv., 263). Desiccation removed  $1\frac{1}{2}$  molecules of water and left an opaque white mass, m. p. 213° (Found: equiv., 235.6. Calc. for  $\text{C}_7\text{H}_6\text{O}_6\text{S}, \text{H}_2\text{O}$ : equiv., 236).

The acid sodium, potassium and ammonium salts were prepared (1) by neutralising one half of an aqueous solution of sulpho-*m*-hydroxybenzoic acid with alkali and then mixing it with the other half, (2) by acidifying the neutral solution with hydrochloric acid.

The sodium hydrogen salt separated in shining plates and was recryst-

tallised for analysis (Found : Na, 8.6;  $\text{H}_2\text{O}$ , 10.1; equiv., 267.1.  $\text{C}_7\text{H}_5\text{O}_6\text{SNa} \cdot 1\frac{1}{2}\text{H}_2\text{O}$  requires Na, 8.6;  $\text{H}_2\text{O}$ , 10.1%; equiv., 267). The *potassium hydrogen* salt crystallised in prismatic plates and is more soluble than the acid sodium salt (Found : K, 14.1;  $\text{H}_2\text{O}$ , 6.51; equiv., 274.3.  $\text{C}_7\text{H}_5\text{O}_6\text{SK} \cdot \text{H}_2\text{O}$  requires K, 14.2;  $\text{H}_2\text{O}$ , 6.6%; equiv., 274.1). The *ammonium hydrogen* salt separated in needles (Found : N, 6.1; equiv., 234.9.  $\text{C}_7\text{H}_5\text{O}_6\text{SN}$  requires N, 5.96%; equiv., 235.0).

*4-Sulpho-3-methoxybenzoic Acid* (I).—The sulpho-*m*-hydroxybenzoic acid (22 g. in 50 c.c. of water) was neutralised and treated alternately with 25% potassium hydroxide solution (500 c.c.) and methyl sulphate (80 c.c.) until the violet fluorescence disappeared; the mixture was then heated with potassium hydroxide in excess to hydrolyse the ester formed, neutralised with sulphuric acid, concentrated, and cooled. The filtered solution, when acidified with hydrochloric acid, gave *potassium hydrogen sulpho-m-methoxybenzoate* in rhombic plates, which were washed and recrystallised from water for analysis (yield, 23 g.) (Found for the hydrated salt : K, 13.5;  $\text{H}_2\text{O}$ , 6.5; equiv., 286.8, 288.2.  $\text{C}_8\text{H}_7\text{O}_6\text{SK} \cdot \text{H}_2\text{O}$  requires K, 13.6;  $\text{H}_2\text{O}$ , 6.3%; equiv., 288.1. Found for the anhydrous salt : K, 14.4.  $\text{C}_8\text{H}_7\text{O}_6\text{SK}$  requires K, 14.4%).

The *sodium hydrogen* salt, prepared by using sodium hydroxide, presented much difficulty in its separation, as it carried sodium chloride along with it and was not easily isolated by filtration. For analysis it was recrystallised several times from water, separating as a glossy microcrystalline mass (Found for the anhydrous salt : Na, 8.9.  $\text{C}_8\text{H}_7\text{O}_6\text{SNa}$  requires Na, 9.05%).

The *barium* salt : The above acid potassium salt was neutralised with ammonia, and the neutral solution treated with barium acetate solution. The precipitated barium salt, crystallised from water, formed transparent beady crystals containing  $4\text{H}_2\text{O}$ , of which  $3\text{H}_2\text{O}$  were easily removed at  $120^\circ$  (Found : Ba, 31.1; loss at  $120^\circ$ , 13.4.  $\text{C}_8\text{H}_6\text{O}_6\text{SBa} \cdot 4\text{H}_2\text{O}$  requires Ba, 31.3;  $3\text{H}_2\text{O}$ , 12.3%).

The barium salt, dissolved in water, was treated with the equivalent amount of sulphuric acid, and the filtered solution concentrated to a small bulk; *4-sulpho-3-methoxybenzoic acid* crystallised in long shining plates containing  $2\text{H}_2\text{O}$ , m. p.  $228^\circ$  (Found : S, 11.85; equiv., 133.5.  $\text{C}_8\text{H}_6\text{O}_6\text{S} \cdot 2\text{H}_2\text{O}$  requires S, 11.9%; equiv., 134).

*Fusion of 4-Sulpho-3-hydroxybenzoic Acid with Alkali*.—Finely powdered acid potassium or sodium sulpho-*m*-hydroxybenzoate (7 g.) was added to fused potassium hydroxide or sodium hydroxide (22 g.) in a nickel crucible at  $220^\circ$  and the mass was well stirred. When the temperature was raised gradually, considerable frothing was observed; at  $300^\circ$  the mass became a clear liquid, which was

further heated at  $310^{\circ}$  for  $\frac{1}{2}$  hour. The fused mass was dissolved in water and neutralised with sulphuric acid, and the filtered solution acidified and extracted with ether. The extract on evaporation left a residue which crystallised from water in needles (3 g.), m. p.  $199^{\circ}$  (Found: equiv., 153.8. Calc. for  $C_7H_6O_4$ : equiv., 154). The acid gave all the characteristic reactions of protocatechuic acid, showed no depression in melting point in admixture with this acid, and gave veratric acid, m. p.  $181^{\circ}$ , on methylation. It formed a diacetyl derivative, m. p.  $152^{\circ}$  (compare Herzig, *Monatsh.*, 1885, 6, 872).

*Fusion of 4-Sulpho-3-methoxybenzoic Acid with Alkali.*—Acid potassium 4-sulpho-3-methoxybenzoate (15 g.) was similarly fused at  $310^{\circ}$ , and the fused mass examined as described above. The ethereal extract gave a product, m. p.  $199^{\circ}$ , identical with protocatechuic acid (yield, 6 g.).

In other fusions the temperature was maintained at  $270^{\circ}$  and  $280^{\circ}$ , and the mass examined. The neutral solution after concentration was acidified with hydrochloric acid; acid potassium sulpho-*m*-hydroxybenzoate then crystallised in prismatic plates, showing in alkaline solutions the violet fluorescence of sulpho-*m*-hydroxybenzoic acid (Found: K, 14.2;  $H_2O$ , 6.5%; equiv., 274.0). The acid mother-liquor on extraction with ether gave some protocatechuic acid, which showed that in the fusion of sulpho-*m*-methoxybenzoic acid with alkali demethylation preceded the replacement of the sulpho-group by hydroxyl.

*4-Chlorosulphonyl-3-methoxybenzoyl Chloride.*—The anhydrous acid potassium salt of 4-sulpho-3-methoxybenzoic acid (I) (15 g.) was triturated with phosphorus pentachloride (35 g.) and heated on a water-bath for 5 hours. The mixture became syrupy and hydrogen chloride was copiously evolved. The mixture was poured into ice-water and the insoluble portion was washed and dried (yield, 14 g.). The substance gradually changed in cold water, and in boiling water was readily hydrolysed to 4-sulpho-3-methoxybenzoic acid. It dissolved freely in benzene and toluene and moderately readily in carbon tetrachloride. *4-Chlorosulphonyl-3-methoxybenzoyl chloride* separated in rectangular plates, m. p.  $87^{\circ}$  (Found: S, 11.8; Cl, 26.15.  $C_8H_6O_4Cl_2S$  requires S, 11.9; Cl, 26.4%).

*4-Chlorosulphonyl-3-methoxybenzoic Acid.*—Finely powdered 4-chlorosulphonyl-3-methoxybenzoyl chloride (8 g.) was shaken with cold water (800 c.c.), the course of the hydrolysis being followed by the rise observed in the melting point of the product. After 8 days, the residue, which consisted solely of 4-chlorosulphonyl-3-methoxybenzoic acid, m. p.  $214^{\circ}$ , was collected, washed, and dried (yield, 5 g.). The substance, which was sparingly soluble in all organic

solvents, crystallised from toluene in small plates [Found : S, 12·7; Cl, 14·1; equiv. (excess of NaOH solution and back-titration), 83·0.  $C_8H_7O_5ClS$  requires S, 12·8; Cl, 14·2%; equiv. (if  $SO_2Cl$  becomes  $-SO_3H$  and  $HCl$ ), 83·5].

4-Sulphonamido-3-methoxybenzamide was obtained in quantitative yield by heating finely powdered 4-chlorosulphonyl-3-methoxybenzoyl chloride (5 g.) with ammonia ( $d$  0·88; 50 c.c.) until the excess of ammonia was expelled. It crystallised from water in fine needles or plates, m. p.  $255^\circ$  (Found : S, 13·8; N, 12·2.  $C_8H_{10}O_4N_2S$  requires S, 13·9; N, 12·2%).

4-Sulphonamido-3-methoxybenzoic Acid (II).—(1) 4-Chlorosulphonyl-3-methoxybenzoic acid (3 g.) was dissolved in concentrated aqueous ammonia (30 c.c.), and the excess of ammonia expelled by boiling. The solution on acidification gave 2·9 g. of 4-sulphonamido-3-methoxybenzoic acid (II), m. p.  $290^\circ$  (decomp.).

(2) 4-Sulphonamido-3-methoxybenzamide (2 g.) was boiled under reflux with concentrated hydrochloric acid (20 c.c.) for 24 hours and the solid product after cooling was collected, washed, and dried (yield, 2 g.). It had m. p.  $290^\circ$  (decomp.) and was identical with that obtained in (1).

(3) Another method of preparation is described on p. 1300.

The sulphonamido-3-methoxybenzoic acid was readily soluble in methyl alcohol, ethyl alcohol and acetone, moderately readily soluble in hot water, and almost insoluble in benzene and toluene. It crystallised from 50% alcohol in small rhombic plates [Found : S, 13·8; N, 6·1; equiv. (excess of NaOH solution and back-titration), 115·2.  $C_8H_9O_5NS$  requires S, 13·85; N, 6·1%; equiv. (if  $SO_2-NH_2$  becomes  $SO_3H$  and  $NH_3$ ), 115·5].

4-Thiol-3-methoxybenzoic Acid (monothiovanillic acid).—4-Chlorosulphonyl-3-methoxybenzoic acid (5 g.) was treated with tin (15 g.) and hydrochloric acid (40 c.c.) in the cold. After 2 hours the mixture was heated on a water-bath until the tin had dissolved. Excess of hydrochloric acid was then added and, after cooling, the solid, which floated on the surface, was collected, washed with dilute hydrochloric acid, dried (yield, 4 g.), and purified by repeated dissolution in sodium hydroxide and precipitation with hydrochloric acid. The acid dissolved readily in almost all organic solvents but with difficulty in water. It separated from dilute alcohol in microcrystalline form, m. p.  $180^\circ$  (Found : S, 17·3.  $C_8H_8O_3S$  requires S, 17·4%).

3-Methoxybenzoic Acid 4-Disulphide.—4-Chlorosulphonyl-3-methoxybenzoic acid (1 g.) was dissolved in alcohol and reduced with zinc dust (1·5 g.) and hydrochloric acid (10 c.c.) in the cold. After removal of the excess of zinc dust the clear liquid was treated with

solid ferric chloride in presence of hydrochloric acid and kept for 1 hour. The *disulphide*, which separated on dilution with water, was washed, dissolved in aqueous sodium carbonate, and reprecipitated with hydrochloric acid; it then crystallised from dilute alcohol as a fine white powder (0.9 g.), m. p.  $270^{\circ}$ , to a dark red liquid after softening at  $250^{\circ}$  [Found: equiv., 181.8.  $(C_8H_7O_3)_2S_2$  requires equiv., 183].

4-Methylthiol-3-methoxybenzoic acid (monothioveratric acid) was prepared from the thiol acid (3 g.), 25% sodium hydroxide solution (40 c.c.), and methyl sulphate (6 c.c.) in the usual way. A sodium salt which separated in short silky needles redissolved on addition of water. The solution on acidification gave a flocculent mass, which crystallised readily from all organic solvents, except chloroform and carbon tetrachloride, in lustrous needles (3 g.), m. p.  $193^{\circ}$  (Found: S, 16.1; equiv., 197.8.  $C_9H_{10}O_3S$  requires S, 16.2%; equiv., 198.0).

3-Methoxybenzoic Acid 4-Methylsulphone (V).—4-Methylthiol-3-methoxybenzoic acid (2 g.) was dissolved in aqueous sodium hydroxide and treated with 5% potassium permanganate solution on a boiling water-bath until the purple colour persisted. After addition of a little alcohol and filtration, the solution was concentrated to a small bulk and acidified; 3-methoxybenzoic acid 4-methylsulphone then separated in well-defined plates (1.9 g.), m. p.  $227^{\circ}$ , which were recrystallised from dilute alcohol (Found: S, 13.9; equiv., 230.1.  $C_9H_{10}O_5S$  requires S, 13.9%; equiv., 230.0). The sulphone is readily soluble in alcohol and acetone, moderately easily soluble in hot water, and almost insoluble in benzene, toluene, chloroform, and carbon tetrachloride.

[With Mr. C. T. BHATT.] 3-Methoxytoluene-4-sulphinic Acid (III) and 3-Methoxytoluene-4-sulphonic Acid.—These were prepared by following the experimental work of Haworth and Lapworth (*loc. cit.*). *m*-Cresol was nitrated by Staedel's method (*Annalen*, 1883, 217, 49; 1890, 259, 208) and 4-nitro-*m*-cresol, m. p.  $56^{\circ}$ , was separated from its 6-isomeride by distillation with steam. 4-Nitro-*m*-cresol thus obtained was dissolved in xylene, treated with potassium carbonate and methyl sulphate and converted into 4-nitro-3-methoxytoluene (m. p.  $61^{\circ}$ ) by heating under reflux for 20 hours. The methyl ether on reduction with stannous chloride and hydrochloric acid produced 4-amino-3-methoxytoluene, which was distilled with steam, diazotised, and treated with sulphur dioxide in presence of finely divided copper, all the necessary precautions suggested by Haworth and Lapworth in the conversion of diazo-salt into sulphinic acid being taken.

3-Methoxytoluene-4-sulphinic acid (III), which crystallised in

long needles, m. p.  $111^{\circ}$ , was digested with barium carbonate, and its barium salt oxidised with 1% barium permanganate solution. The barium 3-methoxytoluene-4-sulphonate which was thus held in solution was recovered and treated with the equivalent of potassium carbonate to give the corresponding potassium salt. The anhydrous potassium salt when digested with phosphorus pentachloride gave 3-methoxytoluene-4-sulphonyl chloride, m. p.  $79^{\circ}$ , which on treatment with ammonia produced 3-methoxytoluene-4-sulphonamide (IV), m. p.  $169^{\circ}$ . Haworth and Lapworth give  $79^{\circ}$  and  $168^{\circ}$  respectively.

*4-Sulpho-3-methoxybenzoic Acid (I) from 3-Methoxytoluene-4-sulphinic Acid (III).*—The above potassium 3-methoxytoluene-4-sulphonate, prepared from 3-methoxytoluene-4-sulphinic acid (III) (5 g.), was oxidised with 5% permanganate solution. After the manganese dioxide had been removed, the filtrate was concentrated and acidified with hydrochloric acid; the characteristic acid potassium 4-sulpho-3-methoxybenzoate, then obtained in well-shaped rhombic plates (3 g.), was recrystallised from water (Found: K, 13.5;  $H_2O$ , 6.35%; equiv., 287.5). This salt was successively converted into 4-chlorosulphonyl-3-methoxybenzoyl chloride, m. p.  $87^{\circ}$ , 4-chlorosulphonyl-3-methoxybenzoic acid, m. p.  $214^{\circ}$ , 4-sulphonamido-3-methoxybenzamide, m. p.  $255^{\circ}$ , and 4-sulphonamido-3-methoxybenzoic acid, m. p.  $290^{\circ}$  (decomp.), which were identical with those prepared from sulpho-*m*-hydroxybenzoic acid methyl ether (I).

*4-Sulphonamido-3-methoxybenzoic Acid (II) from 3-Methoxytoluene-4-sulphonamide (IV).*—3-Methoxytoluene-4-sulphonamide (IV) (2 g.) was oxidised with 5% potassium permanganate solution and the filtered liquid was concentrated and acidified with hydrochloric acid. 4-Sulphonamido-3-methoxybenzoic acid crystallised in small rhombic plates (1.8 g.) which, alone or mixed with specimens obtained by the two methods already described, melted and decomposed at  $290^{\circ}$  (Found: equiv., 115.4)\*.

*4-Thiol-3-methoxytoluene.*—3-Methoxytoluene-4-sulphinic acid (III) (5 g.) was reduced with tin (15 g.) and hydrochloric acid (40 c.c.) by the method described on p. 1298. 4-Thiol-3-methoxytoluene, isolated by steam-distillation and extraction with ether, was obtained as a colourless oil (4 g.), b. p.  $254^{\circ}$ , readily soluble in organic solvents (Found: S, 20.7.  $C_8H_{10}OS$  requires S, 20.8%). In alcoholic solution it gave with mercuric chloride a white mercaptide and with lead acetate a canary-yellow mercaptide [Found: Pb, 40.1.  $(C_8H_9OS)_2Pb$  requires Pb, 40.4%]. The benzoyl derivative, prepared by shaking an alkaline solution of 4-thiol-3-methoxytoluene with benzoyl chloride, crystallised from dilute methyl alcohol in

thin plates, m. p.  $76^{\circ}$ . The disulphide separated readily when a solution of iodine in potassium iodide was added to a solution of the mercaptan in sodium hydroxide; it crystallised from methyl alcohol in prismatic plates, m. p.  $83^{\circ}$ .

4-Methylthiol-3-methoxytoluene.—The above mercaptan (3 g.), dissolved in 25% sodium hydroxide solution (30 c.c.), was heated with methyl sulphate (6 c.c.) on a water-bath for 2 hours. The methylthiol, which separated as an oil and was extracted with ether, had an aromatic odour and boiled at  $269\text{--}270^{\circ}$  (yield, 3 g.) (Found: S, 19.0.  $\text{C}_9\text{H}_{12}\text{OS}$  requires S, 19.0%). When oxidised with hot alkaline 5% potassium permanganate solution, it was converted into 3-methoxybenzoic acid 4-methylsulphone, which, alone or mixed with the specimen described above, melted at  $227^{\circ}$  (Found: S, 13.8%; equiv., 229.6).

# CLXV.—The Action of Substituted Aromatic Amines on Camphoric Anhydride. Hydroxy-, Methoxy-, and Ethoxy-camphoranic Acids and Camphoromethoxy- and -ethoxy-phenylimides.

By MAHAN SINGH and RAM SINGH.

THE work on the effect of the substituents on the rotatory powers of substituted camphoranic acids and camphorophenylimides (J., 1925, 127, 1966; 1927, 1944; 1928, 2410) has been extended to include 2'- and 4'-hydroxy-, -methoxy-, and -ethoxy-camphoranic acids and the corresponding phenylimides.

Table I records the values of  $[M]_D$  for the 2'- and the 4'-substituted camphoranic acids in the four solvents formulated. In every case

TABLE I.

2'-Substituent.	MeOH.	EtOH.	Me <sub>2</sub> CO.	MeEtCO.
OH .....	-37°	-47°	-45°	-53°
OMe .....	+30	+28	-16	-10
OEt .....	-50	-62	-90	-89
4'-Substituent.				
OH .....	+246°	+266°	+154°	+203°
OMe .....	+163	+152	+122	+99
OEt .....	+180	+154	+116	+104

the 4'-substituted compound exceeds the 2'- in molecular rotatory power. The relative influence of the substituents on the rotatory power is in the order OEt > OH > OMe for the 2'- and OH > OEt > OMe for the 4'-substituted acids. Methoxyl, which in the

2'-position produces an exceptionally large depression (compare Bretscher, Rule, and Spence, J., 1928, 1493), stands at one end of the polar series, carboxyl being at the other. Ethoxyl, instead of occupying a position near methoxyl, follows iodine in the polar series: this position is also indicated by the values of the acid/imide ratio (see J., 1928, 2411) for the phenetidines (see below).

The rotatory powers of cyclic compounds are generally greater than those of the corresponding open-chain derivatives, but the camphoranilic acids and the camphorophenylimides are exceptions to the rule (Wootton, J., 1910, 97, 405; see also Singh and Puri, J., 1926, 504). Wootton has cited the cases of  $\alpha$ -naphthyl and *o*-bromophenyl derivatives of camphoranilic acid, where the molecular rotatory powers of the imides are greater than those of the corresponding acids. It has, however, been shown (Singh, Ahuja, and Lal, J., 1928, 2410) that the *o*-bromo-acid prepared by Wootton was impure and that the pure acid has  $[M]_D = -61^\circ$  (in acetone) and not  $-41^\circ$ . Examples are now given in camphoro-*o*-methoxyphenylimide and camphoro-*o*-ethoxyphenylimide (in methyl alcohol and in ethyl alcohol) which have greater rotatory powers than the corresponding acids.

#### EXPERIMENTAL.

Camphoric anhydride was condensed with the hydroxy-, methoxy-, and ethoxy-anilines by the general method (J., 1928, 2410). The condensations were carried out at different temperatures to ascertain the effect of temperature on the acid/imide ratio.

*2'-Hydroxycamphoranilic Acid*.—The condensation product, which had a repulsive odour, was dissolved in alcohol, water was added, and the precipitated oil was removed and extracted with dilute sodium bicarbonate solution. The reddish-brown extract on acidification with dilute acetic acid gave the camphoranilic acid as a gummy mass. A solution of this in aqueous ammonia was boiled with animal charcoal and filtered, and the acid reprecipitated. *2'-Hydroxycamphoranilic acid* finally separated from an alcoholic solution (charcoal), after addition of a little water, in minute prisms, m. p.  $183^\circ$  after shrinking at  $159^\circ$  (Found: N, 4.9.  $C_{16}H_{21}O_4N$  requires N, 4.8%).

*4'-Hydroxycamphoranilic acid* crystallised from dilute alcohol in deep violet prisms, which gave a light grey mass when powdered; m. p.  $241-242^\circ$  (Wootton, *loc. cit.*, gives m. p.  $239^\circ$ ) (Found: N, 4.9. Calc.: N, 4.8%).

*2'-Methoxycamphoranilic Acid and Camphoro-*o*-methoxyphenylimide*.—The condensation was carried out at  $125^\circ$ , at  $140^\circ$ , and at  $150^\circ$ : the yield of imide was 38–40% at  $150^\circ$ .

The *acid* crystallised from dilute alcohol in small plates, m. p. 152° after shrinking at 141° (Found: N, 4.8; equiv., 309.  $C_{17}H_{23}O_4N$  requires N, 4.6%; equiv., 305). The *imide* crystallised in needles, m. p. 136° (Found: N, 4.9.  $C_{17}H_{21}O_3N$  requires N, 4.9%). The acid is more soluble than the imide in the usual organic solvents.

4'-Methoxycamphoranilic acid formed colourless prismatic needles, m. p. 204° (Found: N, 4.7%; equiv., 303).

Camphoro-p-methoxyphenylimide separated from alcohol in needles, m. p. 122—123° (Found: N, 5.0%). The following yields were obtained: at 120°, 0; at 140°, trace; at 150°, 33—34%; above 200°, 100%.

2'-Ethoxycamphoranilic Acid and Camphoro-o-ethoxyphenylimide.—The *acid* crystallised in short prismatic needles, m. p. 146—147° (Found: N, 4.5; equiv., 319.  $C_{18}H_{25}O_4N$  requires N, 4.4%; equiv., 319).

The *imide*, obtained by heating the condensation mixture at 220° for 1½ hours or by Wootton's method (*loc. cit.*), melted at 138° (Found: N, 4.7.  $C_{18}H_{25}O_3N$  requires N, 4.65%). The yield of the imide was: at 125°, 0; at 140°, 0; at 150°, very small; above 200°, 100%.

4'-Ethoxycamphoranilic Acid and Camphoro-p-ethoxyphenylimide.—The *acid* crystallised in small thick prisms, m. p. 202—203° (Found: N, 4.5%; equiv., 316).

The *imide* crystallised from alcohol in thin needles, m. p. 122° (Found: N, 4.7%). The yield was negligible at 125° and at 140° and 27% at 150°.

If anisidine and phenetidine compounds are heated too rapidly in the combustion tube during analysis, methane is evolved (compare Forster, J., 1909, 95, 952).

# CLXVI.—The Validity of the Interference Method for the Measurement of the Specific Area of a Copper Surface.

By FREDERICK JAMES WILKINS.

THE surfaces of all solids are rough, and possess irregularities of both microscopic and macroscopic dimensions: even optically plane surfaces probably contain roughnesses of a molecular order. In general, therefore, the specific area of a surface will be very different from its apparent area. Of the methods proposed for the measurement of the specific area, those due to Bowden and Rideal (*Proc. Roy. Soc.*, 1928, A, **120**, 80), Constable (*ibid.*, 1927, A, **115**, 570), and Wilkins (*Nature*, 1930, **125**, 236) are particularly suitable for use with metals. Bowden and Rideal calculate the specific area from the amount of hydrogen which must be deposited upon an electrode in order to bring about a given change of potential, as compared with the amount required to bring about the same change of potential at a liquid mercury electrode. Wilkins has pointed out that the specific area may be measured if the vapour pressure and rate of vaporisation of the surface are known. Constable's method is entirely different, however; having shown that the colour of the oxide film formed on metals, such as nickel, copper, and iron, is due to interference and is consequently determined uniquely by its thickness, he calculates the volume of a film from its weight and the density of the oxide, and combines this with its thickness, as determined by its colour, to estimate the specific area of the surface.

It is difficult to compare results obtained by these three methods. Bowden and Rideal measure the area accessible to hydrated hydrogen ions, and Wilkins measures that accessible to condensing atoms of the vaporising solid; thus these two methods should give similar results, and although the experimental evidence to which the latter method can be applied is at present scanty, yet the respective results are not contradictory. The relation between the results obtained by these methods and that of Constable is much more complex. In the particular case of an activated nickel surface, the results obtained by Constable and by Bowden and Rideal are widely different. The former (*Proc. Roy. Soc.*, 1928, A, **119**, 196) finds that the ratio ( $A$ ) of the specific to the apparent area is 1.3—4.5, depending upon the degree of activation of the surface, while the other workers obtain the much higher value of 46 for a recently activated surface, and 29 for the same surface after it has been allowed to "age." Bowden (*Nature*, 1928, **122**, 647), discussing the difference between these figures, has pointed out that the interference method is unable to take account of irregularities which are of an order less than  $10^{-5}$  cm. It would appear, therefore, that these minute irregularities are able to increase the specific area by a factor of at least 10.

During the course of a study of the kinetics of the oxidation of copper, an opportunity arose for the application of the interference method to this metal. Constable, while providing the necessary optical data for this case, has studied only nickel in detail. It is clearly important that the values of  $A$  obtained for nickel should be confirmed (as far as order of magnitude is concerned) by experiments on another metal, so that the reality of the ten-fold factor may be substantiated.

#### EXPERIMENTAL.

The copper was used as pieces (1 sq. dm. in area) of pure electrolytic foil which had been carefully cleaned by abrasion first with emery paper of gradually increasing fineness and finally with Hubert 000. It was further cleaned by rubbing with cotton-wool dipped in alcohol and then with dry grease-free cotton-wool. The oxidations were carried out by heating either in air or in a closed system of known volume containing pure oxygen. In the first case, the amount of oxide formed was determined by weighing the copper before and after oxidation on a Sartorius microbalance; in the second, the weight of oxide was determined from the fall of pressure in the system. The pressures were determined accurately by measuring the movement of a mercury column with a travelling microscope. Activation of the copper was brought about by reduction with hydrogen. A detailed account of the experimental technique will appear in a forthcoming paper.

*Results.*

(1) *Values of A for Copper Surfaces which have not been activated.*—The first series of experiments refers to the oxidation of copper foil at 183°. The results are shown in Table I in the order of increasing film thickness. In all the tables, weights of oxide are given as mg. per sq. dm. The figures of column 2 were determined from the colour of the oxide film, Constable's data being used to correlate this with the thickness (see *Proc. Roy. Soc.*, 1928, A, 119, 196).

TABLE I.

Wt. of oxide.	Wt. of oxide, from colour.	Ratio, A.
2.22	5.01	0.443
2.54	5.18	0.490
3.64	5.76	0.632
3.82	5.88	0.65
4.56	7.23	0.63

TABLE II.

Temp. of oxidation.	Wt. of oxide.	Wt. of oxide, from colour.	Ratio, A.
125°	0.843	2.47	0.341
150	1.73	2.82	0.614
175	3.37	5.41	0.623
200	5.68	7.41	0.767

All the experiments give anomalous values of  $A$ , a value of less than unity being physically impossible, since it suggests that the specific area is less than the apparent area.

In order to confirm the result, Vernon's data (J., 1926, 2273) were used for the calculation of  $A$  (see Table II). The figures of Tables I and II are in complete agreement, showing that over the experimental range  $A$  is always less than unity, and increases as the temperature of oxidation and the thickness of the oxide film increase. The thickness of the surface film containing oxide does not, therefore, determine uniquely the colour of the film. In an attempt to obtain further information, a few determinations of  $A$  were made with activated copper surfaces, for all Constable's work has been carried out on activated metallic surfaces.

(2) *Values of A for Activated Copper Surfaces.*—The first experiments were made with a sample of copper which had been oxidised and reduced many times until it had reached a state of maximum activation. The results were :

Temp. of oxidation .....	183°	305°
Wt. of oxide .....	3.61	5.00
Wt. of oxide, from colour .....	2.24	2.53
A .....	1.62	1.98

The change in the value of  $A$  given by the experiment at 305° is particularly interesting. The reduction after the first experiment was carried out at 183°. Since the subsequent oxidation at 305° required only a few minutes, the deactivation accompanying it must have been slight. The increase in  $A$  is therefore to be attributed solely to the increase in the temperature of oxidation. This phenomenon was confirmed in a second series of experiments in

which  $A$  was determined for a specimen of copper during a period of gradually increasing activation (see Table III). The value of  $A$  seems to be dependent chiefly upon the temperature of oxidation—at least, to such an extent as to mask any changes due to activation.

TABLE III.

No. of expt.	Temp. of oxidn.	No. of oxidns. after reduction.	Wt. of oxide.	Wt. of oxide, from colour.	$A$ .
1	305°	2	5.79	2.71	2.14
2	305	3	5.39	2.53	2.13
3	183	4	4.92	3.44	1.43
4	183	6	4.01	2.94	1.37
5	183	20	4.35	2.53	1.72
6	183	21	4.47	2.53	1.76

Expt. 1 was carried out on a piece of copper which had been already oxidised once and reduced at 305°. The activation of the surface gives a value of  $A$  greater than unity and of the order of those obtained by Constable in his work. The oxide film formed in this experiment was reduced at 305°. Notwithstanding the increase of activation (as measured by the increased rate of oxidation) between Expts 1. and 2, any change in the value of  $A$  was smaller than the experimental error, which is about 0.1 unit. Even more striking is the value of the ratio obtained from Expt. 3. Before this oxidation, the oxide film had been reduced at 183°, and reduction at this low temperature should be accompanied by a considerable increase in area owing to the decrease in the sintering of the surface. Instead of an increase in  $A$ , however, an unexpected decrease was obtained. Subsequent activation at 183° gave at the terminal state (see Expts. 5 and 6) values in reasonable agreement with that of the first experiment in the previous series (p. 1306).

#### Discussion.

The experimental results may be summarised by saying that copper which has not been activated gives anomalous values for  $A$ , which are dependent upon the temperature and the thickness of the oxide film; further, while the values of  $A$  given by activated copper are greater than unity, they are also very largely dependent upon the temperature of heating, and are scarcely affected by the activation of the surface.

The interference theory of the colours of thin films of oxide on metals seems to be well established qualitatively (see, *e.g.*, Evans, J., 1925, 127, 2484; *Proc. Roy. Soc.*, 1925, A, 107, 228; *Chem. and Ind.*, 1926, 45, 213). Constable's work provides the chief quantitative evidence in its favour, in that he has shown that if the quantity of oxide determined directly is corrected by an area factor ( $A > 1$ ) it is equal to the quantity of oxide given by the colour of the film.

This work has shown, however, that in the case of copper, the nature of the correcting factor  $A$  is not so simple as Constable has supposed. In order to interpret the anomalies two courses are open, *viz.*, (a) to reject the interference theory as an explanation of the colours; (b) to amend the calculations of Constable. In view of the qualitative evidence in favour of the interference theory, the second course would seem to be the more hopeful.

Experiments on the kinetics of the low-temperature oxidation of copper (shortly to be published; compare also Wilkins, *Z. Elektrochem.*, 1929, **35**, 500) have shown that oxygen diffuses through the oxide film to the underlying copper along the grain boundaries of the oxide. The oxidation of copper appears, therefore, to proceed grain by grain; and it is to be expected, in consequence of this granular oxidation, that the oxide film will contain appreciable quantities of unchanged copper. Further, one would expect the proportion of unchanged copper in the film to be the greater the larger the grain size of the copper and the thinner the film. Direct experimental evidence demonstrating the existence of this unchanged copper has been recently obtained by Evans and Stockdale (J., 1929, 2651), who heated a square sheet of copper along one edge, obtaining a film of oxide of thickness gradually decreasing as the distance from the hot edge is increased. They found that the thin oxide films formed at the low-temperature points contained "much residual metallic copper"; the proportion of metallic copper to oxide gradually diminished as the high-temperature edge was approached.

An explanation of the experimental results is now possible on the basis that the colour of the oxide films is an interference phenomenon. Copper which has not been activated is made up of large grains. The film which gives rise to the colour will not, therefore, be pure oxide, but will contain large amounts of unchanged metal. The volume of the film as calculated by Constable's method will consequently be much too great, and values of  $A$  will be obtained which are less than unity. The gradual increase in  $A$  with increasing film thickness is in perfect agreement with this interpretation.

Activated copper, on the other hand, has a much smaller grain size, and the oxide films formed by it will contain less unchanged copper. Further, the proportion of unchanged copper will, as before, be smaller the higher the temperature.

We therefore conclude that, as far as copper is concerned, Constable's interference method possesses very narrow limitations; for it is clear that, if results of accuracy are to be obtained, one must determine the optical properties and the density of each film.

This restriction will not apply to nickel, for Evans and Stockdale (*loc. cit.*) have shown that its oxide films are remarkably free from metallic occlusions. The values of  $A$  for this metal determined by the interference method are trustworthy. Further, although the values of  $A$  found in this work for activated copper are not a true indication of the specific area, they are of such a nature that they may be said to confirm, as far as order of magnitude is concerned, the results of Constable for activated nickel. The remarkable increase of  $A$  when determined with the hydrogen-ion method is therefore real; and the irregularities of dimensions less than  $10^{-5}$  cm. would appear to increase the specific area by as much as ten times.

*Summary.*

It is shown that, when Constable's interference method for the measurement of the specific area of a surface is applied to oxide films formed on copper which has not been activated, the values obtained for the ratio ( $A$ ) of the specific to the apparent area are anomalous in that they are always less than unity. Further,  $A$  is not a constant for a given surface but increases with the thickness of the oxide film and the temperature of oxidation. Activation of the copper surface by oxidation and reduction gives values of  $A$  which are greater than unity but are still dependent upon the temperature of oxidation. The interference method, therefore, does not give trustworthy values for the specific area when applied to the measurement of copper surfaces.

It is suggested that these results may be explained by assuming that the oxide film contains unchanged metallic occlusions, the proportion of unchanged metal to oxide varying with the conditions and extent of oxidation. Experimental evidence is cited in favour of this interpretation.

My thanks are due to Dr. W. H. Mills for the use of his micro-balance, and to the British Non-Ferrous Metals Research Association for a grant. I should, further, like to express my indebtedness to Dr. E. K. Rideal for his constant interest and advice during the progress of this research.

CLXVII.—*The Lower Trialkyl Orthophosphates.*  
*Part I.*

By DAVID PHILIP EVANS, WALTER CULE DAVIES, and WILLIAM JACOB JONES.

ALTHOUGH fairly complete information respecting some of the physical properties of trimethyl and triethyl orthophosphates is available, little is known concerning those of the other lower alkyl orthophosphates. Boiling points and densities of tri-*n*-propyl, triisopropyl, and triisobutyl phosphates have been recorded, but tri-*n*-butyl and tri-*n*-amyl orthophosphates have not hitherto been prepared. The preparation and properties of several phosphoric esters have been recently described by Plimmer and Burch (J., 1929, 279, 292). The present series of investigations is confined to the determination of certain physical constants of the lower trialkyl phosphates from methyl to amyl. In view of the paucity and the conflicting character of the results hitherto recorded concerning the physical properties of the phosphoric esters, it was considered advisable to carry out new measurements.

EXPERIMENTAL.

The phosphates were prepared by the action of phosphorus oxychloride on the sodium alkoxides. For instance, in the preparation of tri-*n*-butyl orthophosphate, sodium *n*-butoxide was first made by adding gradually 46 g. of sodium to 600 c.c. of *n*-butyl alcohol and then distilling off the excess of alcohol under reduced pressure. To the butoxide, 200 c.c. of dry ether were added, and 60 c.c. of phosphorus oxychloride in 100 c.c. of ether were run in with ice-cooling. The mixture was then boiled gently for an hour, water added, and the ethereal layer separated and dried over anhydrous sodium sulphate. The ether having been expelled, the residual liquid was distilled under 50 mm. pressure, 70 g. of ester being thus obtained. It was purified by several redistillations [Found: P, 11.9.  $(C_4H_9)_3PO_4$  requires P, 11.7%]. Tri-*n*-amyl orthophosphate was prepared in a similar way [Found: P, 10.0.  $(C_5H_{11})_3PO_4$  requires P, 10.1%].

The determination of phosphorus in these esters was effected gravimetrically by oxidation with a mixture of concentrated nitric and sulphuric acids, neutralisation with ammonia, and precipitation with ammonium molybdate.

On being distilled, even under 5 mm. pressure in the absence of air, tri- $\beta$ -methylbutyl, tri- $\gamma$ -methylbutyl, and tri-*n*-hexyl orthophosphates decomposed, whilst the tri-*n*-amyl ester gave distinct

indications of decomposition on being distilled under 150 mm., and, similarly, tri-*n*-butyl phosphate under 760 mm.

The lower trialkyl orthophosphates, with the exception of the methyl and ethyl members, are incompletely miscible with water at the ordinary temperature, but they mix in all proportions with alcohol, ether, or benzene. The methyl ester possesses a buttery smell, the ethyl a sharp apple-like one, whilst the propyl, butyl, and amyl esters have musty, but pleasant, odours. The *n*-butyl and *n*-amyl phosphates were very slightly yellowish, the colour apparently indicating incipient decomposition.

The boiling points under 50 mm., 100 mm., and 150 mm. were determined in an apparatus which permitted of the constant maintenance of any low pressure by means of a controllable air-leak into a reservoir in conjunction with a "Hyvac" air-pump. Thermometers and barometers standardised at the National Physical Laboratory were employed, and all necessary corrections were applied. In the determinations of density, weighings were corrected for displacement of air. The coefficients of thermal expansion,  $\alpha$ , have been calculated by means of the formula,

$$\alpha = (d_4^{25^\circ} - d_4^{40^\circ}) / (40d_4^{40^\circ} - 25d_4^{25^\circ}).$$

TABLE I.

*Boiling Points, Densities, and Coefficients of Thermal Expansion of Trialkyl Orthophosphates.*

Phosphate.	B.p. under given pressure (mm.Hg).					$d_4^{25^\circ}$ .	$d_4^{40^\circ}$ .	$\alpha \times 10^5$ .
	10	50	100	150	760			
Methyl	73°	110°	129°	142°	196°	1.2052	1.1872	104
Ethyl	90	128	148	159	215	1.0637	1.0490	96
<i>n</i> -Propyl	121	161	180	193	252	1.0023	0.9884	96
<i>n</i> -Butyl	150	196	211	227	289	0.9727	0.9596	93
<i>iso</i> Butyl	138	177	196	209	264	0.9617	0.9483	96
<i>n</i> -Amyl	—	225	—	—	—	0.9497	0.9373	90

When plotted against temperature, the present values of the density of the methyl ester agree with those of Weger (*Annalen*, 1883, **221**, 89) at 0° and of Cavalier (*Bull. Soc. chim.*, 1898, **19**, 887; *Ann. Chim. Phys.*, 1899, **18**, 460) at 15°, but not with the values given by Arbusov (*J. Russ. Phys. Chem. Soc.*, 1907, **38**, 161) and by Drushel (*Amer. J. Sci.*, 1915, **40**, 643). Similarly, in the case of the ethyl ester the present values are in fair agreement with those given by Zecchini (*Gazzetta*, 1894, **24**, 34) for 28.1°, by Arbusov for 19°, by Arbusov and Ivanov (*J. Russ. Phys. Chem. Soc.*, 1915, **47**, 2015) for 20°, and by Sugden, Reed, and Wilkins (*J.*, 1925, **127**, 1538) for 15° and 38°, but not with those of Cavalier and of Limpricht (*Annalen*, 1865, **134**, 347). The present results accord fairly well

with those of Arbusov and of Drushel for tri-*n*-propyl phosphate, and of Drushel for triisobutyl phosphate at 22°.

In the series of normal phosphates, the average increase in molecular volume from one member to its next homologue is 17.4 c.c. per CH<sub>2</sub> group at 25°, and 17.7 c.c. at 40°. It is noteworthy that at 25° the average difference for a CH<sub>2</sub> group in the case of the lower fatty esters is also *ca.* 17.4 c.c., and at 40° *ca.* 17.5 c.c.

Throughout the range of pressure, *p*, from 10 mm. to 760 mm., the value of the boiling point, *t*°, given by the following equations agrees within an average error of 0.6° with our direct observations :

Methyl ester :	$8.1440 - \log_{10} p = 2468.4/(t + 273)$
Ethyl ester :	$8.3283 - \log_{10} p = 2658.4/(t + 273)$
<i>n</i> -Propyl ester :	$8.5188 - \log_{10} p = 2960.0/(t + 273)$
<i>n</i> -Butyl ester :	$8.5861 - \log_{10} p = 3206.5/(t + 273)$
<i>iso</i> Butyl ester :	$8.9945 - \log_{10} p = 3283.1/(t + 273)$

The boiling points under 10 mm. given in Table I have been calculated with these equations, and agree well with the direct measurements of Arbusov (*Ber.*, 1905, **38**, 1172) for trimethyl, tri-*n*-propyl and triisobutyl phosphates under this pressure. Further, the data of Drushel for the last two esters at 15 mm., and of Sugden, Reed, and Wilkins for the triethyl compound at 25 mm., are confirmed by the above equations, but all the boiling points given by Cavalier are too low.

The corresponding values of the molar latent heat of vaporisation are as follows: Trimethyl phosphate, 11,300 cal.; triethyl, 12,170 cal.; tri-*n*-propyl, 13,550 cal.; tri-*n*-butyl, 14,680 cal.; triisobutyl, 15,030 cal.

The refractive indices were measured with a Pulfrich refractometer, made by Wolz of Bonn, and an Abbé refractometer, by Hilger of London. Both instruments were standardised by the use of water and of benzene.

TABLE II.

*Refractive Indices of Trialkyl Orthophosphates.*

Phosphate.	$n_D^{25}$ .	$n_D^{20}$ .	$n_D^{25}$ .
Methyl .....	1.3990	1.3950	1.3934
Ethyl .....	1.4082	1.4039	1.4021
<i>n</i> -Propyl .....	1.4182	1.4136	1.4118
<i>n</i> -Butyl .....	1.4274	1.4224	1.4203
<i>iso</i> Butyl .....	1.4222	1.4173	1.4152
<i>n</i> -Amyl .....	1.4332	1.4283	1.4262

Previous investigators (Zecchini, *loc. cit.*; Arbusov and Ivanov, *loc. cit.*) have measured the refractive index of triethyl phosphate only; it is noteworthy that, on plotting their values for  $n_D$  and the present one against temperature, the points obtained all lie on a straight line. Further, the values of  $n_F$  and  $n_C$  for triethyl phosphate

given by Arbusov and Ivanov agree excellently with those found in the present work.

Owing to the circumstance that the values of the atomic refractivities of oxygen bound to phosphorus are unknown, it is impossible to calculate the atomic refractivity of phosphorus from the values of the molecular refractivities of the phosphoric esters. If it could be assumed that oxygen in an alkyloxy-group possessed the same refractivity as in an ether, use could be made of Lorentz-Lorenz refractivities, *e.g.*, those of Eisenlohr (*Z. physikal. Chem.*, 1910, **75**, 585), to calculate the value of the refractivity of the orthophosphoryl group,  $\text{OP:}$ . However, it appears preferable to derive a value for the refractivity of the orthophosphoric group,  $\text{OP(O)}_3$ , by deducting the values for carbon and hydrogen from the molecular refractivity of the ester. Values of the refractivity for this group so obtained are given in Table III, where they are denoted by the symbol  $[r_L]$ , values of molecular refractivity,  $(n^2 - 1)M/(n^2 + 2)d$ , being denoted by  $[R_L]$ .

TABLE III.

*Molecular and Group Refractivities.*

Trialkyl phosphate.	$[R_L]_f$ .	$[R_L]_b$ .	$[R_L]_c$ .	$[r_L]_f$ .	$[r_L]_b$ .	$[r_L]_c$ .
Methyl	28.119	27.869	27.769	10.770	10.715	10.702
Ethyl	42.263	41.870	41.706	10.910	10.862	10.848
n-Propyl	56.394	55.849	55.635	11.037	10.987	10.986
n-Butyl	70.336	69.616	69.312	10.975	10.900	10.872
iso-Butyl	70.383	69.666	69.358	11.022	10.950	10.918
n-Amyl	84.401	83.567	83.209	11.036	10.997	10.978
			Mean for $\text{PO}_4$	10.958	10.902	10.884

It is hoped that work, now in progress, on the optical properties of alkyl phosphites and of related compounds will help to elucidate the problem of the evaluation of the atomic refractivity of phosphorus when bound to oxygen.

## CLXVIII.—*Studies in the Reactivity of Aromatic Hydroxyl Groups. Part I.*

By HAROLD LLEWELYN BASSETT.

THIS work has been undertaken with a view to investigate the influences affecting the reactivity of hydroxyl groups in aromatic compounds. Many investigations with the same general object have been carried out, and those most closely connected with the work now described are the determinations of velocity coefficient

by Panoff (*A.*, 1903, ii, 357) for the reaction between acetic anhydride and various phenols in benzene solution at 100°, and by Bernoulli and Goar (*Helv. Chim. Acta*, 1926, 9, 730) for the reaction between benzoyl chloride, or substituted benzoyl chlorides, and a number of phenols.

In the present case the reaction between phenols and acetyl bromide in ethyl acetate solution at 0° is used, and the half-periods of the reactions are obtained from a time-titration curve. The reciprocals of these half-periods are the comparative figures quoted.

A previous attempt on similar lines, using ether as solvent, failed owing to the ether unexpectedly taking part in the reaction (Bassett and Taylor, *J.*, 1929, 1568).

The half-periods obtained for the compounds studied (in minutes) were as follows: Phenol, 14.5 (1); *o*-cresol, 25.25 (0.574); *m*-cresol, 8.5 (1.71); *p*-cresol, 6.17 (2.35); thymol, 31 (0.468); carvacrol, 20 (0.725). The reciprocals of these figures, against phenol as unity, are given in parentheses. Panoff, and Bernoulli and Goar (*loc. cit.*), obtained similar results in the reactions which they studied, except that they found *m*-cresol to react slightly more rapidly than *p*-cresol. In all cases they found ortho-substituted phenols to react slowly.

The figures obtained in the present work do not depend upon the particular high concentrations chosen, since the ratio for phenol and thymol was found to be unchanged at half the concentration, although for some phenols the more dilute solution gives an inconveniently slow reaction.

While changes in the concentration of the phenol affect the rate of the reaction, material changes in the proportion of acetyl bromide (*e.g.*, 0.75, 1, 1.25 equivs. per equiv. of phenol) have no effect. This suggests that the reaction measured is not the simple bimolecular one, but that there is a preliminary rapid addition of the two reactants, followed by a slower unimolecular breakdown, which is the reaction actually measured. The point may be of importance, especially in connexion with the "ortho effect."

The effect of adding a little water to the reacting mixture is interesting. The titrations fell as though no water were present, but before reaching the lowest point they began to rise again, finally reaching a point nearly equal to the initial titration. It is evident, therefore, that when only a little water is present the formation of phenyl acetate proceeds almost to completion and is followed by a slower hydrolysis. This preferential reaction of acetyl bromide with phenol instead of with water is curious, since in the absence of phenol the reaction with water is very rapid. It may perhaps be connected with the above suggestion as to the rapid formation of an addition compound of phenol and acetyl bromide as the first stage

in the reaction. Such a course for the reaction had already been inferred from the work done with ethereal solutions (*loc. cit.*). It is proposed to carry out these determinations on a larger number of phenols, selected with a view to throw light on the problems involved.

#### EXPERIMENTAL.

The ethyl acetate was treated with acetyl chloride to remove final traces of alcohol, washed with sodium carbonate and water, dried, and distilled. The acetyl bromide was of A.R. quality, and was found to be of about 94% purity, the remainder being acetic acid and hydrogen bromide. For the purpose of calculating equivalents, it was treated as the pure substance, since it was shown that comparatively large variations in the amount of acetyl bromide had no effect on the half-period of the reaction. The phenols used were carefully purified and dried.

A determination was carried out by dissolving in ethyl acetate a weight of the phenol equivalent to 1 c.c. of acetyl bromide and making up the solution to 8 c.c. To this solution 1 c.c. of acetyl bromide was added after both had been brought to 0°. The mixture was well shaken and quantities of 1 c.c. were withdrawn at suitable intervals (commencing at 1 min. from the time of mixing), added to about 100 c.c. of water, and titrated with *N*/5-sodium hydroxide. The reaction was carried out in a small stoppered flask which was maintained at 0° throughout with crushed ice. The small quantities of liquid used permitted of very efficient cooling, and the 1 c.c. of the mixture withdrawn for each titration dissolved quickly and almost completely in about 100 c.c. of water, thus permitting practically instantaneous quenching of the reaction. Frequent shaking of the flask was necessary in order to secure uniform results. The infinity reading was usually taken on the following day, and was shown to be unchanged in the course of a further 24 hours. It was found most satisfactory to derive the zero titration from that taken at one minute, and a typical example is given. The half-periods quoted are the means of two or three concordant determinations.

#### *Carvacrol.*

CLXIX.—*The Critical Solution Temperature of the System Methyl Alcohol-cycloHexane as a Means of detecting and estimating Water in Methyl Alcohol.*

By DAVID CHARLES JONES and SIMON AMSTELL.

THE sensitiveness to impurities of a critical solution temperature (*C.S.T.*), either binary or ternary, varies considerably with the impurity: in some cases the effects produced are very small, but in others they are so large as to constitute one of the most sensitive of the known criteria of liquid purity (J., 1923, 123, 1374, 1384).

It is now shown that the *C.S.T.* in the system methyl alcohol-cyclohexane is very sensitive indeed to the presence of water in the alcohol. This is of interest because, in many investigations, it is this impurity in the alcohol which it is necessary to detect and estimate from time to time. Moreover, the other common impurities are removable by chemical means and do not reappear in the alcohol. *cycloHexane* was chosen as the second component because it is readily obtained, can be purified easily, and has, in its melting point, a very sensitive criterion of its own purity.

EXPERIMENTAL.

*Preparation of Materials.*—*Methyl alcohol.* This was from two sources, commercial "absolute" and A.R. methyl alcohol (B.D.H.). Large quantities (2000 c.c. approx.) were fractionated through a ten-foot column of the type suggested by Clarke and Rahrs (*J. Ind. Eng. Chem.*, 1923, 15, 349), and the intermediate fractions (1500 c.c. approx.) subjected to the treatment of Bates, Mullaby, and Hartley (J., 1923, 123, 401) to remove acetone, and again fractionated through the column. The result is shown in Table I. Throughout the process of purification the dryness of the alcohol was tested by a miscibility temperature (*M.T.*) with pure *cyclohexane*, 69.15% of the latter being present. For the dry alcohol the value is 45.52°, very close to the *C.S.T.*; 0.01% of water in the alcohol produces a rise of 0.15°. The details of the determination of the miscibility temperature are described later.

TABLE I.

Fraction.	Vol., c.c.	<i>M.T.</i>	Water content, %, calc. ( $\pm 0.01\%$ ).	Alcohol content, %.
Original	2400	—	42 (app.)	58 (app.)
First	750	47.42°	0.12	99.88
Second	300	49.90	0.29	99.71
Third	200	52.28	0.48	99.52

These results show very clearly the efficiency of the ten-foot column. A 90% yield of the alcohol, containing less than 0.5% of

water, is obtained after one distillation from a solution originally containing 58% of alcohol. The acetone in the fractions was estimated as 0.002% by the method suggested by Bates, Mullaby, and Hartley (*loc. cit.*). The mercuric cyanide test for acetone (Hartley and Raikes, J., 1925, 127, 524) and Mayer's test for pyridine gave negative results.

In order to dry the alcohol, Fractions 2 and 3 (above) were mixed and treated with aluminium amalgam, following the procedure of Hartley and Raikes (*loc. cit.*). The alcohol was distilled off in an apparatus where every care was taken to exclude moisture, and the two middle fractions were collected. The miscibility temperatures of these were determined and the results are in Table II. Fraction I, Table I, was fractionally distilled through the ten-foot column, with the results shown in Table III. It would appear that distillation through an efficient column gives a drier alcohol than the use of aluminium amalgam.

TABLE II.

Fraction.	Vol., c.c.	M.T.
Original	500	50.8°
First	200	48.22
Second	200	52.96

TABLE III.

Fraction.	Vol., c.c.	M.T.
Original	750	47.42°
First	40	46.55
Second	500	45.51
Third	100	45.52
Fourth	100	46.65

Fractions 1 and 2, Table II, were mixed, distilled through the column, and examined, with the results shown in Table IV. Again the distillation method is effective.

TABLE IV.

Fraction.	Vol., c.c.	M.T.
Original	400	50.0°
First	30	46.2
Second	100	45.72
Third	250	45.64

TABLE V.

Fraction.	Vol., c.c.	M.T.
Original	620	47.02°
First	20	46.85
Second	200	45.52
Third	50	45.56
Fourth	200	45.60

It has been shown by several workers (*e.g.*, Noyes, *J. Amer. Chem. Soc.*, 1923, 43, 857) that freshly burnt lime removes water very effectively from alcohol, although it is a wasteful process. A fairly dry specimen of our alcohol, that had been freed from other impurities, was treated with lime. The alcohol was siphoned off from the lime and distilled through the column. The miscibility temperature results are in Table V. It will be noticed that 73% of the total distillate gives a miscibility temperature of approximately 45.5°. This was the value given by the one distillation alone through the column (see Table III, Fractions 2 and 3) and for 80% of the original material. Certainly, therefore, distillation alone produces quite as

dry a product as the lime treatment followed by distillation, and the large loss of alcohol is avoided. In view of the known efficacy of the lime treatment, the result indicated that acetone-free, dry methyl alcohol gave a miscibility temperature with *cyclohexane*, when the concentration of the latter was 69.15% by weight, of 45.52°.

A number of fractions of almost dry alcohol were mixed and twice redistilled through the column, every possible precaution being used to avoid the incursion of moisture. Table VI shows the miscibility temperature corresponding to the fractions collected in the second distillation. The results show that the alcohol is almost entirely water-free. The main fractions were siphoned over into a storage flask and used in the subsequent miscibility work. From time to time, redeterminations of the miscibility temperature were made to ensure that no moisture had entered the alcohol. The b. p. was 64.70°/760 mm., as determined in the apparatus described by Jones and Betts (J., 1928, 1177).

TABLE VI.

Fraction	Original	1	2	3	4	5	6
Vol., c.c.	2000	80	400	500	500	400	80
M.T.	45.62°	45.56°	45.53°	45.52°	45.53°	45.54°	45.66°

*cycloHexane*. This was from three sources: (a) *cyclohexane* "pur," Poulenc Frères, (b) *cyclohexane* "pure," Hopkin and Williams, and (c) synthetic material obtained by the catalytic method. The first two specimens had m. p. 2.6° and 1.0° respectively. Sabatier and Senderens give m. p. 6.5° for the pure material, whilst we have observed 6.48° both from the two purified commercial samples, and from the synthetic material obtained by us. Fractional freezing did not raise this m. p.

The *cyclohexane* melting at 2.6° was subjected to the usual process of purification by fuming sulphuric acid, but after two repetitions of the process the m. p. of the product still remained low, 4.2°. Moreover, there was considerable loss of material. The *cyclohexane* failed to decolorise potassium permanganate, and the impurity could not be removed by nitration. Fortunately, although distillation through a 12-bulb pear still-head produced no improvement, distillation through the ten-foot column, previously mentioned, gave good results, as the following record shows, 50% of the material being obtained pure in one distillation:

Fraction.	Vol., c.c.	M. p.	Fraction.	Vol., c.c.	M. p.
Original	430	2.6°	Fifth	40	5.8°
First	20	— 5.0	Sixth	50	6.1
Second	20	3.2	Seventh	30	6.3
Third	20	4.4	Eighth	200	6.48
Fourth	30	5.0	Residue	10	— 6.0

A similar difficulty was experienced with the second commercial sample (m. p.  $1^{\circ}$ ). Very slight purification resulted on continued sulphonation, but on distillation through the column, 50% of the original quantity was obtained with m. p. above  $6.0^{\circ}$ , and there was no difficulty in getting a pure specimen from this.

*Acetone.* A.R. Acetone (B.D.H.) was purified as described by Reilly and Ralph (*Sci. Proc. Roy. Dublin Soc.*, 1919, **15**, 597), and distilled twice through a twelve-pear column. It had b. p.  $56.35^{\circ}/760$  mm.

*Benzene.* Kahlbaum's benzene (for analysis) was fractionally crystallised several times, and a fraction of m. p.  $5.45^{\circ}$  was used throughout the work.

*Determination of the Solubility Curves.*—The synthetic method of determining the solubility curves has been described by Jones and Betts (J., 1928, 1177). Owing to the hygroscopic nature of the alcohol, simple but quite effective precautions were taken to avoid contact with atmospheric moisture. The containers of the alcohol and *cyclohexane* were fixed in desiccators containing phosphoric oxide. The lid of each desiccator had a ground-in vacuum stopper to which was firmly attached the stopper of the container, so that the two vessels were opened simultaneously. Small pipettes, themselves carefully protected against moisture, could be inserted into the liquid which yet remained in contact with the dry atmosphere. The lower stopper was of cork covered with tinfoil. The liquid was transferred to the experimental tubes, which were made of Pyrex glass and had been thoroughly dried by heating in the blowpipe and then kept in a desiccator. The filling of the tubes was effected inside a small box, 12" long,  $5\frac{1}{2}$ " wide, and  $5\frac{1}{2}$ " deep, with a glass front and back, and containing a vessel filled with calcium chloride. In the top of the box was a small hole which allowed a pipette to be inserted, and directly below this was a larger hole fitted with a cork, in which the weighed experimental tubes could be placed. Air, dried by calcium chloride and phosphoric oxide, was blown through the box during the filling. The *cyclohexane* was first run into the tube, the tube reweighed, reinserted in the cork, and the alcohol run in, forming the bottom layer. The tube was quickly taken out, sealed off, allowed to cool, and reweighed. That this simple procedure was sufficient to prevent any incursion of moisture was proved by the constancy of the miscibility temperature of dry methyl alcohol throughout several months. In the case of the systems methyl alcohol-acetone-*cyclohexane* and methyl alcohol-benzene-*cyclohexane*, solutions were made up in double stoppered bottles, the fillings being carried out as described above.

The thermometers used had been standardised recently at the N.P.L.

*Solubility Curve: Methyl Alcohol-cycloHexane.*—The miscibility temperatures,  $t^\circ$ , corresponding to various proportions (% by weight) are given in Table VII, and shown graphically in Fig. 1, Curve F. The critical phenomena are exceedingly clear, persistent emulsions are formed on shaking, and the intense blue colour

observable when the solution is examined in reflected light persists for several degrees above the *C.S.T.*

*The Effect of Water on the Solubility Curve.*—Solutions of methyl alcohol-water were made up in the dry box, and the determinations were carried out as usual. The results are in Table VIII and are shown graphically in Fig. 1, Curves E, D, C, B, A. The critical phenomena were slightly diminished in the presence of a trace of water, but with larger amounts they were more intense in the region of the ternary critical point; this was not the maximum point on these curves. Significant points are annotated as follows :

1 = Lower layer greater.  
2 = Volumes equal.

3 = Upper layer greater  
4 = Maximum point.

The ternary critical solution points,  $K_1$  to  $K_5$ , Fig. 1, and the corresponding maximal points,  $M_1$  to  $M_5$ , show increasing divergence as the concentration of water is increased. It is clear from the

figure that, by choosing a concentration of *cyclohexane* greater than the critical concentration, a greater rise in miscibility temperature would be obtained for a given percentage of water present in the alcohol. But it is necessary to preserve the accuracy of the reading itself, therefore 75% by weight of *cyclohexane* has been chosen as the optimum concentration, and pipettes were calibrated to give these proportions by weight in the system *cyclohexane*-anhydrous methyl alcohol. Our pipettes, which were constructed as described by Orton and Jones (J., 1919, 115, 1065), had the following volumes at 15°: for *cyclohexane*, 0.7570 c.c.; for anhydrous and aqueous methyl alcohol, 0.2485 c.c. We have confirmed in this work the great accuracy which can be obtained with this kind of pipette. A further improvement was made by grinding the tip, and bending the capillary at right angles about 4 mm. from the end. Table IX gives the miscibility temperatures which are obtained by using the relative volumes of liquids given above. The results when plotted indicate that the method becomes more sensitive as the percentage of water in the alcohol decreases. It is possible to estimate water within  $\pm 0.002\%$  if the miscibility temperature is read to  $0.02^\circ$ , a degree of accuracy which is readily obtainable with a little practice. An estimation within  $\pm 0.01\%$  could be made with ease.

TABLE IX.

Water content of alcohol, % ...	0.0	0.331	0.800	1.114	2.031	3.900
M.T. ....	45.55°	50.52°	55.74°	58.75°	66.50°	81.56°

The pipette volumes could be varied to give a percentage of *cyclohexane* within the limits 73—75% without appreciably affecting either the sensitiveness of the experimental reading or the quantitative figures given in Table IX, so long as the percentage of water in the alcohol was not greater than 1%.

A similar method may be developed in the case of ethyl alcohol, since this forms a *C.S.T.* with *cyclohexane* at (very roughly)  $-15^\circ$ , and preliminary experiments show that traces of water affect the binary *C.S.T.* to a large extent.

*Effect of Benzene and Acetone on the System Methyl Alcohol-cycloHexane.*—Solutions of benzene in *cyclohexane* and of acetone in methyl alcohol were prepared, and used for the determination of the miscibility temperatures.

*Benzene in cyclohexane.* The miscibility results obtained when 10.19% of benzene is present in the *cyclohexane* are in Table X. It was found that the *C.S.T.* was lowered by approximately  $12.3^\circ$ , i.e., 1% of benzene lowers the *C.S.T.* by  $1.21^\circ$ . A noteworthy point was that the critical phenomena which were so marked in the system methyl alcohol-*cyclohexane* were almost entirely absent at

the ternary critical point, but nevertheless the saturation points were very sharp and easily read to  $0.02^\circ$ . At the ternary critical point the percentage by weight of methyl alcohol was less than at the maximum saturation point.

\* Critical point—volumes equal.

† Maximum saturation point.

*Acetone in methyl alcohol.* In Table XI are given similar results obtained when 9.18% of acetone is present in the methyl alcohol. The *C.S.T.* was lowered by  $6.15^\circ$ , i.e., 1% of acetone lowers the *C.S.T.* by  $0.67^\circ$ . The mixture at the maximum saturation point contained a greater percentage of *cyclohexane* than that at the ternary critical point. The critical phenomena were more pronounced than in the binary system.

\* Critical point—volumes equal.

† Maximum saturation point.

The sensitiveness of the miscibility temperature to such impurities as acetone in the alcohol or benzene in the *cyclohexane* is of advantage when the purpose is to estimate the percentage of water present. Moreover, their effects on the miscibility temperature are but slightly altered by the presence of up to 0.5% of water in the alcohol.

## CLXX.—The System *cyclohexanol* and Water.

By NEVIL VINCENT SIDGWICK and LESLIE ERNEST SUTTON.

WORK on this system had previously been done by de Forcrand, who, after obtaining *cyclohexanol* in a purer condition than previous workers had done, measured several of its physical properties, including the freezing point and mutual solubility with water at  $11^\circ$  (*Compt. rend.*, 1912, 154, 1327, 1767); he then investigated the

binary system of the alcohol and water over a range of concentrations of *cyclohexanol* from 89.86 to 100% by weight, and concluded from his results that a compound  $C_6H_{12}O, \frac{1}{2}H_2O$  existed (*ibid.*, 1912, 155, 118).

The present work is an investigation of the greater part of the system, the range of concentration of *cyclohexanol* being 0—93% by weight, which is sufficient to include the two-liquid-phase region and most of the ice line.

#### EXPERIMENTAL.

*Purification of cycloHexanol.*—The *cyclohexanol* was obtained from British Drug Houses, Ltd., and purified by fractional distillations at a pressure of about 10 mm. of mercury, the head and tail fractions being rejected. Schreiner and Frivold (*Z. physikal. Chem.*, 1926, 124, 1) claim to have obtained a product melting at 23.3—23.9° (de Forcrand gives 22.45°) by two fractionations at 2—3 mm., but in the present case no fraction melting higher than 20.6° could be obtained from successive fractionations (the m. p.'s being taken in the first receiver of the distillation apparatus itself). A solution of this *cyclohexanol* in water gave no trace of a precipitate with bromine water, nor did it immediately destroy the bromine colour, indicating that no appreciable amount of phenol was present and that the most probable remaining impurity was water. Since the cryoscopic constant of *cyclohexanol* is so large (382.8 according to de Forcrand), the m. p. of our specimen would correspond to a purity of 99.85% by weight, if 23.6° is taken as the true melting point; hence, as water was to be the other component and its concentration was not to be less than 7%, further purification was deemed unnecessary.

Owing to the extremely hygroscopic nature of the alcohol, stock solutions containing about 95% of it were used, as these were not at all hygroscopic.

*Measurement of Points in the Binary System.*—The points on the liquid-liquid curve were obtained by the usual synthetic method, sealed glass bulbs being used at the higher temperatures. When the proportion of *cyclohexanol* was large, the temperature at which turbidity appeared increased with successive heatings, and, as this was presumably due to decomposition, the first reading was taken in such cases. It was found impossible to obtain points on this curve from 87.9% onwards, for, owing to the steepness of the curve after this point, the turbidity was extremely faint and no accurate determination of the temperature at which it occurred could be made.

The solid separation points over the range 88—93% of *cyclohexanol* were difficult to obtain, since considerable supercooling

was necessary before a solid would separate, and when this eventually occurred the temperature did not rise appreciably. However, by supercooling to produce the solid and then allowing the mixture to warm slowly, and noting at what temperature a trace of the solid could just be retained, approximate values (accurate probably to within  $0.5^\circ$ ) were obtained. This difficulty did not arise in tracing the ice line from 0 to 5% of *cyclohexanol*, for here, when supercooling ceased, there was the usual quick rise to a steady temperature.

The results obtained are given in the following tables and are plotted, together with those of de Forcrand, in Fig. 1.

(1) *The Ice Line.*

*Discussion of Results.*

The liquid-liquid system has been examined for water and the following alcohols: *n*-butyl (Orton and Jones, J., 1919, **115**, 1194), *isobutyl* (Alexejew, *Wied. Ann.*, 1886, **28**, 305), *sec*-butyl (*idem*, *ibid.*; Dolgolenko, *Z. physikal. Chem.*, 1908, **62**, 499; Timmermanns, Thèse, Bruxelles, 1911), and *isoamyl* (Fontein, *Z. physikal. Chem.*, 1910, **73**, 212). All these resemble *cyclohexanol* in showing reversed solubility curves on the water side, and all except *sec*-butyl alcohol in not showing this on the alcohol side.

The existence of the solid hydrate described by de Forcrand (*loc. cit.*) was not confirmed. His solid curve resembles ours but is at a lower temperature, probably because supercooling was not sufficiently avoided. The rapid decrease of steepness of the slope of the curve YX' as the two-liquid-phase region is approached is a consequence of the flattening out of the vapour pressure-concen-

tration curve prior to becoming a straight line parallel to the concentration axis in this region itself (Sidgwick and Turner, J., 1922, 121, 2262). There is no sign of a maximum at the concentration corresponding to the composition  $C_6H_{12}O, \frac{1}{2}H_2O$  (91.74% *cyclohexanol*) or of a sharp discontinuity after it; moreover, since a mixture whose total composition lies between X and X' can be in equilibrium with

Present research—○—. Schreiner and Frivold—□—. de Forcrand—×—

only one solid phase, the solid separating out along either OX or X'Y must be the same substance and, since there is no eutectic in OX, this substance must be ice. Its appearance agreed with that given by de Forcrand, viz., "small opaque crystals." The occurrence of some combination in solution between the alcohol and the water may, however, be assumed to be probable from the existence of the reverse solubility curve.

Our thanks are due to Imperial Chemical Industries, Ltd., for a grant towards the cost of this work.

[Received, April 29th, 1930.]

CLXXI.—*Dehydro-2-naphtholsulphone.*

By LEONARD ARTHUR WARREN and SAMUEL SMILES.

HINSBERG has shown (*J. pr. Chem.*, 1914, **90**, 345; 1915, **91**, 307; 1916, **93**, 277) that alkaline ferricyanide removes two hydrogen atoms from 2-naphtholsulphone (I), forming the dehydro-sulphone, and that the latter substance by alkaline reduction yields *iso*-2-naphtholsulphone, two hydrogen atoms being reabsorbed in the process. He regarded these isomerides as having identical structures and as providing a further illustration of the valency isomerism advocated by him to explain the relations between 2-naphthol 1-sulphide and *iso*-2-naphthol sulphide. The last-named substance has been shown (this vol., p. 956) to be the 2-hydroxy-1'-thiol derivative (II) of 1:2'-dinaphthyl ether; moreover it evidently is closely related to the *iso*-sulphone, since Hinsberg (*loc. cit.*) has shown that it is formed from an anhydride of this by reduction.

It is thus evident that the structures of *iso*-2-naphtholsulphone and of the dehydro-sulphone need reconsideration; experiments have now been made further to elucidate the nature of these derivatives of 2-naphtholsulphone and their relationship to the corresponding derivatives of 2-naphthol 1-sulphide (I, SO<sub>2</sub> being replaced by S). Of the many important facts bearing on these issues recorded by Hinsberg (*loc. cit.*), it is sufficient to mention the isolation of 2-hydroxy-1:2'-dinaphthyl ether (III) from the reduction products of the dehydro-sulphone and the spontaneous formation of this ether and sulphur dioxide from the *iso*-sulphone. These facts appear to indicate the presence in these substances of the 1:2'-dinaphthyl ether structure which has been found (this vol., p. 956) in the dehydro- and the *iso*-sulphide. Hinsberg, indeed, discussed the question whether the *iso*-sulphone should be regarded as the sulphinic acid derived from this ether, but rejected the suggestion for the following reasons: (a) both 2-naphthol-1-sulphone (I) and the *iso*-sulphone yield the dehydro-sulphone by oxidation, (b) the

*iso*-sulphide by methylation and oxidation gives the dimethyl ether of the *iso*-sulphone, (c) the *iso*-sulphone can be converted into the *iso*-sulphide by reduction of a substance regarded as its anhydride,

Since the *iso*-sulphide is now known to be (II), the relations (b) and (c), if confirmed, entirely lose their effectiveness in refuting the 1:2'-oxide structure; on the contrary, they now appear strongly to support this structure for the *iso*-sulphone. The first of the three relations quoted has clearly little value unless the dehydro-sulphone is known or assumed not to contain the 1:2'-oxide structure. Important evidence on this question is afforded by reduction of the dehydro-sulphone; with sodium amalgam or with zinc and acetic acid (also Hinsberg, *loc. cit.*) the 2-hydroxy-1:2'-dinaphthyl ether (III) is formed, whilst with zinc and hydrochloric acid the *iso*-sulphide (II) is obtained. The dehydro-sulphone therefore contains the 1:2'-oxide structure and, since it is formed merely by removal of two hydrogen atoms from 2-naphthol-1-sulphone (I), the structure (IV) must be ascribed to it. As was shown by Hinsberg (*loc. cit.*), the dehydro-sulphone reacts slowly with *p*-nitrophenyl-

hydrazine, fission of the substance occurring with formation of the hydrazone of  $\beta$ -naphthaquinone. This behaviour is analogous to that of dehydro-1-bromo-2-naphthol with aniline (Pummerer and Cherbuliez, *Ber.*, 1919, 52, 1412), which yields the anilino-derivative of  $\beta$ -naphthaquinone.

The chief relations between the members of this group are summarised as follows; the substances are numbered to facilitate reference.

Previous experiments have shown (this vol., p. 956) that (1), (2), (3), and (4) yield the hydroxydinaphthyl ether (III) with suitable reducing agents; it is now shown that (6) and (7) also yield this substance with sodium amalgam, and (8) gives the methyl ether (III, OH being replaced by OMe). The 1:2'-dinaphthyl ether

structure has in fact been established for all these with the exception of (5). The important relationships of (3), (4), and (5) to (8) indicated by Hinsberg (*loc. cit.*) have been confirmed, but the substance, m. p.  $88^{\circ}$ , described by him as the dimethyl ether of the *iso*-sulphone (8) has not been encountered. Moreover the conversion of (6) and (7) into the *iso*-sulphide (II) has been effected by suitable reduction.

The nature of the *iso*-sulphone is clearly revealed by the formation of the mercaptan (II) from it by reduction and by the fact that its *dimethyl* ether has the structure (V), which is assigned to it because reduction yields the methoxydinaphthyl ether (III, OH being replaced by OMe) and the substance is formed by methylation of the methyl sulphone (II, SH being replaced by  $\text{SO}_2\text{Me}$ ) (this vol., p. 956) or by oxidation of the dimethyl ether of the *iso*-sulphide (II, OH and SH being replaced by OMe and SMe respectively). Hence the *iso*-sulphone itself is to be regarded as the sulphinic acid corresponding to the thiol (II, SH being replaced by  $\text{SO}_2\text{H}$ ), and its formation from the dehydro-sulphone (IV) by reduction as taking place by rupture of the 5-membered ring as indicated, the process being analogous to the formation of the *iso*-sulphide (II) from the dehydro-sulphide (IV,  $\text{SO}_2$  being replaced by S) (this vol., p. 956). Moreover, conversion of the *iso*-sulphone and 2-naphthol-1-sulphone into the dehydro-sulphone is thus seen to proceed similarly to the oxidation of *iso*-2-naphthol sulphide and 2-naphthol 1-sulphide to the dehydro-sulphide.

#### EXPERIMENTAL.

*Dehydro-2-naphthol-1-sulphone* (IV).—Details of the preparation of this substance were not described by Hinsberg. The following method gave the best results. An aqueous solution (150 c.c.) of potassium ferricyanide (10 g.) was gradually added to a shaken mixture of chloroform (100 c.c.) and water (125 c.c.) which contained 2-naphthol-1-sulphone (5 g.) and sodium hydroxide (1.2 g.). After further agitation (1 hour) the chloroform solution was dried and concentrated. The dehydro-sulphone separated (yield, *ca.* 50%) in the crystalline state and after purification from acetic acid formed bright yellow prisms, m. p.  $245^{\circ}$  (Found : C, 68.9; H, 3.7. Calc. : C, 68.9; H, 3.4%).

*The Dimethyl Ether of the iso-Sulphone* (V).—The *iso*-sulphone was obtained from the dehydro-sulphone by reduction with sodium sulphide as described by Hinsberg. The chief properties attributed by him to the substance and its solubility in aqueous sodium carbonate were confirmed. A solution of this material in excess of aqueous sodium hydroxide (2*N*) was treated in the usual way with

methyl sulphate. The viscous product was further treated with boiling 1% alkali solution. It solidified when cooled and was obtained from acetone-methyl alcohol (charcoal) in prisms, m. p. 144° (Found: C, 69.8; H, 4.9; *M*, 385.  $C_{22}H_{18}O_4S$  requires C, 69.8; H, 4.7%; *M*, 378).

The same substance was obtained by the following methods: (a) A suspension of the sodium salt of the methyl sulphone (II, SH being replaced by  $SO_2Me$ ) derived (this vol., p. 956) from the *iso*-sulphide was treated in warm aqueous sodium hydroxide with methyl sulphate as usual. The semi-solid product was purified by the treatment already described; it then had the same m. p. as the product prepared from the *iso*-sulphone, whether taken alone or mixed with it. (b) A solution of the viscous dimethyl ether of the *iso*-sulphide (II, OH and SH being replaced by OMe and SMe respectively) (1.7 g.) in acetic acid (15 c.c.) containing hydrogen peroxide (2 c.c., 30% sol.) was warmed (1 hour, 100°). When sodium chloride was added to the cooled and diluted liquid, the desired product separated in the crystalline state; this was purified from acetic acid and identified in the usual manner with the products from the two other methods described.

*iso*-2-Naphthol Sulphide (II).—(a) Dehydro-2-naphtholsulphone (IV; 1 g.) was suspended in boiling acetic acid (40 c.c.) containing concentrated hydrochloric acid (5 c.c.). Zinc dust was gradually added until the colour of the solution was discharged. The clear solution was mixed with a little concentrated hydrochloric acid, cooled, and stirred, and water (20 c.c.) slowly added. The crystalline precipitate obtained, after further purification (77% yield), was identified with an authentic sample of *iso*-naphthol sulphide (Found: C, 75.5; H, 4.4. Calc.: C, 75.5; H, 4.4%). This *iso*-sulphide responds to Rheinboldt's test (*Ber.*, 1927, 60, 184) for aromatic thiols.

(b) Reduction of *iso*-2-naphtholsulphone (II, SH being replaced by  $SO_2H$ ) was effected by zinc and concentrated hydrochloric acid in boiling alcohol. Addition of water to the cooled liquid gave a crystalline precipitate. This was purified from alcohol and found to be identical with an authentic sample of *iso*- $\beta$ -naphthol sulphide.

2-Hydroxy-1:2'-dinaphthyl Ether (III).—(a) Zinc dust was added to a hot solution of the dehydro-sulphone (IV; 1 g.) in acetic acid (30 c.c.) until the colour had faded. The cooled solution deposited the hydroxydinaphthyl ether (90% yield), m. p. 197° (Found: C, 83.6; H, 5.2. Calc.: C, 83.9; H, 4.9%), which was further identified by a close comparison of its methyl ether with synthetic material (this vol., p. 956). Reduction of the dehydro-sulphone with sodium amalgam in warm aqueous alcohol gave a poorer yield

of the same material. It was isolated from the product of reaction by addition of sulphuric acid after alcohol had been removed by evaporation (charcoal); it was purified from acetic acid and had m. p. 197°.

(b) The *iso*-sulphone (II, SH being replaced by SO<sub>2</sub>H) also yielded the hydroxydinaphthyl ether by reduction with these reagents. Reduction with zinc and acetic acid was effected as described in the case of the dehydro-sulphone; the yield was poorer. A solution of the *iso*-sulphone (from 1 g. of dehydro-sulphone) in *N*-sodium hydroxide was stirred and treated with sodium amalgam (35 g.; 5%) for 3 hours. The clear aqueous liquid (charcoal) was rendered acid and set aside. The required substance separated and was purified (m. p. 197°) and identified in the usual manner.

2-Methoxy-1:2'-dinaphthyl ether (III, OH being replaced by OMe) was obtained by alkaline methylation of the product of reduction of the dehydro-sulphone with zinc and acetic acid. It was purified from acetic acid and had m. p. 161° (Found: C, 84.0; H, 5.7. Calc.: C, 84.0; H, 5.3%) and was identical with the product obtained by synthesis (this vol., p. 956). The same substance was obtained by reduction of the dimethyl ether of the *iso*-sulphone (V). Sodium amalgam (5%) was gradually added (6 hours) to alcohol (40 c.c.) and water (20 c.c.) which contained this ether in suspension. The alkaline liquid was mixed with acetic acid and boiled (charcoal). When diluted and cooled, the solution yielded the required substance (0.2 g.), which was purified in the usual manner; m. p. 161° (Found: C, 83.7; H, 5.4. Calc.: C, 84.0; H, 5.3%).

In conclusion we wish to thank Dr. A. Cohen for a quantity of the dehydronaphtholsulphone and for information concerning its preparation.

KING'S COLLEGE, LONDON.

[Received, April 8th, 1930.]

## CLXXII.—*The Solubilities of Nitrophenols in Aqueous Ethyl-alcoholic Solutions.*

By JAMES COOPER DUFF and EDWIN JOHN BILLS.

It was shown by one of us (Duff, J., 1929, 2789) that *p*-nitrophenol in aqueous methyl-alcoholic solutions at 25° and 40° had solubility curves in which critical points occurred where the solvent was composed of methyl alcohol and water in simple molecular proportion. The positions of the critical points varied with the tem-

perature. *o*-Nitrophenol gave no indication of an alcohol hydrate at 25°, and only one ( $3\text{CH}_4\text{O}\cdot\text{H}_2\text{O}$ ) was indicated at 40°.

The behaviour of *o*-, *m*-, and *p*-nitrophenols in aqueous ethyl-alcoholic solutions has now been examined. Solubilities for *m*-nitrophenol were determined at 0°, 12·5°, and 25°; and these three temperatures and also 40° were used for *p*-nitrophenol, since this isomeride yielded the most characteristic results. *o*-Nitrophenol was considered only at 25°, this being sufficient for comparison with the results obtained from the other two isomerides.

The solubilities of the three nitrophenols in water have been determined by Sidgwick, Spurrell, and Davies (J., 1915, 107, 1202); and those in absolute ethyl alcohol over a wide range of temperature by Carrick (*J. Physical Chem.*, 1921, 25, 628). His method, synthetic in character, differs from ours, but our results for absolute alcohol agree with his.

Solubilities are expressed as g. per 100 g. of solvent throughout.

#### EXPERIMENTAL.

Kahlbaum's ethyl alcohol of 99·8% purity was used. The nitrophenols were recrystallised by the usual methods before use. The solubilities were determined for *o*- and *p*-nitrophenols in the same way as for aqueous methyl-alcoholic solutions (Duff, *loc. cit.*). The results for *m*-nitrophenol were obtained by the same synthetic method as that previously used for *p*-nitrophenol.

*o*-Nitrophenol (Fig. 1).—The solubility was determined at 25° in aqueous-alcoholic solutions over the range 0—100% alcohol. The results are given below, and the resulting curve (AB) presents no unusual features. During solution at 25° the *o*-nitrophenol did not form any oily liquid phase.

EtOH, % ...	0	30	40	50	60	70	80	90	100
S .....	0·25	0·7	1·7	3·9	7·4	12·2	21·0	32·5	46·0

*m*-Nitrophenol (Fig. 1).—(a) *Solubilities at 0°*. No oily phase was formed. The solubility curve (CDEF) is a straight line between D and E, points which correspond approximately to 33% and 90% of alcohol in the solvent.

EtOH, %	0	20	30	40	50	60	70	80	90	100
S .....	0·9	1·6	5·0	19·8	36·8	53·7	71·5	89·5	106·6	115·5

(b) *Solubilities at 12·5°*. The results for the curve CKHM are given in Table I. In solvents ranging from 24 to 46% of ethyl alcohol, *m*-nitrophenol produces two liquid phases, and saturation with this phenol ended with two liquid phases in contact with the solid. Determinations of these end points gave the straight line GLH, the results for which are in Table II. Since GLH is a straight

line, the two saturated liquid phases are evidently the saturated aqueous solution for solvent containing 24% of alcohol and the oily saturated solution for solvent of 46% alcohol. The area GLHKG is the field in which two liquid phases co-exist.

\* Two liquid phases remain at end-point.

(c) *Solubilities at 25°.* The results for the curves CNO and O'RS are given in Table III. In solvents ranging from 15 to 42% of ethyl alcohol, *m*-nitrophenol produces two liquid phases, which co-exist in the area NOPQN. The results yielding the lines NP and PO are given as  $S_1$  in Table IV. Along the line PO the two liquid phases become one on addition of sufficient *m*-nitrophenol.

The minimum alcoholic content of solvent in which this occurs is 36% (P) and the maximum is 42% (O). By saturation of the solutions which gave PO, the values  $S_2$  (Table IV) and hence the curve PO' were obtained. Along the line NP are two saturated liquid phases which, since NP is a straight line, are composed of the saturated aqueous solution for 15% alcoholic and the saturated oily solution for 36% alcoholic solvent. At 25° *m*-nitrophenol was

more soluble in 63% alcohol (R) than in absolute alcohol, whereas at the lower temperatures no maximum occurred.

*p*-Nitrophenol (Fig. 2).—(a) *Solubilities at 0°*. The results are given in Tables V (curve ACG) and VI (straight line BED). The curve as a whole resembles that obtained for *m*-nitrophenol at 12.5°. The alcohol limits in the solvent for producing two liquid phases (co-existing in the area BCDEB) are 25% and 51%. Along the straight line BED two saturated liquids are in equilibrium with solid *p*-nitrophenol. These liquids are respectively aqueous saturated solution in 25% alcohol and oily saturated solution in 51% alcohol.

\* Two liquids become miscible at end-point.

The above results show that in aqueous ethyl-alcoholic solutions *p*-nitrophenol has a maximum solubility at 0° and 12.5° in 72% alcohol, at 25° in 56% alcohol, and at 40° in 39% alcohol.

*Discussion of Results.*

The results obtained for the solubility of *o*-nitrophenol serve to emphasise the special features of the solubility curves of the *m*- and *p*-isomerides. The last two exhibit a marked tendency to form oily solutions at low temperatures, therein differing from *o*-nitrophenol, although this isomeride has a much lower m. p. ( $44^{\circ}$  as against  $116^{\circ}$  for *p*-nitrophenol) than the others. The greatest tendency to produce two liquids during solution in dilute alcoholic solutions is shown by *p*-nitrophenol: this is possibly connected with the greater ease with which this isomeride forms addition compounds with weak bases and with its own metallic derivatives; moreover, the salts of *p*-nitrophenol show the highest degree of hydration, whilst those of *o*-nitrophenol are, in general, the least hydrated. It seems probable, therefore, that the additive powers of *m*- and *p*-nitrophenol enable them to produce the oily liquid phases which characterise the looped portions of their solubility curves. The curves show that, as the temperature rises, there is a fall in the maximum alcohol concentration of the solvent determining the area in which two liquid phases co-exist.

Some of the curves show as many as four significant points; e.g., in the curve (Fig. 2) for *p*-nitrophenol at  $25^{\circ}$ , the point S shows maximum solubility, points P and O are the upper and lower limits, respectively, for the co-existence of two liquids, and point Q indicates the minimum alcohol concentration of solvent in which two liquid phases can be made completely miscible. The occurrence of maximum solubility for *m*- and *p*-nitrophenol at temperatures above  $12^{\circ}$  in aqueous ethyl-alcoholic solutions was unexpected, since this was not the case for methyl alcohol (Duff, *loc. cit.*). In considering the direction changes of the curves in Figs. 1 and 2, it is noteworthy that McCombie and his co-workers (J., 1921, 119, 970; 1922, 121, 243, 2308), studying the rates of saponification of esters by potassium hydroxide in aqueous ethyl-alcoholic solutions, found significant points in the resultant curves at which the alcohol and water in the solvent were present in simple molecular proportions. These points, however, were not all evident at any one temperature. Dexter, McCombie, and Scarborough (J., 1923, 123, 1229) studied an example of isomeric change in aqueous ethyl-alcoholic solutions and obtained a curve changing in direction at three points corresponding to alcohol-water complexes.

Since the significant points of the curves now recorded vary with temperature and differ for the two nitrophenols, there is no evidence for the existence of alcohol hydrates in the solutions. It is more probable that the points are of eutectic character. In view of the results obtained by McCombie and his co-workers (*loc. cit.*), it is

a remarkable coincidence that so many of the significant points in Figs. 1 and 2 occur where the alcohol and water in the solvent are in simple molecular proportion, as Table XIII shows.

TABLE XIII.

Fig 1.					
Point .....	H	J	P	O	R
EtOH, % .....	46	72	36	42	63
Ratio EtOH:H <sub>2</sub> O	1:3.00	1:0.993	2:9.08	2:7.06	2:3.00
Fig. 2.					
Point .....	D	F	K	J	M
EtOH, % .....	51	70	41	45	72
Ratio EtOH:H <sub>2</sub> O	2:4.91	1:1.09	2:7.23	1:3.12	1:0.993
Point .....	Q	P	S	V	Y
EtOH, % .....	27	39	56	33.8	39.0
Ratio EtOH:H <sub>2</sub> O	1:6.91	1:4.00	1:2.00	1:5.00	1:4.00

Although the presence of alcohol-water complexes in the solvent is improbable, it seems necessary to assume that *m*- and *p*-nitrophenols are both capable of association with the solvent. This especially applies to the co-existence of two saturated liquids along, *e.g.*, the straight line NP for 25° in Fig. 1. In this case, if the solvent used is 24% in alcoholic content, it will be induced, by addition of *m*-nitrophenol, to act as an equilibrium mixture of 15% alcohol (point N) and of 36% alcohol (point P), and with the requisite amount of *m*-nitrophenol, it will produce the two saturated liquid phases. The results found for the line NP agree with those calculated from the foregoing assumption, and this applies to the corresponding sections of the other curves.

### CLXXIII.—Glucosides. Part III. The Abnormal Replacement of Halogen in Glucosyl Halides: The Formation of $\beta$ -Glucosides from $\beta$ -Glucosyl Chlorides.

By WILFRED JOHN HICKINBOTTOM.

IN continuation of previous work on the formation of glucosides from  $\beta$ -glucosyl chlorides (J., 1929, 1676), the action of sodium alkoxides on 2-trichloroacetyl 3:4:6-triacetyl  $\beta$ -glucosyl chloride (II) and on 3:4:6-triacetyl  $\beta$ -glucosyl chloride (I) has been examined. It would be expected, by analogy with the behaviour of 2:3:4:6-tetra-acetyl  $\alpha$ -glucosyl bromide (IV) towards similar reagents (compare Zemplén and Kunz, *Ber.*, 1923, 56, 1710), that glucoside formation would occur with the normal change in con-

figuration. Indeed, Pictet and Castan (*Helv. Chim. Acta*, 1921, 4, 319) have stated that the glucosyl chloride, prepared by the addition of hydrogen chloride to  $\alpha$ -glucosan—and identified by them as  $\beta$ -glucosyl chloride, since its tetra-acetate has the same melting point as Fischer and Armstrong's labile 2 : 3 : 4 : 6-tetra-acetyl  $\beta$ -glucosyl chloride—gives  $\alpha$ -methylglucoside by reaction with a solution of sodium methoxide in methyl alcohol.

It was found, however, that  $\beta$ -glucosides were the principal products of the action of sodium alkoxides on 3 : 4 : 6-triacetyl  $\beta$ -glucosyl chloride and on 2-trichloroacetyl 3 : 4 : 6-triacetyl  $\beta$ -glucosyl chloride. These results are in direct contrast to the behaviour of the same  $\beta$ -glucosyl chlorides towards alcohols in presence of silver oxide or carbonate, or silver nitrate and pyridine. For comparison, the results are summarised in the following table :

*2-Trichloroacetyl 3 : 4 : 6-triacetyl  $\beta$ -glucosyl chloride.*

*3 : 4 : 6-Triacetyl  $\beta$ -glucosyl chloride.*

Hickinbottom ( <i>loc. cit.</i> ) " " " "	Methyl alcohol and $\text{Ag}_2\text{O}$ or $\text{Ag}_2\text{CO}_3$	70	30
	Methyl alcohol, $\text{AgNO}_3$ , and pyridine	80	20
	Methyl alcohol and $\text{NaOMe}$	Approx. 100	

It is possible, therefore, to obtain either the  $\alpha$ - or the  $\beta$ -glucoside from each of these glucosyl chlorides by selecting the appropriate conditions. On current conceptions, it is assumed that, in the usual replacement of halogen in glucosyl halides by the action of silver carbonate and alcohol, a change in configuration occurs

(VI and VIII). This applies both to the  $\alpha$ - and to the  $\beta$ -series of glucosyl halides. It is then remarkable to find that both series of glucosyl halides yield glucosides of the same configuration by reaction with sodium alkoxides in alcohols. For instance, sodium methoxide in methyl alcohol produces  $\beta$ -methylglucosides (VI) from the  $\beta$ -glucosyl chlorides (V) used in the present investigation and also from 2:3:4:6-tetra-acetyl  $\alpha$ -glucosyl bromide (VII).

These observations appear to find a parallel in the behaviour of the  $\alpha$ - and  $\beta$ -penta-acetyl glucoses, which normally give the same tetra-acetyl glucosyl halide by the action of hydrogen halides. It is certain, when hydrogen chloride is used, that the first products have different configurations, but under the experimental conditions 2:3:4:6-tetra-acetyl  $\beta$ -glucosyl chloride isomerises to the more stable  $\alpha$ -glucosyl chloride (Schlubach, Stadler, and Wolf, *Ber.*, 1928, 61, 293; compare Fischer and Armstrong, *Ber.*, 1901, 34, 2894).

A somewhat similar explanation may account for the anomalous formation of  $\beta$ -glucosides from  $\beta$ -glucosyl chlorides, namely, that by the action of the sodium alkoxides the  $\beta$ -glucosyl chlorides are isomerised to  $\alpha$ -glucosyl chlorides, which then react in the normal way to give  $\beta$ -glucosides. This explanation was advanced by Fischer and Armstrong (*loc. cit.*) to account for the non-formation of  $\alpha$ -phenylglucoside from the unstable 2:3:4:6-tetra-acetyl  $\beta$ -glucosyl chloride. Their view was supported by the observation that the  $\beta$ -glucosyl chloride was converted completely into the  $\alpha$ -glucosyl chloride in an ethereal solution in contact with powdered hydrated sodium carbonate, or the wet sodium compound of glucose.

It appears at first sight that the extension of this hypothesis to account for the formation of  $\beta$ -glucosides from the  $\beta$ -glucosyl chlorides examined in the present work would be justifiable. A fuller consideration of the experimental facts, however, indicates that it can only be accepted if certain assumptions are made.

Although no accurate determinations of the velocity of the reaction between sodium methoxide or ethoxide and 2-trichloro-acetyl 3:4:6-triacetyl  $\beta$ -glucosyl chloride have been made owing

to the occurrence of comparatively slow side reactions, qualitative observations of the density of the precipitate of sodium chloride obtained when the reaction is carried out in ethyl alcohol indicate that glucoside formation occurs very quickly, and for 0.5*N*-solutions it is practically complete within a few minutes after mixing. Evidently, if the isomerisation hypothesis of Fischer and Armstrong holds, isomerisation must be complete or almost so before any replacement occurs; the isomerisation must therefore be extremely rapid. 2-Trichloroacetyl 3 : 4 : 6-triacetyl  $\beta$ -glucosyl chloride, however, is comparatively stable and does not isomerise readily. For instance, it does not change in non-hydroxylic solvents which bring about the conversion of 2 : 3 : 4 : 6-tetraacetyl  $\beta$ -glucosyl chloride into the  $\alpha$ -isomeride. Further, the addition of a trace of a methyl-alcoholic solution of sodium methoxide to an acetone solution of 2-trichloroacetyl 3 : 4 : 6-triacetyl  $\beta$ -glucosyl chloride does not cause any change of rotation over a period of 25 minutes. A drop of 20% aqueous sodium hydroxide added to an acetone solution of the  $\beta$ -glucoside brings about a change of  $[\alpha]_D$  only from  $+8^\circ$  to  $+13^\circ$  after 48 hours at room temperature. Further, a xylene solution of the  $\beta$ -glucosyl chloride may be kept in contact with an excess of dry, finely powdered sodium methoxide (free from methyl alcohol) at room temperature for 20 hours without any marked change in the rotation or without any serious amount of glucoside formation; indeed the greater part of the  $\beta$ -glucosyl chloride may be recovered unchanged. Micheel and Micheel (*Ber.*, 1930, 63, 392) have shown that anhydrous trimethylamine has no action on 2-trichloroacetyl 3 : 4 : 6-triacetyl  $\beta$ -glucosyl chloride in benzene at room temperature, and only a small action after 4 hours' heating at  $100^\circ$ .

The alcohol does not appear to be responsible for the isomerisation, since the rate of change of rotation in methyl alcohol is slow compared with the rate of replacement of the halogen (Hickinbottom, *loc. cit.*).

If the isomerisation hypothesis is to be retained, there must be assigned to the sodium alkoxide in the alcohol a catalytic power which is not possessed by the dry alkoxide, nor by the alcohol alone, nor by small quantities of the alcoholic methoxide in acetone.

An alternative hypothesis is to assume that addition to the glucosyl chloride may occur, and that the subsequent behaviour of the compound formed is determined by such factors as electron distribution, polarity, and steric configuration as well as by the relative energies of the systems.

It is known that the relative proportions of  $\alpha$ - and  $\beta$ -glucosides obtained by the replacement of the halogen of the glucosyl halides

may be varied very considerably. For instance, although sodium alkoxides react with 2-trichloroacetyl 3:4:6-triacetyl  $\beta$ -glucosyl chloride to give  $\beta$ -glucosides, sodium phenoxide gives a comparatively high proportion of the  $\alpha$ -phenylglucoside—approximately 60% of the total product.

When glucoside formation is effected from 2-trichloroacetyl 3:4:6-triacetyl  $\beta$ -glucosyl chloride or 3:4:6-triacetyl  $\beta$ -glucosyl chloride in an alcoholic suspension of silver oxide or silver carbonate, the product obtained is  $\alpha$ -glucoside with about 30% of  $\beta$ ; the proportion of  $\alpha$  can be increased if the silver carbonate is replaced by silver nitrate and pyridine. Further, it is possible to obtain some  $\alpha$ -glucosides from 2:3:4:6-tetra-acetyl  $\alpha$ -glucosyl bromide by reaction in presence of quinoline, the formation of  $\alpha$ -glucoside being apparently determined by the nature of the hydroxy-compound reacting.

These facts, together with observations on the opening of the ethylene-oxide ring in 3:4:6-triacetyl glucose anhydride, indicate that the reagents employed to effect glucoside formation determine, to some extent at least, the nature of the product.

Although it would be possible to explain these results by assuming that each reagent has its own isomerising effect, it seems more probable that the effect is determined by some factor such as preliminary addition.

In the reaction between sodium methoxide or ethoxide and 2-trichloroacetyl 3:4:6-triacetyl  $\beta$ -glucosyl chloride in equimolecular proportion in alcoholic solution, the trichloroacetyl group is split off and a 3:4:6-triacetyl  $\beta$ -alkylglucoside (III) is produced. This reaction provides an alternative method of preparing these compounds, which hitherto have only been obtained from 3:4:6-triacetyl  $\beta$ -glucosyl chloride or by the reaction of 3:4:6-triacetyl glucose anhydride with alcohols. It is an additional example of the comparative instability of the trichloroacetyl group in position 2 (Brigl, *Z. physiol. Chem.*, 1921, **116**, 1; Hickinbottom, *loc. cit.*).

#### EXPERIMENTAL.

*Action of Sodium Methoxide in Methyl Alcohol on 2-Trichloroacetyl 3:4:6-Triacetyl  $\beta$ -Glucosyl Chloride.—Formation of 3:4:6-triacetyl  $\beta$ -methylglucoside.* The sodium methoxide used in these experiments was prepared by dissolving sodium in freshly distilled, dry methyl alcohol to yield an approximately 0.5*N*-solution. The concentration was determined accurately by titration against standard acid.

A measured volume of this solution, diluted with methyl alcohol,

was added to 2-trichloroacetyl 3 : 4 : 6-triacetyl  $\beta$ -glucosyl chloride so that the glucosyl chloride and sodium methoxide were present in equimolecular proportion. The changes in specific rotation (calc. on the glucosyl chloride) were as follows ( $c = 5.23$ ;  $l = 2$ ) :

$t$ (mins.) ...	2	3	4	8	14	42	62	88
$[\alpha]_D^{25}$ .....	+27.3°	28.8°	27.3°	26.8°	24.2°	20.7°	19.2°	20.0° (const.)

A number of other determinations of the change of rotation, also made at room temperature, were in general agreement with those recorded above:  $[\alpha]_D +27-30^\circ$  about 2 minutes after mixing, changing to a constant end value between  $+14^\circ$  and  $+25^\circ$ .

The solutions obtained were clear and neutral to moist litmus. Evaporation under diminished pressure at room temperature, followed by repeated extraction of the residue with boiling chloroform to eliminate inorganic salts, and subsequent evaporation of the chloroform, yielded the product of the reaction as a colourless transparent gum. It slowly solidified in a vacuum desiccator to a crystalline mass (A).

The inorganic residue remaining after the extraction with chloroform was sodium chloride. In one or two experiments it contained a small quantity of acetate.

The crystalline mass (A) was not entirely free from lower-melting compounds. The products from two typical experiments showed  $[\alpha]_D +32.7^\circ$  ( $c = 1.65$ ) and  $[\alpha]_D +37.6^\circ$  ( $c = 1.78$ ) in ethyl alcohol. On deacetylation with alcoholic ammonia a mixture of  $\alpha$ - and  $\beta$ -glucosides resulted. From the two specimens for which the specific rotations are recorded above, methylglucosides were obtained which, after removal of amides and drying at  $78^\circ/12$  mm., had  $[\alpha]_D -6^\circ$  ( $c = 1.38$ ) and  $[\alpha]_D +4^\circ$  ( $c = 2.63$ ) in water. These values correspond to mixtures of  $\beta$ -methylglucoside containing 14% and 19% respectively of  $\alpha$ -methylglucoside. Crystallisation of the crude glucoside from alcohol furnished pure  $\beta$ -methylglucoside,  $[\alpha]_D -32^\circ$  in water ( $c = 1.07$ ), m. p.  $107-108^\circ$  (alone or mixed with a genuine specimen of  $\beta$ -methylglucoside). The presence of  $\alpha$ -methylglucoside was established by adding ether to a concentrated alcoholic solution of the product of deacetylation of the crude product (A). Two forms of crystal, which could be separated mechanically, were deposited on keeping. The greater part consisted of stout transparent prisms of  $\beta$ -methylglucoside. A few aggregates of small needles were also present, and after further purification from absolute alcohol these were identified as  $\alpha$ -methylglucoside by melting point and rotation.

*Isolation of 3 : 4 : 6-triacetyl  $\beta$ -methylglucoside (III).* Extraction of the solid (A) with ether left a gummy residue which showed

little sign of crystallising. The ethereal solution on slow spontaneous evaporation deposited aggregates of prismatic needles, which after crystallisation from carbon tetrachloride or alcohol were obtained pure; m. p. 93—94°,  $[\alpha]_D +20^\circ$  in ethyl alcohol ( $c = 4.5$ ) (Found: C, 49.0; H, 6.4; OMe, 9.6. Calc. for  $C_{13}H_{20}O_9$ : C, 48.6; H, 6.4; OMe, 9.6%). The analysis corresponds to triacetyl methylglucoside, and the constants are in good agreement with those recorded for 3:4:6-triacetyl  $\beta$ -methylglucoside prepared from 3:4:6-triacetyl glucose anhydride (Hickinbottom, J., 1928, 3144). The substance did not depress the melting point of an authentic specimen of 3:4:6-triacetyl  $\beta$ -methylglucoside, and yielded 2:3:4:6-tetra-acetyl  $\beta$ -methylglucoside on acetylation.

*Action of an Excess of Sodium Methoxide in Methyl Alcohol on 2-Trichloroacetyl 3:4:6-Triacetyl  $\beta$ -Glucosyl Chloride.*—A freshly prepared solution (0.404*N*) of sodium methoxide (1.154 mols.) in dry methyl alcohol was added to 2-trichloroacetyl 3:4:6-triacetyl  $\beta$ -glucosyl chloride (0.5421 g.; 1 mol.). The solution was rapidly diluted with dry methyl alcohol to 25 c.c. The following changes in rotation at room temperature were observed ( $l = 2.0$ ;  $c = 2.17$ ):

$t$ (mins.)	2	4	6	10	12	14	17
$\alpha_D$	+0.94°	0.66°	0.45°	0.29°	0.25°	0.20°	0.13°
$t$ (mins.)	19	23	29	54	88	1080	
$\alpha_D$	+0.10°	0.03°	-0.10°	-0.28°	-0.35°	-0.54° (const.)	

The solution was neutral after 24 hours. The final value, calculated on the assumption that only  $\beta$ -methylglucoside is present, is  $[\alpha]_D -31.2^\circ$ .

The product obtained on evaporation, however, did not consist entirely of  $\beta$ -methylglucoside. After solution of the glucosides in absolute alcohol and filtration to remove mineral matter, no appreciable amount of  $\beta$ -methylglucoside could be separated, even after concentration of the alcoholic solution and nucleation with  $\beta$ -methylglucoside. A determination of the acetyl content by hydrolysis with alcoholic potash showed that the product consisted largely of monoacetyl  $\beta$ -methylglucoside (Found: Ac, 13.2. Calc. for  $C_7H_{13}O_6Ac$ : Ac, 18.4%). It is evident that extensive deacetylation is brought about even in the cold by the action of a slight excess of sodium methoxide.

*Action of a Solution of Sodium Ethoxide in Ethyl Alcohol on 2-Trichloroacetyl 3:4:6-Triacetyl  $\beta$ -Glucosyl Chloride.*—The formation of 3:4:6-triacetyl  $\beta$ -ethylglucoside. The  $\beta$ -glucosyl chloride (1.1393 g.) was mixed with sodium ethoxide (1 mol.) in ethyl alcohol at room temperature, and the solution diluted to 25 c.c. No readings of the change of rotation were taken owing to the precipit-

ation of sodium chloride. After 24 hours, the solution was neutral to moist litmus, and after filtration had  $\alpha_D + 0.21^\circ$  ( $l = 0.5$ ); hence  $[\alpha]_D + 9^\circ$ , calculated on the glucosyl chloride, or  $[\alpha]_D + 11^\circ$ , calculated on triacetyl ethylglucoside.

Saturation of the solution with dry ammonia at room temperature, and subsequent evaporation after 20 hours, followed by extraction with ether to remove trichloroacetamide, and then drying at  $78^\circ/12$  mm., left a mixture of ethylglucosides,  $[\alpha]_D - 14^\circ$  in water ( $c = 1.95$ ;  $l = 0.5$ ). The solution was almost indifferent to Fehling's solution, and showed no detectable mutarotation after 24 hours. This value of the specific rotation corresponds to a mixture of 91% of  $\beta$ -ethylglucoside and 9% of  $\alpha$ -ethylglucoside. The presence of  $\beta$ -ethylglucoside as the major constituent of the mixture was also demonstrated by acetylation, whereby 2:3:4:6-tetra-acetyl  $\beta$ -ethylglucoside was obtained which, after one crystallisation from alcohol, melted, alone or mixed with a genuine specimen, at  $103-104^\circ$ .

*Isolation of 3:4:6-triacetyl  $\beta$ -ethylglucoside.* The filtered solution resulting from the action of sodium ethoxide (1 mol.) on 2-trichloroacetyl 3:4:6-triacetyl  $\beta$ -glucosyl chloride in alcohol had  $[\alpha]_D + 4^\circ$  ( $c = 4.78$ ), calculated on the original glucosyl chloride, and  $[\alpha]_D + 6^\circ$ , calculated on triacetyl ethylglucoside. It was evaporated under reduced pressure, and the dry residue extracted with ether. The ethereal solution deposited, on spontaneous evaporation, needles, m. p.  $105-110^\circ$ , which were contaminated by a small quantity of a substance having the odour of an ester. After three crystallisations from ethyl alcohol, the solid melted at  $119-120^\circ$ , and was identified by its m. p., mixed m. p., and specific rotation as 3:4:6-triacetyl  $\beta$ -ethylglucoside (Hickinbottom, *loc. cit.*).

*Action of Sodium Phenoxide and Phenol on 2-Trichloroacetyl 3:4:6-Triacetyl  $\beta$ -Glucosyl Chloride.*—Sodium phenoxide solution was prepared by the action of metallic sodium on an excess of molten phenol, precautions being taken to exclude moisture. The crystalline compound which separated on cooling, and probably consisted of the additive compound of phenol and sodium phenoxide (compare Gentsch, D.R.-P. 156761), was dissolved in sufficient dry acetone to give an approximately 0.5*N*-solution. The concentration of phenoxide was determined accurately by titration.

2-Trichloroacetyl 3:4:6-triacetyl  $\beta$ -glucosyl chloride (0.7816 g.) was treated with sodium phenoxide (1 mol.), and the solution made up to 25 c.c. with acetone. A precipitate of sodium chloride formed rapidly. After 2 hours the filtered solution had  $[\alpha]_D + 33^\circ$ , calculated on the basis of the glucosyl chloride, and this value did not alter during 48 hours. The filtered solution was evaporated, and

the residue heated at 100°/15 mm. to remove phenol. A brownish gum was obtained,  $[\alpha]_D +106.5^\circ$  in benzene ( $c = 2.16$ ;  $l = 0.5$ ). After deacetylation with alcoholic alkali, a mixture of phenylglucosides remained,  $[\alpha]_D +88^\circ$  in water ( $c = 1.48$ ;  $l = 0.5$ ). Acetylation of the glucosides gave a brownish mixture of the tetra-acetyl phenylglucosides,  $[\alpha]_D +95^\circ$  in benzene ( $c = 1.35$ ;  $l = 0.5$ ). This value corresponds to a mixture containing approximately 64% of tetra-acetyl  $\alpha$ -phenylglucoside and 36% of the  $\beta$ -isomeride. Crystallisation of the crude mixture from alcohol furnished pure 2:3:4:6-tetra-acetyl  $\alpha$ -phenylglucoside, m. p. 110–112° alone or mixed with an authentic specimen.  $[\alpha]_D +168^\circ$  in benzene.

*Action of a Solution of Sodium Methoxide in Methyl Alcohol on 3:4:6-Triacetyl  $\beta$ -Glucosyl Chloride.*—Sodium methoxide (1 mol.) in methyl-alcoholic solution (0.6683*N*) was diluted with methyl alcohol and added to 0.6655 g. of pure 3:4:6-triacetyl  $\beta$ -glucosyl chloride (m. p. 154°). The solution was made up to 25 c.c. as rapidly as possible: 4 minutes after mixing,  $[\alpha]_D$  (calc. on the glucosyl chloride) was  $-7.5^\circ$ , and it fell to a constant value of  $[\alpha]_D -22.5^\circ$  on keeping over-night at room temperature. The solution then contained no free glucosyl chloride. It was evaporated under diminished pressure, and the residue extracted repeatedly with boiling ethyl acetate. Evaporation of the extract left a transparent colourless gum which was inactive towards boiling Fehling's solution. Deacetylation of the gum with alcoholic ammonia at room temperature left a product which consisted very largely of  $\beta$ -methylglucoside,  $[\alpha]_D -32^\circ$  in water ( $c = 1.57$ ;  $l = 0.5$ ). The identification as  $\beta$ -methylglucoside was established by its m. p., mixed m. p., and specific rotation, after crystallisation from absolute alcohol.

*Action of Sodium Phenoxide on 3:4:6-Triacetyl  $\beta$ -Glucosyl Chloride.*—A solution (0.4161*N*) of sodium phenoxide (1 mol.) in acetone containing free phenol was added to 3:4:6-triacetyl  $\beta$ -glucosyl chloride (0.5364 g.), and the solution diluted rapidly to 25 c.c. The separation of sodium chloride commenced in less than a minute after mixing. Filtration after 18 hours gave a solution having  $[\alpha]_D +50^\circ$ , calculated on the basis of the glucosyl chloride. In another experiment, with 0.5031 g. of  $\beta$ -glucosyl chloride in 25 c.c. of acetone containing 1 mol. of sodium phenoxide, there resulted a solution which had  $[\alpha]_D +49^\circ$  after being kept for 50 hours at room temperature. Both solutions were faintly alkaline to moist litmus. They were combined, and the acetone was removed under reduced pressure. The residue, after being heated at 100°/15 mm. to remove phenol, was a light brown, transparent gum,  $[\alpha]_D +42^\circ$  in alcohol ( $c = 1.62$ ;  $l = 0.5$ ).

Acetylation of this residue in pyridine furnished a product having,

after the usual treatment to remove pyridine,  $[\alpha]_D + 40^\circ$  in benzene ( $c = 2.1$ ). This value corresponds to a mixture of approximately 65% of the tetra-acetyl  $\beta$ -phenylglucoside and 35% of the  $\alpha$ -isomeride. Crystallisation from alcohol gave pure 2:3:4:6-tetra-acetyl  $\beta$ -phenylglucoside, m. p. 125–126°,  $[\alpha]_D - 28^\circ$  in benzene.

*Action of Sodium Methoxide in Methyl Alcohol on 2:3:4:6-Tetra-acetyl  $\alpha$ -Glucosyl Bromide.*—In order to compare the behaviour of the  $\beta$ -glucosyl halides towards sodium methoxide with that of the  $\alpha$ -glucosyl halides the action of sodium methoxide in methyl alcohol on 2:3:4:6-tetra-acetyl  $\alpha$ -glucosyl bromide was followed polarimetrically.

Sodium methoxide (1 mol.) in methyl-alcoholic solution (0.4*N*) was added to 1.1969 g. of 2:3:4:6-tetra-acetyl  $\alpha$ -glucosyl bromide at room temperature, and methyl alcohol then added to make the volume up to 50 c.c. The changes in rotation were:

<i>t</i> (mins.) ...	1.5	3	5	8	45	1135
$\alpha_D$ ( $l = 0.5$ )	-0.01°	-0.05°	-0.07°	-0.09°	-0.13°	-0.15° (const.)

The solution after acetylation yielded tetra-acetyl  $\beta$ -methyl-glucoside.

*The Stability of 2-Trichloroacetyl 3:4:6-Triacetyl  $\beta$ -Glucosyl Chloride.*—Attempts were made to effect the isomerisation of 2-trichloroacetyl 3:4:6-triacetyl  $\beta$ -glucosyl chloride by the action of traces of alkali or sodium methoxide in acetone.

A solution of the  $\beta$ -glucosyl chloride in dry acetone ( $[\alpha]_D + 8^\circ$ ;  $c = 4.41$ ;  $l = 0.5$ ), treated with 2 drops of 0.5*N*-solution of sodium methoxide in methyl alcohol, showed no change in rotation after being kept at room temperature for 25 minutes. The subsequent addition of 1 drop of 5*N*-sodium hydroxide gave a solution which had  $[\alpha]_D + 10.5^\circ$  after 24.5 hours and  $[\alpha]_D + 13.1^\circ$  after 47.5 hours. The tube contained a small deposit, presumably sodium chloride. The solution, however, on evaporation gave unchanged  $\beta$ -glucosyl chloride.

A suspension of an excess of sodium methoxide (e.g., 2 mols.) in dry xylene free from methyl alcohol had only a slow action on 2-trichloroacetyl 3:4:6-triacetyl  $\beta$ -glucosyl chloride. After 17 hours, with intermittent shaking, the filtered solution had  $[\alpha]_D + 17^\circ$ , calculated on the basis of the glucosyl chloride. Evaporation under reduced pressure gave a residue which partly crystallised, and from which a large proportion of unchanged  $\beta$ -glucosyl chloride was isolated.

The addition of 1 drop of concentrated hydrochloric acid to an acetone solution of 2-trichloroacetyl 3:4:6-triacetyl  $\beta$ -glucosyl chloride ( $c = 4.4$ ) brought about a change in specific rotation from  $+7.2^\circ$  to  $+9.6^\circ$  after 92 hours. The solution had become

darker in colour. On evaporation it yielded a somewhat impure product, m. p. 120—125°, from which the pure  $\beta$ -glucosyl chloride, m. p. 135—136°, was obtained by one crystallisation from ethyl alcohol.

## CLXXIV.—*The Synthesis of meso-Alkyl and meso-Aryl Anthracene Derivatives. Part VII.*

By EDWARD DE BARRY BARNETT and NORMAN FREDERICK GOODWAY.

THE isolation of 3-chloro-9-anthrone (Barnett and Matthews, J., 1923, 2549) from the mixture of 2- and 3-chloro-9-anthrone obtained by the reduction of 2-chloroanthraquinone with tin and hydrochloric acid or with aluminium powder and concentrated sulphuric acid can be readily effected by the method used by Barnett and Goodway (J., 1929, 1754) for the isolation of 3-methyl-9-anthrone, *viz.*, acetylation and fractional crystallisation of the mixed anthranyl acetates.

2- and 3-Chloro-9-anthrone condense readily with benzyl chloride in the presence of potassium hydroxide and yield, as would be expected, the *chlorodibenzylanthrones*.

By interaction with magnesium alkyl halides (Barnett and Goodway, J., 1929, 20, 1745), 10-benzhydrylanthrone (I,  $X = C_6H_4$ ) gives dihydroanthranols (II,  $X = C_6H_4$ ) which undergo transannular loss of water to form the alkylbenzhydrylanthracenes (III), whereas 1 : 5-dichloro-10-benzhydrylanthrone (I,  $X = C_6H_3Cl$ ) gives dihydroanthranols (II,  $X = C_6H_3Cl$ ) which undergo transannular loss of benzhydrol to give the alkylanthracene (IV).

As it seemed possible that this difference in behaviour was due to the co-ordination of the hydrogen atom at 10 with the chlorine atom at 5 (compare Barnett and Wiltshire, *Ber.*, 1929, 62, 3063; Barnett, Goodway, and Wiltshire, *ibid.*, 1930, 63, 472), the behaviour of the dihydroanthranols obtained by the action of magnesium benzyl chloride on some other *Bz.*-chloro-10-benzhydrylanthrones has been examined. The results obtained, which are summarised below, show that co-ordination of the *meso*-hydrogen atom cannot possibly

be the factor determining the type of transannular loss suffered under the influence of hydrogen ions: for instance, 1-chloro-, 2-chloro-, 4-chloro-, 1:4-dichloro-, and 4:5-dichloro-9-benzyl-10-benzhydryl-9:10-dihydro-9-anthranol all underwent loss of benzhydrol and yielded the corresponding chlorinated 9-benzylanthrane; 1:8-dichloro-9-benzyl-10-benzhydryl-9:10-dihydro-9-anthranol (V), on the other hand, lost water and passed into 1:8-dichloro-9-benzyl-10-benzhydrylanthrane (VI).

1:8- and 4:5-Dichloro-9-anthrone differ markedly from anthrone itself in their behaviour towards benzophenone chloride, for whereas anthrone yields diphenylmethyleanthrone (anthrafuchsone) (Padova, *Compt. rend.*, 1906, **143**, 121; *Ann. Chim.*, 1910, **19**, 388), the two dichloroanthrones are merely oxidised to the dianthrones. Also, after boiling for 3 hours with phthaloyl chloride in xylene solution, they were largely recovered unchanged and, although some resinous matter was formed in each case, no compound corresponding to the phthalylidene derivative obtained by Padova (*Compt. rend.*, 1909, **418**, 290) from anthrone itself could be detected.

As was foreseen, 1:4-dichloroanthrone condenses with benzyl chloride in the presence of sodium hydroxide to give 1:4-dichloro-10-benzylanthrone (VII), and the dihydroanthranol (VIII) obtained from this by the action of magnesium benzyl chloride undergoes loss of water to form the benzylidene derivative (IX). This behaviour is in harmony with the suggestion (Barnett, Goodway, and Wiltshire, *loc. cit.*) that a *meso*-hydrogen atom forms a chelate ring with the chlorine atom in the *peri*-position, as indicated in the formulæ below.

The failure of 1:4-dichloro-10-benzylanthrone to undergo enolisation when boiled with alcoholic sodium hydroxide furnishes further evidence of the immobilisation of the *meso*-hydrogen atom.

## EXPERIMENTAL.

**3-Chloro-9-anthrone.**—The mixture of anthrones obtained by the reduction of 2-chloroanthraquinone by the tin-hydrochloric acid method was acetylated on the water-bath with pyridine and acetic anhydride and the resulting anthranyl acetates were recrystallised from benzene-light petroleum or toluene-light petroleum. 3-Chloro-9-anthranyl acetate (m. p. 146°; Barnett and Wiltshire, J., 1928, 1822) was thus easily obtained in the pure state; it yielded the corresponding anthrone on hydrolysis with alcoholic alkali in an inert atmosphere (compare Barnett and Goodway, J., 1929, 1754).

**2-Chloro-10:10-dibenzylanthrone.**—2-Chloro-9-anthrone (10 g.) and benzyl chloride (10 c.c.) were boiled under reflux with a solution of potassium hydroxide (7 g.) in water (25 c.c.) for an hour. After being washed with water and with ice-cold ether, the product was recrystallised from glacial acetic acid and from benzene-light petroleum. It was then colourless and melted at 185° (Found: C, 82.0; H, 5.3.  $C_{23}H_{21}OCl$  requires C, 82.2; H, 5.1%).

**3-Chloro-10:10-dibenzylanthrone**, prepared in exactly the same way as the above compound, formed colourless crystals, m. p. 174° (Found: C, 82.3; H, 5.4%).

**Bz.-Chloro-10-benzhydrylanthrones.**—In all cases the anthrone (5–10 g.) was boiled with an excess of crude benzhydryl chloride (10–20 c.c.) and aqueous sodium hydroxide (75–100 c.c.; about 12% strength) until the black tar at first formed vanished (10–30 minutes). After cooling, the viscous product was washed with water, triturated with ice-cold ether to remove resinous by-products, and crystallised from acetic acid or acetone and then from benzene-light petroleum. The products were all colourless and, when boiled with alcoholic alkali, gave a distinct colour only when there was no chlorine atom in position 4 or 5.

In the following table the figures under "Analysis" refer to carbon and hydrogen, the calculated figures being given in parentheses.

Cl at	M. p.	Analysis.	Cl at	M. p.	Analysis.
1	204°	82.3; 5.0 (82.1; 4.8)	1:4	191°	75.4; 4.4 (75.5; 4.2)
2	171	82.1; 5.0 " "	1:8	242	75.4; 4.4 " "
4	175	82.0; 4.8 " "	4:5	224	75.4; 4.3 " "

A crystalline product could not be isolated from the resin obtained when 3-chloro-9-anthrone was boiled with benzhydryl chloride and alkali.

**Bz.-Chloro-9-benzyl-10-benzhydryl-9:10-dihydro-9-anthranols.**—In all cases the benzhydrylanthrone was added slowly to an ethereal solution of magnesium benzyl chloride (3 mols.) cooled in a freezing mixture, and after being kept over-night at the ordinary temperature the whole was poured on a mixture of ice and solid ammonium

chloride. Sparingly soluble dihydroanthranols were isolated by filtration, and the more soluble dihydroanthranols by evaporation of the washed and dried ( $\text{Na}_2\text{SO}_4$ ) ethereal solution. In the latter case the dihydroanthranol was sometimes left as an oil which became solid on treatment with aqueous acetone or light petroleum, but the dihydroanthranol obtained from 1-chloro-10-benzhydryl-anthrone refused to crystallise. Purification was effected by recrystallisation from aqueous acetone and then from benzene-light petroleum. The products were all colourless.

Dehydration was brought about by means of acetic acid containing a little concentrated hydrochloric acid, either by keeping over-night at the ordinary temperature or by brief heating on the water-bath. The resulting *Bz.*-chloro-9-benzylantracenes were identified by direct comparison with authentic specimens.

Cl at	M. p.	Analysis.	Cl at	M. p.	Analysis.
2	166°	83.8; 5.7 (83.9; 5.6)	1:4	199°	78.2; 5.2 (78.3; 5.0)
4	208	83.6; 5.8 „ „	1:8	190	78.4; 5.3 „ „
			4:5	186	78.5; 5.1 „ „

1:8-Dichloro-9-benzyl-10-benzhydrylanthrane (VI) formed pale yellow crystals, m. p. 139°, from acetone (Found: C, 81.1; H, 4.8.  $\text{C}_{34}\text{H}_{24}\text{Cl}_2$  requires C, 81.1; H, 4.8%).

*Action of Benzophenone Chloride on 1:8- and 4:5-Dichloro-anthrone.*—The anthrone (5.4 g.) was boiled for 3 hours with benzophenone chloride (5.5 g.) and xylene (50 c.c. in the case of 1:8-dichloroanthrone; 15 c.c. in the case of 4:5-dichloroanthrone). 1:8:1':8'-Tetrachloro-10:10'-dianthrone separated from the boiling solution, and after being washed with xylene was recrystallised from nitrobenzene (Found: C, 64.0; H, 2.7. Calc.: C, 64.1; H, 2.7%). 4:5:4':5'-Tetrachloro-10:10'-dianthrone was isolated by the addition of light petroleum and subsequent recrystallisation from benzene-ethyl acetate. On heating, it darkened but did not melt below 315° (compare Barnett, Cook, and Matthews, *Rec. trav. chim.*, 1926, 45, 75).

Neither of the above dianthrone gave any colour on boiling with alcoholic alkali. The latter, however, was enolised by pyridine and after boiling for 3 minutes with this solvent gave an immediate red colour on the addition of a drop of sodium hydroxide. The former gave no colour after similar treatment, presumably owing to the immobilisation of the *meso*-hydrogen atoms by co-ordination with the chlorine atoms.

1:4-Dichloro-10-benzyl-9-anthrone (VII).—1:4-Dichloroanthrone (10 g.) was boiled with benzyl chloride (10 c.c.) and a solution of potassium hydroxide (7 g.) in water (30 c.c.) for an hour. The product having been washed with water and freed from volatile

material by distillation with steam, the resinous residue was triturated with cold ether and crystallised from benzene-light petroleum. The resulting colourless crystals melted at  $123^{\circ}$  (Found: C, 71.3; H, 4.1.  $C_{21}H_{14}OCl_2$  requires C, 71.4; H, 4.0%).

1:4-Dichloro-9:10-dibenzyl-9:10-dihydroanthranol (VIII).—1:4-Dichloro-10-benzylanthrone (6 g.) was added slowly to an ethereal solution of magnesium benzyl chloride (3 mols.) cooled in a freezing mixture, and the whole kept over-night at the ordinary temperature and then poured on a mixture of ice and solid ammonium chloride. The oil obtained by evaporation of the washed ethereal solution became solid on cooling and was then recrystallised from aqueous acetone and from benzene-light petroleum. The resulting colourless crystals melted at  $165^{\circ}$  (Found: C, 75.5; H, 5.1.  $C_{28}H_{22}OCl_2$  requires C, 75.5; H, 4.9%).

1:4-Dichloro-10-benzylidene-9:10-dihydroanthracene (IX).—The above dihydroanthranol was kept over-night at the ordinary temperature in glacial acetic acid solution to which a little concentrated hydrochloric acid had been added. The resulting solid separated from benzene-light petroleum in colourless non-fluorescent crystals, m. p.  $186^{\circ}$  (Found: C, 78.7; H, 4.9.  $C_{28}H_{20}Cl_2$  requires C, 78.7; H, 4.7%).

One of the authors (E. de B. B.) desires to express his thanks to Imperial Chemical Industries, Ltd., for a gift of 1:8-dichloro-anthraquinone and for a grant out of which some of the expenses of this research have been paid.

## CLXXV.—The Space Configuration of the Trithioacetaldehydes.

By FREDERICK DANIEL CHATTAWAY and EDWIN GEOFFREY  
KELLETT.

RECENT work (Fromm and Engler, *Ber.*, 1925, 58, 1916; Bell, Bennett, and Mann, J., 1929, 1462) has supported the earlier view of Baumann and Fromm (*Ber.*, 1889, 22, 2600) that trithioacetaldehyde,  $(CH_3 \cdot CH:S)_3$ , exists in two isomeric forms, the so-called  $\alpha$ -trithioacetaldehyde, m. p.  $101^{\circ}$ , and  $\beta$ -trithioacetaldehyde, m. p.  $126^{\circ}$ , and that the supposed  $\gamma$ -form (Marckwald, *Ber.*, 1886, 19, 1826; Polack and Thummel, *Ber.*, 1889, 22, 2871; Mann and Pope, J., 1923, 123, 1178) is a mixture of these two. Although it has been customary to regard the  $\alpha$ -form as the *cis*-isomeride

(having all three methyl groups on the same side of the plane of the ring), there is no direct chemical evidence for this view. Baumann and Fromm regarded the  $\beta$ -form as *trans*- (Ber., 1891, 24, 1428) because it is the more stable isomeride, arguing by analogy with the hexahydrophthalic acids. Auwers and Ottens (Ber., 1924, 57, 439) support this view from comparisons of physical data.

The oxidation products of these two isomerides which have previously been described are anomalous in that both isomerides give one and the same trisulphone (Baumann and Fromm, Ber., 1889, 22, 2606; Lomnitz, Ber., 1894, 27, 1667) and one and the same disulphone (Baumann and Fromm, Ber., 1893, 26, 2074); while only one trisulphoxide of  $\alpha$ -trithioacetaldehyde and one of the  $\beta$ -form have been obtained (Fromm and Engler, *loc. cit.*), though the stereoisomeric possibilities, having regard to the possible dispositions of the semipolar double bonds in relation to the plane of the ring (compare Bell and Bennett, J., 1927, 1798), are much more numerous than this (six trisulphoxides of the *trans*-form, and four of the *cis*-form, may be predicted).

It is shown in the present paper that  $\alpha$ -trithioacetaldehyde forms *two* isomeric monosulphoxides, and  $\beta$ -trithioacetaldehyde *one*. The maximum number theoretically possible is *two* from the *cis*-form and *four* from the *trans*-form. Each of the three monosulphoxides actually obtained has, however, been further oxidised to a distinct monosulphone. Hence, since  $\alpha$ -trithioacetaldehyde yields two isomeric monosulphones, and the  $\beta$ -form only one, the  $\alpha$ -form must have the *trans*-structure.

#### EXPERIMENTAL.

*Oxidation of  $\beta$ -Trithioacetaldehyde to a Monosulphoxide.*—10 G. of finely powdered  $\beta$ -trithioacetaldehyde, m. p. 126°, were suspended

in 100 c.c. of glacial acetic acid, and 6 c.c. of "perhydrol," dissolved in 150 c.c. of acetic acid, added during 8 hours, with vigorous shaking. (The reaction is rapid, since 15 minutes after addition of the last drop of "perhydrol" solution no free hydrogen peroxide could be detected in the reaction mixture by the perchromic acid test.) The clear solution thus obtained was diluted to 1500 c.c. with cold water and 220 g. of anhydrous sodium carbonate were added; it was then filtered, and the filtrate extracted with 400 c.c. of chloroform in eight portions. The extract was dried over calcium chloride and the chloroform evaporated, leaving 9.5 g. of crude product. On crystallisation from 20% aqueous alcohol (60 c.c.), this proved to be a single pure compound.

*β-Trithioacetaldehyde monosulphoxide* crystallises from alcohol, in which it is very readily soluble, in large, compact, colourless crystals of ill-defined shape, m. p. 118.5° (Found: S, 49.2.  $C_6H_{12}OS_3$  requires S, 49.1%). It is moderately easily soluble in cold water, and readily soluble in all the usual organic solvents. On warming with zinc dust in dilute hydrochloric acid, it is reduced to *β*-trithioacetaldehyde.

*Oxidation of β-Trithioacetaldehyde Monosulphoxide to a Monosulphone.*—3 G. of potassium permanganate, dissolved in 300 c.c. of water, were added during 6 hours to a stirred solution of 5.6 g. of *β*-trithioacetaldehyde monosulphoxide in 750 c.c. of water containing 10 g. of magnesium sulphate. Each drop of permanganate was decolorised almost instantaneously. When all had been added, the precipitated manganese dioxide was dissolved by passing sulphur dioxide through the mixture. The resulting liquor, containing the product partly in suspension and partly in solution, was extracted with 120 c.c. of chloroform in eight portions. The extract was dried and evaporated, and the residue recrystallised from 50% aqueous alcohol (yield, 4 g.).

*β-Trithioacetaldehyde monosulphone* crystallises from alcohol, in which it is moderately easily soluble, in slender colourless prisms, m. p. 190° (Found: S, 45.6.  $C_6H_{12}O_2S_3$  requires S, 45.3%). It is only sparingly soluble in cold water. It is not reduced by zinc in hydrochloric acid, nor by tin in a mixture of hot hydrochloric and acetic acids, nor by hydriodic acid in the cold. On boiling for some time with fresh, constant-boiling hydriodic acid, it is to some extent decomposed, hydrogen sulphide being liberated and tarry products formed; any crystallisable product recovered from this reaction, however, is the unchanged sulphone.

It may be noted (a) that *β*-trithioacetaldehyde is not oxidised by "perhydrol" in neutral acetone solution, (b) that, if it is attempted to oxidise *β*-trithioacetaldehyde directly to its lower oxidation

products with a limited amount of either neutral or acid permanganate, a complex mixture of products is formed, even though the process be protracted over several days, and (c) that, if it is attempted to oxidise  $\beta$ -trithioacetaldehyde monosulphoxide with a limited amount of acid permanganate, a complex mixture of products is again obtained.

*Oxidation of  $\alpha$ -Trithioacetaldehyde to a Pair of Isomeric Monosulphoxides.*—10 G. of  $\alpha$ -trithioacetaldehyde, m. p.  $100^\circ$ , were suspended in 75 c.c. of acetic acid and oxidised with "perhydrol" as above. Yield of crude product, 9.5 g. This was recrystallised from 20% aqueous alcohol (75 c.c. for the first operation) until it had a constant m. p.  $136^\circ$  (4.6 g.). The mother-liquors were concentrated on the water-bath and evaporated to dryness in a vacuum desiccator. The residue was extracted by rinsing it several times with quantities of 25 c.c. of water at  $50^\circ$ ; these extracts were evaporated to dryness and the residue was recrystallised from 10% aqueous alcohol until it had m. p.  $93^\circ$  (1 g.).

$\alpha$ -Trithioacetaldehyde  $\alpha$ -monosulphoxide crystallises from 20% alcohol, in which it is readily soluble, in large, colourless, rhombic plates, m. p.  $136^\circ$  (Found: S, 49.4%). It is moderately easily soluble in cold water and very readily in organic solvents. It is reduced to  $\alpha$ -trithioacetaldehyde by warming with zinc dust and dilute hydrochloric acid.

$\alpha$ -Trithioacetaldehyde  $\beta$ -monosulphoxide crystallises from 10% alcohol in slender colourless prisms, m. p.  $93^\circ$  (Found: S, 49.4%). Its solubilities are only slightly greater than those of the  $\alpha$ -form, above. It is reduced by nascent hydrogen to  $\alpha$ -trithioacetaldehyde.

Each of the three isomeric monosulphoxides lowers the m. p. of either of the others.

*Oxidation of  $\alpha$ -Trithioacetaldehyde to a Pair of Isomeric Monosulphones.*—8.3 G. of  $\alpha$ -trithioacetaldehyde were oxidised to the monosulphoxide stage, as above, with "perhydrol." To the solution in acetic acid, aqueous caustic potash was added until the mixture was just alkaline to phenolphthalein; the total volume of the solution was then about 1200 c.c. 20 G. of magnesium sulphate were dissolved in this, and 4.9 g. of potassium permanganate, dissolved in 500 c.c. of water, added with mechanical stirring during 9 hours. The resulting reaction mixture was worked up as described for  $\beta$ -trithioacetaldehyde monosulphone. Yield of crude product, 9.5 g. By fractional crystallisation from alcohol, two isomeric products were isolated.

$\alpha$ -Trithioacetaldehyde  $\alpha$ -monosulphone is sparingly soluble in water, more readily in alcohol. It crystallises in two polymorphic forms. When a hot alcoholic solution is cooled, the labile form

separates as a felted mass of colourless needles. These, on standing in contact with the solvent for 24 hours at the ordinary temperature, dissolve, and the stable form separates as large, colourless, rhombic crystals. Both forms melt at  $157.5^{\circ}$ , transformation into the stable form occurring before melting (Found : S, 45.3%).

$\alpha$ -Trithioacetaldehyde  $\beta$ -monosulphone crystallises from alcohol, in which it is appreciably more soluble than the  $\alpha$ -monosulphone, in slender colourless prisms, m. p.  $115-116^{\circ}$  (Found : S, 45.1%).

These two isomerides are stable towards reducing agents in the same way as is  $\beta$ -trithioacetaldehyde monosulphone. They do not undergo stereoisomeric inversion under the influence of hydrogen iodide, iodine or acetyl chloride. The  $\alpha$ -monosulphone corresponds to the  $\alpha$ -monosulphoxide, since if the latter compound is oxidised with the appropriate amount of neutral permanganate, the  $\alpha$ -monosulphone is obtained alone in practically quantitative yield.

OXFORD.

[Received, April 12th, 1930.]

## CLXXVI.—Attempts to find New Antimalarials. Part V. Some Piperidino- and Piperazino-derivatives of Quinoline.

By WILLIAM OGILVIE KERMACK and JAMES FERGUS SMITH.

4-CHLORO-2-METHYLQUINOLINE and its derivatives, which are readily obtained by the treatment with phosphoryl chloride and phosphorus pentachloride, of the corresponding 4-hydroxy-2-methylquinolines, prepared according to the method of Conrad and Limpach (*Ber.*, 1887, 20, 947) by the condensation of ethyl acetoacetate with the requisite derivatives of aniline, condense readily with various primary and secondary amines. For instance, 4-piperidino-2-methylquinoline and 4-piperidino-6-methoxy-2-methylquinoline were obtained from piperidine and 4-chloro-2-methylquinoline and 4-chloro-6-methoxy-2-methylquinoline, respectively, at  $180^{\circ}$ .

When 4-chloro-2-methylquinoline was heated at  $140^{\circ}$  with a considerable excess of piperazine hexahydrate for 2—3 hours, a white solid separated, from which 4-piperazino-2-methylquinoline was

isolated, besides a small quantity of 1:4-di-2'-methyl-4'-quinolyl-piperazine (I). When relatively less piperazine was used, a corre-

spondingly larger quantity of (I) was formed. Under similar conditions 4-chloro-6-methoxy-2-methylquinoline condensed with piperazine hydrate with the formation of 4-*piperazino*-6-methoxy-2-methylquinoline and 1 : 4-di-6'-methoxy-2'-methyl-4'-quinolylpiperazine.

The preparation of mono-*N*-substituted derivatives of piperazine usually presents considerable difficulty, and, with the simpler reactive halides, the disubstituted compound is usually obtained exclusively, or in preponderating amount (compare Moore, Boyle, and Thorn, J., 1929, 39). *p*-Chloronitrobenzene is said to yield the monosubstituted derivative readily; it is therefore of some interest that 4-chloro-2-methylquinoline and its derivatives can without difficulty be made to react with piperazine so as to yield monosubstituted products.

Certain of the above compounds have been tested in respect of their antimalarial action, and the results of these biological experiments will be published elsewhere. As in other papers of this series, the numbers, given in parentheses, after certain compounds are to facilitate reference to the biological tests.

#### EXPERIMENTAL.

4-*Piperidino*-2-methylquinoline (Km. 10).—Equimolecular quantities of piperidine (2.5 g.) and 4-chloro-2-methylquinoline (5.3 g.) were heated together at 180° under reflux for 3—4 hours. The purple solid which separated was extracted with dilute hydrochloric acid (3%), and the solution made alkaline with caustic soda. The dark red oil which separated was subjected to steam distillation to remove any excess of piperidine or chloroquinoline. The residue was dissolved in ether, dried over potassium carbonate, and recovered as a dark oil. This, on distillation in a vacuum, gave a somewhat viscous, light yellow oil, b. p. 207°/12 mm., which would not crystallise. The *picrate*, obtained by means of a cold saturated solution of picric acid in benzene, crystallised from alcohol in yellow needles, m. p. 182° (Found : N, 15.4.  $C_{15}H_{13}N_2 \cdot C_6H_3O_7N_3$  requires N, 15.4%).

The *chloroaurate*, obtained by mixing a solution of the hydrochloride, containing an excess of hydrochloric acid, with an aqueous solution of gold chloride, separated as a yellow-brown precipitate, insoluble in hot water, but easily soluble in alcohol, from which it crystallised in dark red, almost rectangular, rhombic plates, m. p. 174° (Found : Cl, 24.9.  $C_{15}H_{13}N_2 \cdot AuCl_4$  requires Cl, 25.1%).

4-*Piperidino*-2-methylquinoline is fairly readily soluble in acids, although concentrated nitric acid, when added to a solution of the hydrochloride, precipitates yellow needles, m. p. 192° (decomp.), presumably the nitrate, which is sparingly soluble in cold, and rather

more soluble in hot water. The hydrochloride could not be obtained as a solid by passing dry hydrogen chloride into a benzene solution of the base. The base is somewhat soluble in most organic solvents, but is sparingly soluble in cold water. Its solution in concentrated sulphuric acid exhibits a very faint bluish fluorescence when illuminated by the arc lamp. Very little darkening of the solution is observed on warming (compare the behaviour of the methoxy-derivative).

**4-Piperidino-6-methoxy-2-methylquinoline**(Km. 12).—When equimolecular quantities of 4-chloro-6-methoxy-2-methylquinoline (6.2 g.) and piperidine (2.5 g.) were heated together under the conditions adopted in the preparation of 4-piperidino-2-methylquinoline, and the purple solid formed was extracted and purified as above, a clear yellow, viscous oil was finally obtained, b. p.  $220^{\circ}/12$  mm. The base, which could not be induced to crystallise, exhibited a strong greenish fluorescence, and in its properties closely resembled 4-piperidino-2-methylquinoline. With concentrated sulphuric acid, however, it gave a strong blue fluorescence which disappeared on dilution. On warming, the solution in concentrated acid developed an orange-brown colour, the blue fluorescence becoming less marked. The *picrate*, obtained as before, crystallised from alcohol in clusters of long yellow prisms, m. p.  $191^{\circ}$  (Found: N, 14.2.  $C_{16}H_{20}ON_2, C_6H_3O_7N_3$  requires N, 14.4%).

The *chloroaurate*, obtained as above, crystallised from alcohol, in which it was readily soluble, in red rhombic plates, m. p.  $156^{\circ}$  (Found: Cl, 24.1.  $C_{16}H_{27}ON_2AuCl_4$  requires Cl, 23.8%).

**4-Piperazino-2-methylquinoline**(Km. 13).—4-Chloro-2-methylquinoline and a large excess of piperazine hexahydrate (15 g.) were heated under reflux for 3–4 hours in an oil-bath at  $140^{\circ}$ . The white solid which separated was extracted with dilute hydrochloric acid (3%), and the solution filtered, leaving behind a small quantity of the white hydrochloride of the corresponding diquinolylpiperazine. The filtrate, when made alkaline with caustic soda, deposited a yellow oil, which slowly crystallised. On recrystallisation from hot water (in which solvent there is a marked tendency to supersaturation), large, yellow-brown, rhombic plates of the *hydrate* were obtained, m. p.  $60^{\circ}$ . These, on drying in a desiccator, lost 24.4% of their weight, corresponding to four molecules of water of crystallisation (24.1%), and yielded the anhydrous *base*, m. p.  $103^{\circ}$  (Found: C, 74.2; H, 7.5; N, 18.3.  $C_{14}H_{17}N_3$  requires C, 74.0; H, 7.5; N, 18.5%).

This compound is very soluble in alcohol, in dilute mineral, and acetic acids, soluble in ether, but very slightly soluble in benzene and in cold water; it dissolves quite readily, however, in hot water. When treated with concentrated sulphuric acid in the cold, the base

dissolves only with difficulty, yielding a clear solution; this exhibits in the arc lamp a very faint blue fluorescence which disappears on dilution. Neither the solution in concentrated sulphuric acid nor that in concentrated nitric acid exhibits any characteristic colour changes on warming (compare the methoxy-derivative).

4-Piperazino-6-methoxy-2-methylquinoline (Km. 9).—4-Chloro-6-methoxy-2-methylquinoline (5 g.) was treated with piperazine hydrate (15 g.) under the same conditions as recorded in the preparation of 4-piperazino-2-methylquinoline. In this case, none of the corresponding diquinolylpiperazine was formed, the compound being obtained in a very pure form by diluting the condensation product with 3—4 times its volume of water and allowing the hot solution to stand; crystals of the *hydrate* soon separated as pink pyramids which, after recrystallisation from hot water, melted at 55°. These crystals, when dried in a desiccator, lost 17.9% of their weight, corresponding to three molecules of water of crystallisation (17.4%), and yielded the anhydrous *base*, m. p. 113° (Found: C, 69.7; H, 7.5; N, 16.0.  $C_{15}H_{13}ON_3$  requires C, 70.0; H, 7.4; N, 16.3%).

This compound resembles 4-piperazino-2-methylquinoline in solubility. Its solution in cold concentrated sulphuric acid, however, exhibits a very strong greenish-blue fluorescence which disappears on dilution. When the concentrated acid solution is warmed, a reddish-brown colour develops and the fluorescence, although less marked, is retained. When treated with hot concentrated nitric acid, this compound develops a red colour.

4'-Acetyl-4-piperazino-2-methylquinoline.—4-Piperazino-2-methylquinoline was heated with acetic anhydride for 2—3 hours on the water-bath, the product warmed with water, and the solution made alkaline with caustic soda. The oily base obtained, which solidified, crystallised from hot water in large, brown, rhombic plates of the *hydrate*, m. p. 70°. When dried in a desiccator, these crystals lost 16.9% of their weight, equivalent to three molecules of water of hydration (16.7%), and yielded the anhydrous base, m. p. 122°.

This acetyl derivative resembles the parent base in solubility and in exhibiting a very faint blue fluorescence in concentrated sulphuric acid solution, by the arc light. In addition, its alcoholic solution exhibits a slight greenish fluorescence.

4'-Acetyl-4-piperazino-6-methoxy-2-methylquinoline (Km. 11).—This compound was prepared in a similar manner to the preceding one. The *hydrate* was obtained from hot water in light brown needles, m. p. 86°, which, when dried in a desiccator, lost 10.9% of their weight, equivalent to two molecules of water of crystallisation (10.7%), and yielded the anhydrous base, m. p. 154°.

Here again, the properties of this acetyl derivative resemble closely

those of the parent base. The distinctive colour reactions shown by 4-piperazino-6-methoxy-2-methylquinoline when warmed with concentrated nitric or sulphuric acid, as well as the fluorescences exhibited, were slightly more marked in this case. In addition, its solution in alcohol exhibits a slight greenish fluorescence.

1 : 4-*Di-2'-methyl-4'-quinolylpiperazine* (Km. 14).—4-Chloro-2-methylquinoline (3.5 g.) was condensed with piperazine hydrate (2 g.) under the same conditions as those adopted in the preparation of the monoquinolylpiperazines. The white solid which had separated after 2—3 hours was treated with cold hydrochloric acid (3%), which removed any unchanged materials, and was then dissolved in a large quantity of boiling water; when this solution was made alkaline with sodium hydroxide, the *base* was obtained as a voluminous white precipitate. It was practically insoluble in most organic solvents, but crystallised from hot pyridine in white rhombohedra, m. p. 314° (Found: C, 78.1; H, 6.7.  $C_{24}H_{24}N_4$  requires C, 78.3; H, 6.5%).

This compound is fairly readily soluble in acetic and lactic acids, but forms sparingly soluble salts with dilute hydrochloric, nitric and sulphuric acids. It dissolves, however, in concentrated nitric acid to give a light yellow solution, which darkens only slightly on warming (compare the methoxy-derivative). With concentrated sulphuric acid, it yields a clear solution which exhibits a very faint violet fluorescence in the arc light. When warmed, this solution rapidly turns green, changing to greenish-brown and finally dirty brown.

1 : 4-*Di-6'-methoxy-2'-methyl-4'-quinolylpiperazine* (Km. 15).—This compound was obtained when 4-piperazino-6-methoxy-2-methylquinoline (2.5 g.) and 4-chloro-6-methoxy-2-methylquinoline (2 g.) were heated together at 140° for 2—3 hours, or when 4-chloro-6-methoxy-2-methylquinoline (4 g.) and piperazine hydrate (2 g.) were heated under the same conditions as in the preparation of the last compound. In either case, the *base* was obtained as a white solid when a hot aqueous solution of the buff-coloured hydrochloride was made alkaline with caustic soda, the hydrochloride being readily isolated from the reaction mixture on account of its insolubility. The *base* crystallised from hot pyridine in pink rhombohedra, m. p. 286° (Found: C, 72.5; H, 6.5.  $C_{26}H_{28}O_2N_4$  requires C, 72.9; H, 6.5%).

In its sparing solubility in most solvents it resembles very closely 1 : 4-di-2'-methyl-4'-quinolylpiperazine, already described. When its solution in concentrated nitric acid is warmed, however, a dark red coloration quickly develops. Its pale yellow solution in concentrated sulphuric acid exhibits a strong green fluorescence which

disappears on warming, the solution becoming successively pale violet, dark violet, and finally reddish-purple.

The authors desire to express their thanks to the Advisory Council of the Department of Scientific and Industrial Research and to the Trustees of the Carnegie Trust for the Universities of Scotland for a grant and a Research Scholarship, respectively, to one of them (J. F. S.), which have enabled this research to be carried out.

## CLXXVII.—*The Passivity of Metals. Part V. The Potential-Time Curves of Some Iron Alloys.*

By L. C. BANNISTER and ULICK R. EVANS.

PREVIOUS work (Evans and Stockdale, J., 1929, 2651) having shown that those oxide films which give the best protection are the most difficult to remove, it seemed necessary to develop a method of studying the character of such films whilst they were still adhering to the metal. The most promising scheme was based on an examination of time-potential curves similar to those obtained by May (*J. Inst. Metals*, 1928, 40, 141), by McAulay and Bastow (J., 1929, 85), by W. J. Müller and Konopicky (*Monatsh.*, 1929, 52, 463), and by Speller (private communication). Such curves have already been studied by one of us (Evans, J., 1929, 92), but the method employed allowed the liquid to have access to the cut edges of the vertical specimens, causing complications due to shearing stresses and exposure of the interior layers, which in rolled metals may differ physically and chemically from the face; furthermore, the inconveniently rapid movement of the potential made it difficult to obtain early values.

A new method has now been worked out in which specimens are placed horizontally and arranged so that their edges do not come into contact with the liquids. The potential movement is here comparatively slow. An improved method of measuring the potential has also been adopted, and in this way a study has been made of the behaviour of different varieties of iron with or without carbon, copper, nickel, chromium, and molybdenum; a few experiments have also been carried out with aluminium.

### EXPERIMENTAL.

*Materials.*—The iron E 28 and steel H 28 were kindly presented by Dr. W. H. Hatfield and the steels K 1 and K 2 by Mr. Taylerson, of

Pittsburgh, Pa.; K 1 is a typical American copper steel. In considering the analyses given below, it should be remembered that practically all commercial irons contain copper, and that amounts below 0.05% are usually recorded in routine analysis as "traces."

	E 28.	H 28.	K 1.	K 2.
Carbon .....	0.03	0.26	0.055	0.11
Silicon .....	Trace	0.15	0.010	0.010
Sulphur .....	0.005	0.014	0.052	0.037
Phosphorus .....	0.020	0.018	0.078	0.060
Manganese .....	0.04	0.57	0.31	0.51
Copper .....	Nil	0.045	0.187	0.052
Thickness (mm.) .....	0.34	0.32	0.86	0.86

In addition a sample of "Staybrite" steel, an austenitic alloy with 18% of chromium and 8% of nickel, was the gift of Dr. W. H. Hatfield, whilst Mr. J. H. G. Monypenny very kindly provided specimens of the following alloys :

	Cutlery "stainless steel."	"Stainless iron."	"Two- score."	"Anka."	"B.B.4K."
Carbon .....	0.27	0.09	0.12	0.12	0.13
Silicon .....	0.19	0.22	0.40	0.24	0.54
Sulphur .....	0.045	0.033	0.032	0.033	0.052
Manganese ...	0.17	0.19	0.82	0.18	0.13
Chromium ...	13.2	13.6	17.4	15.6	17.2
Nickel .....	0.20	0.36	2.15	10.5	10.1
Molybdenum	—	—	—	—	3.42
Tempering temperature	750°	700°	650°	—	—
Thickness (mm.) .....	2.21	1.66	1.66	2.18	1.19

Of these, "Anka" and "B.B.4K" had been heated to 1000—1050° and air-cooled; the structure was wholly austenitic. The others were "hardenable" steels, softened, after rolling, by tempering at the temperature indicated; these exhibited a duplex structure, with carbide as minute particles distributed in the ferrite.

The aluminium was of two types: (a) electro-refined sheet (soft) with 0.013% of silicon, 0.012% of iron, 0.014% of copper, and 0.004% of titanium, kindly supplied by Mr. E. H. Dix of the Aluminium Company of America, and (b) some soft sheet of British origin containing 0.33% of silicon and 0.40% of iron.

*Procedure.*—The materials E 28 and H 28 were ground with French emery paper No. 1. For the harder materials, grinding on a coarse wheel was necessary. In some cases, this was followed by grinding with successively finer grades of emery, ending with French No. 1; this will be called "sequence-finish." After abrasion they were degreased with carbon tetrachloride. A glass cylinder of 3.5 cm.

diameter and 3 cm. height ( $G$ , Fig. 1), ground flat at the bottom, was cemented on to the metal ( $M$ ) by means of nitrocellulose solution, and the whole was exposed to air for a week, with protection from dust and moisture. The calomel electrode  $C$  and connecting tubes  $T_1$ ,  $T_2$ , and  $T_3$  were then placed in position. The whole was introduced into an outer glass vessel surrounded with a water jacket, itself heavily lagged. This vessel contained a dish of 3*N*-sodium hydroxide—the concentration shown by Mitsukuri (*Sci. Rep. Tōhoku Imp. Univ.*, 1929, 18, 245) to be the most efficient in absorbing traces of acid fumes. In the potassium chloride experiments, all the tubes and vessels contained  $M/10$ -potassium chloride (that in  $C$  and  $T_1$  being saturated with calomel). In the potassium chromate experiments,  $T_2$ ,  $T_3$ , and  $G$  contained  $M/10$ -potassium chromate, whilst saturated potassium chloride was used in  $V$ ; some care was necessary to exclude traces of chloride from  $G$ , or low values were obtained.

FIG. 1.

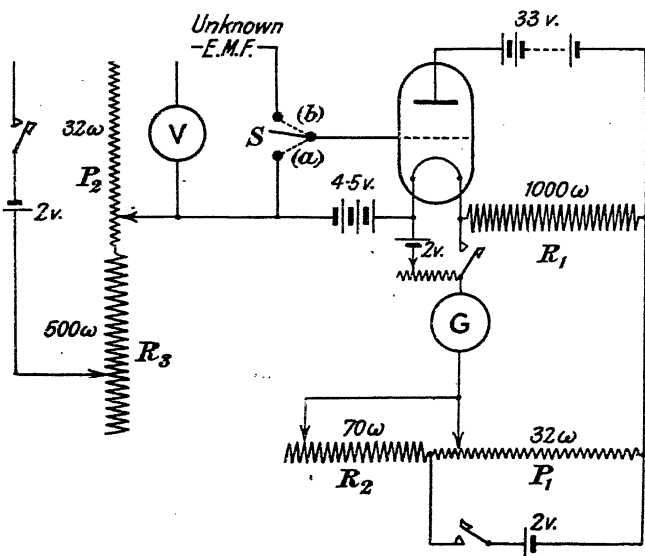

All the tubes and the vessel  $V$  were filled before shutting up the outer vessel, but the liquid was only introduced into  $G$  through a vertical tube at the start of the experiment proper; the depth of the liquid was 1.8 cm. and the bottom of the tubulus was about 1 cm. above the metal.

The arrangement for measuring the potential is shown in Fig. 2. It depends on the principle employed by May (*loc. cit.*), modified to give increased sensitivity; the valve employed was Mullard No. PM 252. When the switch  $S$  is in position ( $a$ ), the grid bias is 4.5 volts, and a small current flows through the anode circuit and causes a fall of potential over the resistance  $R_1$ , producing a deflexion to right or left on the detector  $G$ ; the potentiometer resistance  $P_1$  is adjusted until this deflexion vanishes. A movement of the switch  $S$  into position ( $b$ ) brings the *E.M.F.* to be measured into the grid circuit, and by altering the grid bias, causes again a deflexion on  $G$ . The potentiometer resistance  $P_2$  is then moved until the deflexion on

$G$  is again zero, which will clearly be the case when the potential drop on  $P_2$  is exactly equal and opposite to the  $E.M.F.$  to be measured; this value can then be read directly on the voltmeter  $V$ . Practically no current passes through the experimental cell, even when the apparatus is out of adjustment. The use of the shunt resistance  $R_2$  and the series resistance  $R_3$  was necessary to obtain the required fine adjustment.

FIG. 2.

A list of experiments performed is shown in Table I, together with the general form of the curves, and the value of the (hydrogen scale) potential after 2 hours (it was usually fairly constant after this time); the temperature was  $15^\circ$ . Some of the curves are shown graphically in Figs. 3 and 4. The time scale of the two diagrams is different, and on Fig. 4 it has been necessary to omit some of the early points, but these all lie on the curves. The potentials are expressed on the normal hydrogen scale, and the times measured from the moment of introduction of liquid. The measurements were usually continued for 3 hours. Table I shows that after 2 hours the values reached in duplicate experiments were generally much the same, but there was often rather more discrepancy between the earlier parts of the curves, where the potential was fluctuating in an irregular manner.

*The Significance of the Potential of Film-covered Metal.*—The potential of a metal covered with a discontinuous oxide film will in general be intermediate between the values given by uncoated metal and by solid oxide; the more porous the film is, the nearer will the

potential be to the value for uncoated metal (W. J. Müller, *Monatsh.*, 1929, 52, 221; Evans, J., 1929, 104). With a highly porous film,

FIG. 3.

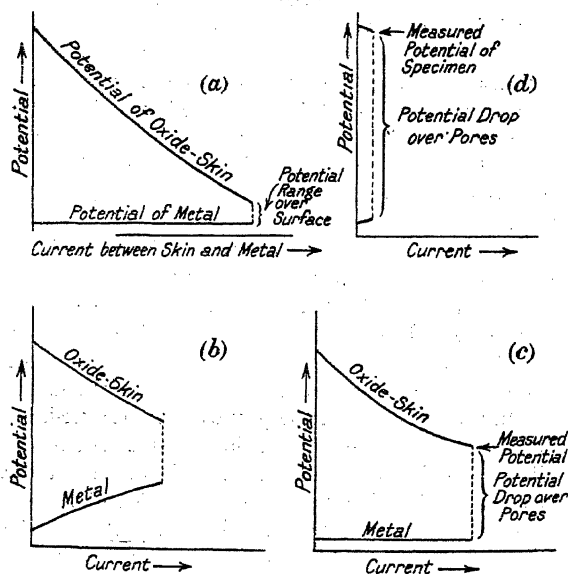

FIG. 4.

the resistance of the short-circuited cell, metal | electrolyte | oxide, will generally be low, and the minute local currents that pass between

the oxide skin as cathode and any accessible metal as anode will be regulated by polarisation, and particularly by the amount of dissolved oxygen (depolariser) reaching the oxide skin. In general, we may expect the potential at the oxide (cathodic) surface to descend with current flowing until it nearly meets the anodic potential, as indicated in Fig. 5(a); the slight difference of potential remaining when the "rest-current" is passing is that needed to force this weak current through the small ohmic resistance of the circuit. In some cases the anode potential may rise to meet the cathodic potential, as in Fig. 5(b).

FIG. 5.

In order to obtain some idea as to whether this is a true picture of the process, an experiment was performed in which, instead of a porous oxide film, a coat of a "noble" metal pierced by a hole was used. A sheet of iron was ground, and covered with a pierced sheet of copper, which was insulated from it with paraffin wax; the whole was covered with  $M/10$ -potassium chloride. The potentials were measured against two calomel electrodes, the tips of the two tubuli being almost in contact with the two metallic surfaces. Whilst electrically insulated, the two metals showed very different potentials (+ 0.083 volt for copper and - 0.102 volt for iron); but when put into electrical contact, the copper potential fell whilst the iron potential rose, so that the whole bi-metallic specimen became

practically equipotential, the value being  $+0.048$  volt at the copper surface and  $+0.043$  volt at the iron. Other experiments confirmed this; the time needed for the mutual approach of the two values varied considerably with the conditions.

The value of the "compromise" potential reached by a bi-metallic system depends on the relative areas of the two metals. An iron sheet was inserted vertically in  $M/10$ -potassium chloride, and the tip of a narrow copper strip was allowed just to touch the liquid. The potential of the iron was  $-0.317$  volt and of the copper  $+0.098$  volt; they were joined, and the copper potential at once fell to  $-0.322$  volt, the value then shown also by the iron. Here the anodic area is large compared with the cathodic area, and only the cathodic polarisation is important. The conditions were then reversed by using a copper sheet and the tip of a narrow iron strip. Here the potentials were  $-0.217$  volt for the iron and  $+0.118$  volt for the copper before the connexion; after short-circuiting, the values moved to  $-0.092$  volt for the iron and  $+0.048$  volt for the copper, whilst 6 minutes later the values were respectively  $-0.057$  and  $-0.037$  volt—a difference of only 20 millivolts.

It has often been assumed that the potential exhibited by a bi-metallic specimen is that of the more reactive metal present; but this is only true provided that, in the short-circuited cell produced, (a) the cathodic greatly exceeds the anodic polarisation, and (b) the resistance is negligible; under such conditions, the cathodic potential will drop almost to the original anodic value. When the anodic area is very small, the rise in the anode potential, as measured, is quite considerable; it is uncertain whether this measured rise is due to a *real* anodic polarisation or to the fact that, when the anodic area is a mere point, a considerable fraction of the ohmic resistance of the circuit falls between the tubulus and the metal, thus causing an "apparent anodic polarisation." In either case the "compromise" potential is not equal to the unpolarised potential of the reactive constituent.

Previous work (Evans, *J. Inst. Metals*, 1928, 40, 121) has shown that when the zinc layer of zinc-covered iron is removed gradually with acid, the potential rises as the area of exposed iron increases; any value between the potential of zinc and the potential of iron is possible for the system. Similarly, when a metal is covered with a porous oxide film, it may show *any* value between the potentials of the clean metal and the solid oxide. If the oxide film is highly discontinuous, the potential measured will be practically that of film-free metal [Fig. 5(a)]. If the cracks in the skin are extremely small, the measured potential will be higher; this is pictured in Fig. 5(b) on the assumption that a true anodic polarisation contri-

butes to the rise in the compromise value, and in Fig. 5(c) on the assumption that the elevation in the measured potential is simply due to the high resistance imposed by the narrowness of the pores. If, when this stage has been reached, the breakdown extends from the original weak points, the potential will fall, first rapidly and then more slowly, as the conditions approach the limiting case pictured in Fig. 5(a); the shutting off of oxygen by secondary corrosion product (e.g., rust) will contribute to the fall. Conversely, if repairing influences prevail, causing the pores to become narrower or less frequent, or rendering the film thicker, the measured potential will rise. The limiting case where the pores vanish and the potential becomes equal to that of a "solid" oxide electrode may not often be reached in practice; Fig. 5(d) suggests the state of affairs just before the pores vanish.

The potential of the metal just after immersion is of special interest. It has been shown by independent methods (Freundlich, Patscheke, and Zocher, *Z. physikal. Chem.*, 1927, **128**, 321; **130**, 289; Evans, J., 1927, 1029) that, in dry air, oxidation of iron commences very rapidly; but since interference colours never appear, even after months, it is evident that the film must quickly become impenetrable to oxygen molecules. If therefore the solution contains nothing more penetrating than oxygen molecules, it should show the oxygen potential, at least at the moment of immersion. Experiments 1 and 3 (Fig. 3) show clearly that, on chromium-free iron, even the initial potential is a comparatively low one. Evidently, the solution contains some constituents more penetrating than oxygen molecules; in the chloride solution, these are no doubt the chlorine ions, which will enter pores in the skin inaccessible to oxygen, and allow anodic attack on the metallic iron, generating ferrous chloride, the corresponding amount of potassium hydroxide being formed at the cathodic (oxide) surface outside. The ferrous chloride and potassium hydroxide will interact to give hydroxides of iron. If the pores are very small (approaching molecular size), the iron hydroxide will be produced at the mouth of the pores practically in contact with the iron, and may easily help to heal the defects in the original skin; thus, in some of the iron alloys where the potential is high at first, the potential actually rises (see Fig. 4, Expt. 28). Where the cracks are considerable at first, however, the iron hydroxide will generally be precipitated at a sensible distance as a loose membrane, which will not be protective; indeed, it may actually stimulate the attack by excluding oxygen. Thus in most of the irons and steels which show low initial potentials, the potential drops with the time (see Fig. 3, Expts. 1 and 3).

It will be noticed that chromium-free iron and steel, which show

falling potentials in chloride solution; show rising potentials in chromate solution (Expts. 8 and 9); here the most penetrating anion present will be the hydroxyl ion, and any anodic attack must lead to the production of ferrous hydroxide, which will be oxidised immediately to ferric hydroxide. Thus a sparingly soluble substance is formed actually in contact with the metal, which will tend to repair the damage, however extensive it may be at the moment of immersion. This explains the rise of potential with time. If chlorides are present as well as chromates (Expts. 5 and 7), the initial potential is much the same as with chromate alone, but it falls with time, instead of rising, soon dropping to a value similar to that given by chloride solution free from chromate. But, whereas a second fall occurs after about an hour in pure chloride solution, this is prevented by the presence of chromates, so that a higher final value is obtained.

It will be noticed that the rôle assigned to chromate, and also to dissolved oxygen, is not to act directly on the exposed metal; it is highly unlikely that either type of molecule could enter pores inaccessible to gaseous oxygen. Their function seems to be to act as cathodic depolarisers at the external surface of the film, thus maintaining the current and causing a flow of anions ( $\text{Cl}'$  or  $\text{OH}'$ ) into the pores, which will produce either repair or extension of the damage, according to circumstances.

*Comparison of the Curves given by Different Materials in M/10-Potassium Chloride.*—The ferrous materials may be divided into three classes :

I. Pure irons and carbon steels, with or without copper, which are rusted freely by "ordinary waters."

II. "Stainless" irons or steels, with about 13% of chromium, which are not rusted by ordinary waters.

III. High-chromium alloys, which resist many chemicals that attack Class II.

It is noteworthy that all the materials of Class I show rather low initial potentials, and the curves fall rapidly, finally reaching values below  $-0.4$  volt. Those of Class II show higher initial potentials, but fall to final values of about  $-0.2$  volt. The resistance alloys of Class III show distinctly higher values, and, in spite of some irregularities in the early stages—doubtless due to local breakdown and subsequent repair—maintain these well. It would seem that, on alloys rich in chromium, the skin formed by the direct action of air can protect the material from the moment it enters the liquid. A comparison between Expts. 26 and 27–28 seems to suggest that molybdenum further improves the quality of the skin, although the two alloys involved have not quite the same chromium content; this accords with measurements of corrosion velocity by Rohn

(*Z. Metallk.*, 1926, 18, 387) and Endo (*Sci. Rep. Tōhoku Imp. Univ.*, 1928, 17, I, 1251).

It was noticed that, in general, those steels which attained a final value above about 0.0 volt gave no rust at the end of 3 hours, whilst those which showed negative potentials produced rust; the "stainless" steels with potentials about -0.2 volt yielded far less rust than the chromium-free steels with potentials about -0.4 volt.

Expts. 12 and 13 (Fig. 4) show that the copper steel (K 1) gives the same type of curve as the ordinary carbon steel low in copper, and although the values in the middle stages appear to be somewhat higher, the final values are about the same. Two comparative experiments with K 1 and K 2 steels (respectively high and low in copper) yielded the same potential after one week; at this time, even removal of the rust and renewal of the liquid only produced a temporary rise in the potential, which at once began to fall again. This accords with the general belief that copper does not directly increase the resistance of steel towards chloride solutions under "immersed" conditions. Copper steels do not belong to the same class as chromium steels, and are not to be regarded as non-rusting or even slow-rusting materials; it is probable that the difference of behaviour of high-copper and low-copper steels shown in atmospheric tests in America (*Proc. Amer. Soc. Test. Mat.*, 1928, 28, I, 151) is due to secondary changes in the rust after its formation, or to redeposition of copper, as indicated by the work of Carius and Schulz (*Mitt. aus dem Forschungs-Inst. der Vereinigte Stahlwerke A. G.*, 1929, 1, 177).

All the materials of Class I show (a) an initial rapid drop, followed by (b) an arrest, (c) a further drop to (d) a final constant value. The second drop (c), well shown in Expts. 1, 12, and 13 (Fig. 4), was perhaps due to the formation at this stage of a definite precipitate of ferric hydroxide which settles on the metal, and definitely shuts out oxygen from certain parts (in the early stages, there is only a colloidal suspension).

The effect of a second phase in favouring a breakdown is well brought out. The curves for steel H 28 descend more rapidly than those for electrolytic iron E 28, although the final value is not very different; this had been noticed for vertical specimens, and accords with the fact—established by laboratory and field tests—that the rusting of electrolytic iron develops less quickly than that of steel, although when once started it proceeds quite readily. Likewise, the curve for stainless iron with 0.09% of carbon stands above that for outlery stainless steel with 0.27%; this agrees with the superior resistance to corrosion of the former material. Under comparable

surface conditions, the homogeneous (austenitic) alloys yield higher curves than the duplex (hardenable) materials.

It is well known that a smooth or polished surface often remains passive where a rough surface is corroded. This is entirely in harmony with the exceptionally high value given by polished "Staybrite"—as compared with other surface treatments. Similarly, the curves yielded by electrolytic iron when prepared by abrasion on the wheel show a far more rapid descent than when prepared with French emery No. 1, whilst "Two-score" also gives lower values when prepared on the wheel alone than when afterwards finished with French emery No. 1. A comparison of Expts. 29—32 with 33—36 indicates that the latter finish develops a more resistant film than a wire-brushed surface.

A comparison of the potentials obtained with "Staybrite" after various preliminary treatments (Expts. 29—37) has some interest. Owing to the difficulty of reproducing "abrasive conditions" with this material, a 10 cm. square plate of the material was uniformly wire-brushed, and cut into four quarters, one being used in each of the four experiments 29—32; another sheet was subjected to the "sequence" of abrasive treatments, and its four quarters were used in Expts. 33—36. The curves obtained accorded generally with the known facts that (1) annealing at 500—900° lowers the resistance by causing the precipitation of a second phase, and possibly by producing a thick oxide film, which is visible, easily removed, and therefore non-protective; (2) pre-treatment with nitric acid raises the resistance of alloys of this class (Hatfield, *J. Iron Steel Inst.*, 1923, 108, 123). It should be noticed, however, that the rise of potential after nitric acid treatment, although marked for "Staybrite" both on wire-brushed and "sequence-finished" specimens, is not obtained with stainless steel finished on the coarse wheel (Expts. 18—21). The unexpectedly high value found in Expt. 35 was probably due to the fact that the thick oxide film was very easily removed from the specimen, and left a surface much smoother than the originally abraded surface.

The curves obtained with aluminium all lie very close together, in spite of differences of purity and abrasion. Although there is a slight tendency to rise in the case of the less pure variety, all the curves are nearly horizontal, in contrast with those previously obtained with specimens placed vertically, which rose rapidly (J., 1929, 106). In the case of the latter specimens, the early attack was practically confined to the water-line and cut edges, and the aluminium hydroxide was evidently precipitated at the mouth of the pores in close contact with the metal, since it gave fine rings of interference colours; any hydroxide thus precipitated would tend to heal up the weak

spots in the skin, accounting for the marked rise in potential. In the new experiments, where the water-line and cut edges are excluded, this action is evidently much slower, especially with the highly pure variety, and the potential is nearly constant.

Evidently the observed potential does not indicate the rate of corrosion; steel and aluminium give almost the same final potentials, and yet the steel is far more quickly corroded. When the shape of the potential-time curve is considered along with the "normal electrode potential" of the metal, however, the information obtained is consistent with the results of corrosion-velocity measurements and, indeed, more extensive. For steel shows at first a comparatively high value, which soon sinks to a value probably representing the potential of unprotected metal; but the potential measured for aluminium is always far above the theoretical value for this metal without a protective film, and tends to rise rather than fall with the time.

*Composition of the Protective Oxide Film.*—In previous work (Evans, J., 1927, 1020; Evans and Stockdale, J., 1929, 2651) it was shown definitely that the protective oxide film, after separation from passive iron, consisted of ferric oxide (or perhaps, in part, hydroxide) with some metallic inclusions. Bancroft, however, has written (private communication, July 3rd, 1927) that "electromotive-force measurements preclude the possibility of the film being  $\text{Fe}_2\text{O}_3$ . If one postulates that the film consists of an unstable, higher oxide, adsorbed by iron, the higher oxide would break down to  $\text{Fe}_2\text{O}_3$  as soon as you dissolve off the stabilizing iron backing." He urges that the film, as analysed, has not the composition of the film as actually present on the passive iron. Similar views have been expressed by Hale (*J. Physical Chem.*, 1929, 33, 1637).

Undoubtedly, iron rendered passive by anodic treatment has at first a high potential, due to the oxygen supercharge, which may be present as an unstable higher oxide; but Smits ("Theory of Allostropy," p. 351, Longmans Green and Co., 1922) has found that, on standing, the potential sinks with a marked arrest at about  $+0.54$  volt (hydrogen scale); presumably, if the original high value is due to a higher oxide, the arrest represents ferric oxide. Since the iron is still passive during the arrest, it would seem that a higher oxide is not necessary for passivity.

However this may be, it is clear from Table I and Fig. 3 that iron rendered passive in potassium chromate never reaches the high potentials referred to by Bancroft. Indeed, higher values than this were obtained in some experiments where crystals of natural haematite or even magnetite were used instead of a metallic specimen. Not too much importance should be attached to these measure-

ments, since the crystal could not be wholly immersed, and the measurements of the hæmatite varied from end to end, possibly owing to the zonal variation of oxygen content described by Sosman and Hostetter (*Trans. Amer. Inst. Min. Met. Eng.*, 1917, **58**, 409, 434). Actually the work of these authors, and also that of Smits and Bijvoet (*Proc. K. Akad. Wetensch. Amsterdam*, 1919, **21**, 386), Pfeil (*J. Iron and Steel Inst.*, 1929, **119**, 501), and others has shown that ferric oxide is merely a member of a range of solid solutions. Numerous observations make it doubtful whether the electrode potential can be used—as claimed by Bancroft—to estimate the oxygen content of a solid phase, and the method is particularly unsatisfactory when the phase is an oxide film backed by metal, which is probably not inaccessible to the liquid. But if Bancroft is justified in accepting the potential as evidence, it would seem that the oxide present on iron rendered passive by simple exposure to chromate or air has *not* a higher oxygen content than is represented by the formula  $\text{Fe}_2\text{O}_3$ .

*Summary.*

A new method has been worked out for obtaining potential-time curves, and has been applied in a study of the behaviour of iron, iron alloys and aluminium, after various abrasive, chemical and thermal treatments, in chloride and chromate solutions. The results given correspond to the behaviour of the film, a rising potential indicating that weak points are being repaired, and a falling potential that the breakdown is extending. A high final potential indicates immunity from attack, a middle value slight rusting, and a low value profuse rusting. Treatments known to increase the resistance to attack raise the potential, and those favouring corrosion lower the potential. The character of the curves probably indicates the "liability to corrosion" rather than the velocity of corrosion when fully developed, and gives information regarding the protective character of the skin, which velocity measurements cannot afford.

We wish to acknowledge the generosity of the Salters' Institute of Industrial Chemistry which has enabled this work to be carried out. We are also indebted to Dr. W. A. Wooster for the loan of the hæmatite crystals.

CLXXVIII.—*The Mechanism of, and Constitutional Factors controlling, the Hydrolysis of Carboxylic Esters. Part III. The Calculation of Molecular Dimensions from Hydrolytic Stability Maxima.*

By CHRISTOPHER KELK INGOLD.

AN important consequence, implicit in the results of modern work on homogeneous catalysis, is the removal, at least for catalysis by acids and bases, of the barrier between the conceptions which formerly were often applied on the one hand to catalysed reactions and on the other to reactions independent of catalysis: since the velocity of a catalysed reaction is affected by the catalyst according to the same laws as those which would apply to an ordinary reactant, it is clearly advantageous to regard the catalyst as occupying the status of an ordinary reactant, for example, in Brønsted's theory of reaction-dynamics (*Z. physikal. Chem.*, 1922, **102**, 169). On this view, a reaction becomes a catalysed reaction when, of the various ways in which the critical complex might decompose, that in which it actually decomposes leads to the formation, as one product, of a substance identical with one of the reactants. Having regard both to modern views on the dynamics of reactions in solution, and to recent work on homogeneously catalysed reactions, the formation of a critical complex between an ester group and a catalyst may, without inevitable commitment to any precise constitutional inference, justifiably be regarded as the initial process in the hydrolysis of a carboxylic ester.

Any general discussion of the factors controlling the speed of hydrolysis of an ester by a catalyst must include consideration of (a) statistical requirements, (b) polar influences, (c) steric factors, and (d) effects due to the medium.

(a) *Statistical Requirements.*—Count must be taken of statistical requirements when either the ester or the catalyst has alternative seats of reaction, but discussion will here be restricted to cases in which the existence of alternative reactions is due solely to the constitution of the ester.

The formulation of statistical effects on the relative rates of the successive stages in the hydrolysis of a polycarboxylic ester by a single catalyst at constant temperature may be effected by consideration of a compound with  $s$  ester groups so situated that the hydrolysis of each proceeds independently of the others. In general, the probability that a catalyst molecule or ion will form a complex with a particular ester group will, for constitutional reasons, be different for each ester group. Let  $v_i$  be the catalytic coefficient for the

partial reaction consisting of the hydrolysis of the  $g$ th group in the first stage of hydrolysis, and let  $k_n$  be the total catalytic coefficient for the  $n$ th stage. Then  $k_1 = \Sigma v_g$ , where the summation extends from 1 to  $s$ . In order to calculate  $k_2$ , two points must be noted; the first is that, since the fraction of the total quantity of ester which passes on to the second stage of hydrolysis through the  $g$ th first-stage product is  $v_g/\Sigma v_g$ , the contribution to  $k_2$  made by the hydrolysis of the  $h$ th ester group in this product is  $v_g v_h/\Sigma v_g$ ; the second is that the  $s$  first-stage products yield  $s(s-1)/2$  second-stage products, each of the latter being formed from two of the former. It follows that  $k_2 = 2\Sigma v_g v_h/\Sigma v_g$ , where the summations extend from 1 to  $s$  as before, except that  $h$  is excluded from identity with  $g$ . Generalising, it is seen that each of the  ${}^s C_n$  products of the  $n$ th stage of hydrolysis is formed in  $n$  ways, and that  $k_n = n\Sigma v^{(n)}/\Sigma v^{(n-1)}$ , where  $\Sigma v^{(n)}$  is the sum of all the products of  $n$  different  $v$ 's, so that, in particular  $\Sigma v^{(1)} = \Sigma v_g$  and  $\Sigma v^{(0)} = 1$ . The statistical relation between the velocities of any two stages is therefore

$$\frac{k_m}{k_n} = \frac{m \Sigma v^{(m)} \cdot \Sigma v^{(n-1)}}{n \Sigma v^{(m)} \cdot \Sigma v^{(m-1)}} \quad (1)$$

In the special case of a dicarboxylic ester, for which  $s = 2$ ,  $m = 1$ , and  $n = 2$ , equation (1) becomes

$$k_1/k_2 = (v_1 + v_1)^2/2v_1v_2 \quad (2)$$

Furthermore, if the dicarboxylic ester is symmetrically constituted, so that  $v_1 = v_2$ , this equation reduces to

$$k_1/k_2 = 2 \quad (3)$$

The application of equations (2) and (3) may be illustrated by reference to data by J. Meyer (*Z. physikal. Chem.*, 1909, **66**, 81) for the acid hydrolysis of five dicarboxylic esters (Table I).<sup>\*</sup> In the case of methyl camphorate  $v_1$  and  $v_2$  were independently determined by direct observation on the isomeric methyl hydrogen camphorates.

TABLE I.

Meyer was the first empirically to observe that the ratios  $k_1/k_2$  for the two-stage acid hydrolysis of symmetrical dicarboxylic esters

<sup>\*</sup> As to units, see footnote in Part I (this vol., p. 1032).

are often closely grouped about the value 2. Wegscheider (*Monatsh.*, 1915, **36**, 471) discussed the dynamical significance of this relation, noting especially that it is a peculiarity of the value 2 that the complete reaction may be represented by an integrated equation of one of the simple forms applicable to a single-stage process. Meyer's result shows clearly that, when carbomethoxyl or carbethoxyl groups are separated by a saturated chain of at least two carbon atoms, the speed of hydrolysis of each group is very nearly independent of the state of hydrolysis of the other; but this approximation would be expected to hold less exactly for malonic and oxalic esters and for completely conjugated unsaturated esters (e.g., fumaric, phthalic) owing to the intramolecular transmission of polar effects; and departures are also to be expected amongst esters of higher alcohols and compounds with endocyclic ester groups (e.g., adipodilactone) owing to spatial influences. Since later workers have usually side-stepped the accurate determination of the coefficients for the consecutive stages by regarding a more or less imperfect conformity with Wegscheider's simplified formulæ as sufficient indication that  $k_1/k_2$  is in the neighbourhood of 2, it is not yet known to what degree of approximation Meyer's result is applicable to the classes of esters mentioned. There are indications (Palomaa, *Ann. Acad. Scient. Fennicæ*, 1917, **4**, **10**, No. 16; Skrabal, *Monatsh.*, 1917, **38**, 29) that it is at least approximately applicable to oxalic and malonic esters as well as to their higher normal homologues.

Meyer noticed (*Z. physikal. Chem.*, 1909, **67**, 257) that equation (3) does not even roughly represent the alkaline hydrolysis of symmetrical dicarboxylic esters, and, indeed, this is apparent from the still earlier work of Knoblauch (*ibid.*, 1898, **26**, 96), whose coefficients for ethyl succinate bear the ratio 9.4, and of Goldschmidt and Scholz (*Ber.*, 1903, **26**, 1333), whose values for ethyl malonate give the ratio 88. Meyer remarked that this notable difference between acid and alkaline hydrolysis is probably connected with the fact that in the latter case the ester which undergoes the second stage of the reaction is an ion.

(b) *Polar Effects*.—Influences arising from the polar characteristics of the ester and catalyst may be propagated to the seat of reaction both externally (through the medium-filled space) or internally (through the linkings), and in both cases an ionic centre, if present, will dominate the situation. In the commonly employed ionic catalysts the pole itself is the reactive centre, but in esters which are also ions the pole is necessarily separated from the seat of reaction, and it is for this case, therefore, that the *propagation* of the effect of the pole requires consideration. Furthermore,

internally propagated polar effects become very small after transmission through more than two single linkings (Gane and Ingold, J., 1929, 1692, and cited references); it is therefore evident that a large class of cases must exist in which the externally propagated polar effect is for practical purposes the sole polar influence.

A basis for the calculation of the externally propagated effect is available in several well-known theoretical investigations—*e.g.*, Langevin's calculations relating to a paramagnetic gas, Debye and Hückel's treatment of the effect of interionic attraction on the activity of strong electrolytes, and especially Bjerrum's investigation of the problem presented by the strengths of polybasic acids—the common feature of all of which is the employment of Boltzmann's law. Consider two esters which are identical in all respects, except that, in some position X, the second ester has a univalent positive or negative charge not possessed by the first ester; and suppose that these esters are being hydrolysed at the same temperature by the same catalyst, which also possesses a univalent positive or negative charge. The catalytic coefficients,  $k'$  and  $k''$ , of the two reactions may for the present be assumed (see Section *d*, however) to be proportional to the mass-action rates of formation of the corresponding critical complexes :

The external molecular electric field of the first ester will render the local concentration of  $\text{Z} \oplus$  in the neighbourhood of the ester group different from its macrochemical concentration, and this will be one of the ways in which the effect exerted by polar influences on the rates of hydrolysis of esters (compare Part I, this vol., p. 1032) enters into the determination of the velocity coefficient. The external electric field of a molecule of the second ester may be regarded as equal to that due to an identically placed molecule of the first ester *plus* the radial field of a unit positive charge situated at X. This being so, Boltzmann's theorem shows that the ratio of the local concentration of  $\text{Z} \oplus$  in reaction (II) to its local concentration in reaction (I) is  $\exp(-WN/JRT)$ , where  $W$  is the work done *against the radial field alone* when  $\text{Z} \oplus$  is brought from a great distance to the focus of reaction,  $N$  is Avogadro's number, and  $J$  is the mechanical equivalent of heat. If  $r$  is the distance between the unit charge at X and the focus of reaction,  $W$  is equal to  $\pm e^2/\epsilon r$ , where  $e$  is the charge of an electron,  $\epsilon$  is the dielectric constant of the medium, and the upper or lower sign is taken according as the signs of the charges on X and Z are like or unlike. With  $e = 4.774 \times 10^{-10}$ ,  $\epsilon = 80.0$ ,  $N = 6.06 \times 10^{23}$ ,  $J = 4.19 \times 10^7$ ,  $R = 1.985$ , and  $T =$

298, the exponent has the value  $\mp 6.97 \times 10^{-8}/r$ ; and since the ratio of the local concentrations is also the ratio of the rates of formation of the critical complexes,\*

$$k'/k'' = \exp(\pm 6.97 \times 10^{-8}/r) \approx \exp(\pm 7/10^8 r) \quad (4)$$

If it is legitimate to assume that in the anion of a partly hydrolysed polycarboxylic ester the external field of each carboxylate ion can, at all distances greater than that of the nearest unhydrolysed ester group, be represented as the vector sum of that of a similarly situated carboxylic ester group and that of a superposed electron, equation (4) may be used to take count of the effect, on each stage after the first in the alkaline hydrolysis of polycarboxylic esters, of externally propagated polar fields: in these reactions the catalyst is a negative ion, and each stage of hydrolysis introduces a new negative charge into the ester molecule. Introduction of the requisite modification into equation (1) gives the relation

$$\frac{k_m}{k_n} = \frac{m \sum \{v^{(m)} \rho^{(nC_2)}\} \cdot \sum \{v^{(n-1)} \rho^{(n-1)C_2}\}}{n \sum \{v^{(n)} \rho^{(nC_2)}\} \cdot \sum \{v^{(m-1)} \rho^{(m-1)C_2}\}} \quad (5)$$

where  $\rho$  is written for  $\exp(-6.97 \times 10^{-8}/r)$ ,  $\rho^{(nC_2)}$  is the product of the  ${}_nC_2$  values of  $\rho$  corresponding with the  ${}_nC_2$  distances,  $r$ , between  $n$  ester groups taken in pairs, and brackets  $\{\}$  signify that the product of each group of  $v$ 's is to be multiplied by the corresponding  $\rho$ -product before summation. The equation for the ratio of the velocities of the stages of hydrolysis of a dicarboxylic ester is obtained from (5) by writing  $s = 2$ ,  $m = 1$ , and  $n = 2$ ; and remembering that if  $n < 2$  then  $\rho^{(nC_2)}$ , being the product of zero  $\rho$ 's, is unity:

$$\frac{k_1}{k_2} = \frac{(v_1 + v_2)^2}{2\rho v_1 v_2} = \frac{(v_1 + v_2)^2}{2v_1 v_2} \exp\left(\frac{6.97 \times 10^{-8}}{r}\right) \quad (6)$$

For the special case of a symmetrically constituted dicarboxylic ester,  $v_1 = v_2$ , and equation (6) reduces to

$$k_1/k_2 = 2/\rho = 2 \exp(6.97 \times 10^{-8}/r) \approx 2 \exp(7/10^8 r) \quad (7)$$

Table II contains all the recorded *direct* measurements of the coefficients characterising the catalysis by hydroxide ions of the consecutive stages of hydrolysis of esters of dicarboxylic acids (some measurements on hydrolysis in alkaline buffer solutions are also available and these are considered in Section *d*). The data here tabulated refer to eleven esters of seven normal dicarboxylic acids. The experimental values of  $k_1$  and  $k_2$  are given in cols. 3 and 4, and all relate to the temperature  $25^\circ$  except the two indicated by asterisks for which the temperature is  $22.7^\circ$ . Cols. 5 and 6 contain the values

\* The activity correction, which is here neglected, is considered in Section (*d*).

of  $k_1/k_2$ , which are seen to be nearly identical for methyl and ethyl esters of the same acid. Col. 7 shows the values of the distance,  $r$ , between the carboxyl groups (*i.e.*, between the charge developed on one carboxyl group and the focus of reaction at the other) as calculated from equation (7). It will be seen (a) that the distances are of the right order of magnitude (1–20 Å.U.), (b) that they place the compounds in the order of the length of the carbon chain, (c) that, having regard to the difference of method, they are in fair general agreement with the distances obtained by Gane and Ingold for the corresponding free acids (J., 1928, 1594); these distances are given in the last column for comparison.

† Calculated by Gane and Ingold from data by Auerbach and Smolczek.

In explanation of the approximate values for the oxalic esters, it should be stated that the only directly determined value is  $k_2$  for the methyl ester; for this the value 92 was found, but the time intervals were so short that the second figure is not significant. The same ester was also hydrolysed in carbonate buffers and from these experiments an apparent value of  $k_2$  can be calculated and compared with the directly observed value. This comparison then affords the means of estimating the true value of  $k_2$  for ethyl oxalate from the apparent values derived from similar measurements in buffers. Of the values of  $k_1$  for methyl and for ethyl oxalate, all that can be said is that they are of the order of a million and that  $k_1$  is about three times as great for the methyl as for the ethyl ester. All the other values of  $k_1$  and  $k_2$  recorded in the table represent direct determinations.

The preceding calculations neglect the internally propagated effect of the carboxylate pole, and this is expected to make the calculated

distances for oxalic and malonic esters too small; a similar error would probably affect completely conjugated unsaturated esters, such as maleic, fumaric, phthalic, and terephthalic esters, although none of these has as yet been investigated by the direct method (compare Section *d*, however); internally propagated effects should be entirely negligible in esters higher than succinic esters (Gane and Ingold, J., 1928, 1691). Furthermore, the catalytic ion has been treated as a point-charge, whereas any actual ion must become dipolarised as it approaches the charged ester molecule; this effect is expected to render the calculated distances too large throughout the series considered, and solvation, including pole-dipole association, is a form of dipolarisation which it would be necessary to envisage in any complete discussion of this disturbance. It should also be pointed out that no account has explicitly been taken of the circumstance that even in alkaline solution the electrically neutral alkyl hydrogen ester must exist as such to a minute extent, and that part of the second stage of alkaline hydrolysis of dicarboxylic esters must proceed through this form. The error due to this cause is very easy to evaluate, but it is entirely negligible in all the cases for which the writer has made the appropriate calculation; there is no point, therefore, in encumbering the equations with terms intended to eliminate this effect.

(c) *Steric Hindrance*.—It is necessary now to give attention to the circumstance that the whole of the space in the neighbourhood of a reacting centre is not *free* space in the sense envisaged by the kinetic theory, on which Boltzmann's theorem depends; in short, the effect of steric hindrance must be considered.

A basis for the discussion of this influence is furnished in Part I of this series (this vol., p. 1032) in which it was shown that velocities of hydrolysis can be represented as a simple function of polarity on the assumption that the effect of steric hindrance on the catalytic coefficients is expressible as the product of two factors *C* and *S* respectively dependent on the catalyst alone and the ester alone: if *p* is a catalytic coefficient (it was called *k<sub>p</sub>* in Part I), which is corrected in such a way as to be independent of the variability of the purely steric influences which affect in different degrees the hydrolysis of each of a series of esters by each of a series of catalysts, then the uncorrected catalytic coefficient *k* is equal to *CSp*. Reverting to reactions (I) and (II), and introducing suffixes to indicate the sign of *Z*, the preceding relation shows that

$k'_+ = C_+S'p'_+$ ,  $k''_+ = C_+S''p''_+$ ,  $k'_- = C_-S'p'_-$ ,  $k''_- = C_-S''p''_-$ ,  
and that, consequently,

$$\frac{k'_+/k''_+}{k'_-/k''_-} = \frac{p'_+/p''_+}{p'_-/p''_-} \dots \dots \dots (8)$$

From the foregoing it will be clear that the  $k$ -ratio on the left hand side of equation (4) should really be a  $p$ -ratio, wherefore, having regard to equation (8), the equation which takes account of both polar and steric influences may be written

$$\frac{k'_{-}/k'_{+}}{k''_{-}/k''_{+}} = \exp(\mp 13.94 \times 10^{-8}/r) \approx \exp(\mp 14/10^8 r) \quad (9)$$

where the upper or lower sign of the exponent is taken according as the charge on X is positive or negative in reaction (II).

In applying equation (9) to the stage-wise hydrolysis of a polycarboxylic ester, the assumption must be made that the space occupied by a carboxylate ion is equal to that filled by an undissociated carboxyl group, or at least, that it differs therefrom by a much smaller amount than that by which it differs from the space occupied by an esterified carboxyl group. Introduction of the appropriate modification into equation (5) gives the equation

$$\frac{k_{m-}/k_{n-}}{k_{m+}/k_{n+}} = \frac{\sum \{v_{-}^{(m)} \rho^{(m)C_2}\} \cdot \sum \{v_{-}^{(n-1)} \rho^{(n-1)C_2}\} \cdot \sum v_{+}^{(m)} \cdot \sum v_{+}^{(m-1)}}{\sum \{v_{-}^{(n)} \rho^{(n)C_2}\} \cdot \sum \{v_{-}^{(m-1)} \rho^{(m-1)C_2}\} \cdot \sum v_{+}^{(m)} \cdot \sum v_{+}^{(n-1)}} \quad (10)$$

For a dicarboxylic ester equation (10) reduces to the simple form

$$\frac{k_{1-}/k_{2-}}{k_{1+}/k_{2+}} = \frac{v_{1+}v_{2+}(v_{1-} + v_{2-})^2}{\rho v_{1-}v_{2-}(v_{1+} + v_{2+})^2} \quad (11)$$

The equation for a symmetrically constituted dicarboxylic ester is obtained from (11) by equating  $v$ 's of like suffix-sign. For hydrolysis by hydrogen and hydroxyl ions the equation is

$$\frac{(k_1)_{\text{OH}}/(k_2)_{\text{OH}}}{(k_1)_{\text{H}}/(k_2)_{\text{H}}} = \frac{1}{\rho} = \exp(6.97 \times 10^{-8}/r) \approx \exp(7/10^8 r) \quad (12)$$

This is the equation from which the values of  $r$  given in col. 7 of Table II were originally calculated; but since, to the accuracy with which  $(k_1)_{\text{H}}/(k_2)_{\text{H}}$  is known for the esters of oxalic acid and its normal homologues, this ratio has the value 2.0 (Palomaa), the figures are identical with those obtained from the simpler, but less theoretically defensible, equation (7).

It is not theoretically necessary that *both* the stages in the hydrolysis of a dicarboxylic ester should be investigated in order that  $r$  may be calculated: a suitable study of the second stage of hydrolysis, that is, of the hydrolysis of the acid ester only, would enable equation (9) to be directly applied. The case of acid esters is strictly comparable with that of amino-esters, and, since both forms represent the simplest types of *ionogenic* esters, they may be considered together. It can readily be shown that the curve connecting the velocity of hydrolysis of an acid ester with the hydrion concentration should,

after effects due to any buffers employed have been eliminated (Part II, this vol., p. 1039), correspond to the equation

$$v = \left\{ [H]v' \left( \frac{[H]}{H'} + \frac{H'}{[H]} \right) + K_a v'' \left( \frac{[H]}{H''} + \frac{H''}{[H]} \right) \right\} / 2(K_a + [H]) \quad (13)$$

Similarly the curve for the hydrolysis of a basic ester should be represented by the equation

$$v = \left\{ K_w v' \left( \frac{[H]}{H'} + \frac{H'}{[H]} \right) + K_b [H] v'' \left( \frac{[H]}{H''} + \frac{H''}{[H]} \right) \right\} / 2(K_w + K_b [H]) \quad (14)$$

In these equations  $K_a$  and  $K_b$  are the so-called affinity constants of the acid and base respectively, and  $K_w$  is the ionic product for water. The four quantities,  $H'$ ,  $H''$ ,  $v'$ , and  $v''$ , are constants which have to be determined from the velocity data themselves, and the significance of the first two of these is that they are the hydron concentrations at which the neutral and charged species respectively would show a velocity minimum if conversion into the other form could be prevented. Denoting the corresponding  $p_H$ 's by  $p_H'$  and  $p_H''$ , and remembering the general relation  $\log(k_{OH}/k_H) = -2p_H^* - \log K_w$ , where  $p_H^*$  is the  $p_H$  of maximal hydrolytic stability, the appropriate application of equation (9) gives

$$p_H' - p_H'' = \pm 3.03 \times 10^{-8}/r \approx \pm 3/10^8 r. \quad (15)$$

where the sign must be chosen to correspond with that of the charge developed on the ionogenic ester.

Suitable data for the evaluation of both  $p_H'$  and  $p_H''$  by the application of equations (13) and (14) are not yet available, but in the case of ethyl aminoacetate data leading to an approximate value for  $p_H''$  are on record; the figure thus obtained is not very accurate owing to the absence of data permitting the elimination of buffer effects. The value of  $p_H'$  cannot be similarly obtained, but, in accordance with the principles discussed in Part I (*loc. cit.*), it may be interpolated between the values of  $p_H^*$  for ethyl propionate and ethyl glycollate, both of which are accurately known; the probable uncertainty attending this procedure is unlikely to be much greater than that which relates to the directly measured value of  $p_H''$  in the absence of a correction for buffer effects, and is of the order of 0.1  $p_H$  unit. There is a small difference in the temperatures to which  $p_H'$  and  $p_H''$  apply, but it is negligible in the circumstances. These data are assembled in Table III, and it will be seen that the distance  $r$  for  $\text{NH}_3^+ \cdot \text{CH}_2 \cdot \text{CO}_2 \text{Et}$  is practically the same as for  $\text{CO}_2^+ \cdot \text{CH}_2 \cdot \text{CO}_2 \text{Et}$  ( $1.8 \times 10^{-8}$  cm.); owing to the structural similarity both values are probably subject to the same disturbances.

(d) *Effects due to the Medium.*—Consideration has not yet been given to possible disturbances due to the medium. The expected disturbances are of two kinds.

(1) The dielectric constant of water containing both electrolytes and non-electrolytes will only be approximately equal to that of pure water even at the considerable dilutions to which the measurements in Table II relate; the non-electrolytic solutes would tend to decrease the constant, whilst the electrolytes might decrease it or increase it according to their concentration (Debye). The consideration of this effect involves no new principle and an appropriate correction could readily be introduced if the requisite data were available.

(2) For solutions of considerable ionic strength, the relation,  $v = kC_A C_B$ , hitherto used, requires a correction which, according to Brønsted (*loc. cit.*), is represented by  $f_A f_B / f_{AB}$  in the equation  $v = kC_A C_B f_A f_B / f_{AB}$ . This equation shows that, whilst the simpler equation should be valid for the hydrolysis of neutral esters by ions, the velocity of ion-catalysed hydrolysis of ionic esters will increase or decrease with increasing ionic strength ( $\mu$ ) according as the charges on the reactants are like or unlike in sign. In the second stage of the hydrolysis of a dicarboxylic ester the charges are of like sign, and hence the velocity should increase with increasing ionic strength. In order to show that this effect is not negligible, Table IV is appended, the data in which are taken from Skrabal and Singer's published results.

TABLE IV.

$\text{NaO}_2\text{C}\cdot(\text{CH}_2)_2\cdot\text{CO}_2\text{Me}$	$\text{NaOH}$	—	0.004	2.8
"	"	—	0.032	3.4
"	"	—	0.040	3.9

Now, assuming for the moment that only univalent anions are under consideration, the formulæ already developed for the ratio,  $k_1/k_2$ , obtaining in the two-stage hydrolysis of a dicarboxylic ester,

show that this ratio should be independent of the nature of the catalysing anion, provided that the concentration is so low that the ionic-strength disturbance is negligible. This condition is very approximately fulfilled in the hydrolysis with sodium hydroxide for which the ionic strength is 0.01 or less; but when buffer solutions are employed the ionic strength is usually of the order 0.1—1.0. In the complete hydrolysis of a dicarboxylic ester in alkaline buffers, the first stage escapes the ionic-strength effect, but the second stage is subject to it, and thus the values of  $k_1/k_2$  obtained by the use of buffers are rendered too low. Against this must be set the circumstance that some small part of the total hydrolysis will undoubtedly be effected, not by hydroxide ions, but by the buffer anions themselves, and if these are more than univalent—and carbonate-bicarbonate buffers have usually been employed—the higher valency will create an effect tending to make  $k_1/k_2$  too large. The general conclusion must, therefore, be that little reliance can be placed on anything but the order of magnitude of this ratio when it is deduced from experiments with buffers; nevertheless, in order to complete the survey of existing relevant data, the values of the ratio, which are deduced from measurements with carbonate-bicarbonate buffers, are given in Table V for those esters which have been studied in this way. The values of  $r$  calculated from equation (7) are in the last column. When data become available for the activity coefficients of the electrolytes and the catalytic coefficients of the buffer anions, it should be possible to correct these values; in the meantime it is seen that, where comparison can be made with  $r$ -values based on direct determinations of the  $k$ -ratio, the agreement is poor to moderate. A clear illustration of the importance of the ionic-strength effect appears in the values for methyl *d*-tartrate and methyl racemate, for the hydrolysis of which carbonate-bicarbonate buffers of two concentrations have been employed; it will be noticed that when the ionic strength at the commencement of reaction is increased from about 0.05 to about 0.5, the value of  $k_1/k_2$  falls by 30%.

Finally it may be pointed out, first, that since the maleic and fumaric esters were hydrolysed by buffers of similar concentration, the error in  $r$  caused by ionic-strength effects is probably similar in both cases, and, secondly, that, although, as explained in Section (b), internally transmitted polar effects will make the  $r$ -values too small, the type of conjugation which gives rise to this result is the same for both esters, wherefore the disturbances will probably be nearly the same. Since a little further consideration readily shows that the necessary corrections, which although unknown are presumed to be nearly equal, would be represented by *factors*, and not differences, it follows that the ratio,  $r_{\text{fumaric}}/r_{\text{maleic}}$ , should be subject, certainly to

TABLE V.

less error than are the separate  $r$ 's, and probably to a small error only. It is seen from the table that this ratio is 1.45. Now the same ratio can readily be calculated from the molecular model on the basis of certain assumptions. The assumptions which seem best to conform to existing knowledge of the structures and reactions involved are as follows : (1) The distance between the centres of singly linked carbon atoms is 1.52 Å.U., that is, the value obtaining both for the diamond and for the distance between nuclear and side-chain carbon atoms in hexamethylbenzene. (2) The distance between the centres of doubly linked carbon atoms is 1.35 Å.U., this value being adopted on the ground that the aromatic ortho-distance given by X-ray measurements on graphite and hexamethylbenzene probably approximates to the mean of the distances characteristic of singly and doubly linked atoms. (3) Since the carboxyl group is a symmetrical prototropic system, the charge is symmetrically distributed in the carboxylate ion, and its centre of gravity is therefore at the bisection of the line joining the centres of the oxygen atoms, that is, about 0.7 Å.U. from the carbon centre in line with the carbon-carbon bond. (4) In *alkaline* hydrolysis the attack is at the surface of the carbon atom, the mean focus being about 0.7 Å.U. from the carbon centre in line with the carbon-carbon bond. (5) The angle between the directions of the single linkings of an ethenoid carbon atom is 120° (compare Beesley, Ingold, and Thorpe, J., 1915, 107, 1080). On the basis of these assumptions, the ratio  $r_{\text{fumaric}}/r_{\text{maleic}}$  should be 1.47, and almost any reasonable modification of them leads to values between 1.4 and 1.5.

CLXXIX.—*Conversion of Hydroaromatic into Aromatic Compounds. Part IV. The Influence of the Nitro-group in Nitrophenyldihydroresorcinols.*

By LEONARD ERIC HINKEL and JOHN FREDERICK JAMES DIPPY.

5-m-Nitro- and 5-p-nitro-phenyldihydroresorcinols exhibit properties in common with all dihydroresorcinols, but show a marked difference in their action with the chlorides of phosphorus.

Neither of the nitrophenyldihydroresorcinols reacts with phosphorus trichloride in the usual manner, whereas alkyl- and aryl-substituted dihydroresorcinols yield the corresponding chloro-ketone derivatives with both phosphorus trichloride and phosphorus oxychloride (Crossley and Haas, J., 1903, **83**, 494; Crossley and Le Sueur, *ibid.*, p. 110; Crossley and Pratt, J., 1915, **107**, 191; Boyd, Clifford, and Probert, J., 1920, **117**, 1383).

Phosphorus oxychloride is without action upon *m*-nitrophenyldihydroresorcinol, but yields with the *p*-nitro-compound a small amount of 3 : 5-dichloro-1-*p*-nitrophenyl- $\Delta^{2:4}$ -cyclohexadiene.

Phosphorus pentachloride acts upon *m*-nitrophenyldihydroresorcinol to give 3 : 5-dichloro-1-*m*-nitrophenyl- $\Delta^{2:4}$ -cyclohexadiene together with a small quantity of 3 : 5-dichloro-3'-nitrodiphenyl. In order to effect reaction four molecular proportions of the pentachloride are required instead of the usual two.

The low reactivity of the nitrophenyldihydroresorcinols towards the chlorides of phosphorus may be attributed to the recognised electron-affinity of the nitro-group, since, in any hydroxyl compound, intramolecular electron-attraction (*a*) must oppose the separation of hydroxyl (*b*), just as it assists the separation of hydrogen (*c*) :

The powerful electron-affinity of the nitro-group is also shown by the great readiness with which the nitrobenzaldehydes condense with acetone: our preparative work has convinced us that the order of facility of the condensation of benzaldehydes with acetone is *m*- and *p*-nitro-  $\gg$  methoxy- and chloro-  $>$  unsubstituted benzaldehyde. The position of the nitro-compounds in this sequence is again attributable to the electron-affinity of the nitrophenyl group, since the accepted theory of the aldol reaction involves in its application to the present cases the addition of an anion to aromatic carbonyl carbon.

The effect of the nitrophenyl group upon the properties of the dichlorohexadienes shows no very marked difference from that of

the phenyl group. The chlorination of 3:5-dichloro-1-*m*-nitrophenylcyclohexadiene yields 3:5-dichloro-3'-nitrodiphenyl and 2:3:5(?)-trichloro-3'-nitrodiphenyl (compare Hinkel and Hey, J., 1928, 2786). However, in contrast with the case of the phenyl compound, where trichlorodiphenyl is formed with excess of chlorine in hot solution, the formation of the trichloro-3'-nitrodiphenyl is favoured at low temperature.

The constitution of 3:5-dichloro-3'-nitrodiphenyl has been established by reduction to the amino-derivative and oxidation of this to 3:5-dichlorobenzoic acid.

#### EXPERIMENTAL.

*m*-Nitrobenzylideneacetone.—The method described by Baeyer and Becker (*Ber.*, 1883, **16**, 1969) has been so modified as to need redescription. 0.1*N*-Sodium hydroxide (150 c.c.) was added below 0° to a solution of *m*-nitrobenzaldehyde (30 g.) in acetone (300 c.c.) and the mixture was shaken for 20 minutes, slightly acidified, and evaporated. The orange-coloured liquid residue (probably the aldol intermediate compound) was heated for  $\frac{1}{2}$  hour at 100° with concentrated hydrochloric acid (0.5 c.c.): from a hot alcoholic solution of the dehydrated product, on cooling, *m*-nitrobenzylideneacetone separated in pale yellow needles (25 g.), m. p. 102° (Vorländer, *Annalen*, 1897, **294**, 291, records m. p. 96°) (Found: C, 62.3; H, 4.7. Calc.: C, 62.8; H, 4.7%).

5-*m*-Nitrophenyldihydroresorcinol.—By condensing *m*-nitrobenzylideneacetone with ethyl malonate by Vorländer's method (*loc. cit.*), ethyl *m*-nitrophenyldihydroresorcyate was obtained, m. p. 169° (decomp.); Vorländer records m. p. 163° (Found: C, 59.1; H, 5.15. Calc.: C, 58.8; H, 5.2%).

A solution of the ester (20 g.) in 4% aqueous sodium hydroxide (400 c.c.) was boiled for 5 minutes and cooled, and dilute hydrochloric acid added until the solution became faintly acid; on stirring, a dark brown impurity separated. The filtered solution was boiled with excess of hydrochloric acid until the liberation of carbon-dioxide ceased. The brown solid which separated yielded, on crystallisation from aqueous acetone, 5-*m*-nitrophenyldihydroresorcinol in small plates (14 g.), m. p. 188° (decomp.) (Found: C, 61.8; H, 4.8.  $C_{12}H_{11}O_4N$  requires C, 61.8; H, 4.7%).

5-*p*-Nitrophenyldihydroresorcinol.—The condensation of *p*-nitrobenzylideneacetone with ethyl malonate was conducted in the usual manner and the hydrolysis of the dihydroresorcyate produced was as described above. The solid product when crystallised from aqueous acetone yielded 5-*p*-nitrophenyldihydroresorcinol in faintly brown plates, m. p. 190–191° (decomp.), containing  $1H_2O$  (Found:

C, 57.2; H, 5.2;  $\text{H}_2\text{O}$ , 7.4.  $\text{C}_{12}\text{H}_{11}\text{O}_4\text{N}\cdot\text{H}_2\text{O}$  requires C, 57.2; H, 5.2;  $\text{H}_2\text{O}$ , 7.2%).

*Action of Phosphorus Oxychloride on p-Nitrophenyldihydroresorcinol.*—A suspension of *p*-nitrophenyldihydroresorcinol (5 g.) in dry chloroform (13 c.c.) was mixed with 10 c.c. of phosphorus oxychloride and heated on a water-bath for 2 hours. The chloroform was then removed, and the residue poured into water and extracted with ether. From the extract, washed with sodium hydroxide solution and with water and dried, a small quantity of 3 : 5-dichloro-1-*p*-nitrophenyl- $\Delta^{2:4}$ -cyclohexadiene was obtained, which crystallised from aqueous alcohol in colourless prisms, m. p.  $81^\circ$  (Found : Cl, 26.1.  $\text{C}_{12}\text{H}_9\text{O}_2\text{NCl}_2$  requires Cl, 26.3%).

*Action of Phosphorus Pentachloride on m-Nitrophenyldihydroresorcinol.*—*m*-Nitrophenyldihydroresorcinol (30 g.; 1 mol.) was suspended in dry chloroform (80 c.c.), phosphorus pentachloride (90 g.; 4 mols.) gradually added in the cold, and the mixture heated for  $1\frac{1}{2}$  hours. The chloroform was removed under reduced pressure, and the residue poured on ice and extracted with ether. From the washed and dried extract, 3 : 5-dichloro-1-*m*-nitrophenyl- $\Delta^{2:4}$ -cyclohexadiene was obtained, which crystallised from aqueous alcohol in short colourless needles, m. p.  $66\text{--}68^\circ$  (Found : Cl, 26.3%), together with a small quantity of 3 : 5-dichloro-3'-nitrodiphenyl, m. p.  $162^\circ$  (Found : Cl, 26.35.  $\text{C}_{12}\text{H}_7\text{O}_2\text{NCl}_2$  requires Cl, 26.4%). The separation of the two compounds was effected by fractional crystallisation from methyl alcohol, in which the latter is less soluble.

3 : 5-Dichloro-3'-acetamidodiphenyl.—3 : 5-Dichloro-3'-nitrodiphenyl (0.9 g.), dissolved in alcohol (10 c.c.), was reduced with stannous chloride (3.3 g.) in absolute alcohol (12 c.c.) saturated with hydrogen chloride. The mixture was heated for 1 hour and, after evaporation, excess of sodium hydroxide was added and the base was extracted with ether. It was obtained as a thick oil, from which, by warming with acetic anhydride, 3 : 5-dichloro-3'-acetamidodiphenyl was prepared; this crystallised from aqueous alcohol in colourless plates, m. p.  $168^\circ$  (Found : N, 5.0.  $\text{C}_{14}\text{H}_{11}\text{ONCl}_2$  requires N, 5.0%).

*Oxidation of 3 : 5-Dichloro-3'-aminodiphenyl.*—The oil obtained by the reduction of 3 : 5-dichloro-3'-nitrodiphenyl was dissolved in the minimum quantity of glacial acetic acid and heated under reflux with a solution of chromic anhydride in acetic acid. Further additions of chromic anhydride were made until oxidation was complete. On addition of water, 3 : 5-dichlorobenzoic acid, m. p.  $183\text{--}185^\circ$  after crystallisation from aqueous methyl alcohol, separated.

*Action of Chlorine on 3:5-Dichloro-1-m-nitrophenyl- $\Delta^{2:4}$ -cyclohexadiene.*—(1) *At a low temperature.* Chlorine (1.6 g.; 1 mol.) was passed into a solution of 3:5-dichloro-1-m-nitrophenyl- $\Delta^{2:4}$ -cyclohexadiene (6 g.; 1 mol.) in dry chloroform (16 g.) below 0°. The residue obtained after rapid removal of the chloroform solidified in a vacuum over solid sodium hydroxide and was crystallised from alcohol, 3:5-dichloro-3'-nitrodiphenyl (2.5 g.) being obtained in fine colourless needles which, alone or mixed with the aromatic compound obtained from the phosphorus pentachloride reaction, melted at 162°.

(2) *In excess at a low temperature.* Chlorine was slowly passed into a solution of 3:5-dichloro-1-m-nitrophenyl- $\Delta^{2:4}$ -cyclohexadiene (6 g.) in dry chloroform (25 c.c.) kept at -10°. When chlorine was no longer absorbed, the chloroform was removed and the residue allowed to stand in a vacuum. The sticky mass obtained was dissolved in hot alcohol; on cooling, 2:3:5(?)-trichloro-3'-nitrodiphenyl separated, and after crystallisation from alcohol was obtained as fine colourless needles, m. p. 116° (Found: Cl, 32.0.  $C_{12}H_6O_2NCl_3$  requires Cl, 35.2%). The low chlorine value is probably due to the presence of a small quantity of 3:5-dichloro-3'-nitrodiphenyl.

(3) *In excess at room temperature.* Chlorine was passed into a solution of 3:5-dichloro-1-m-nitrophenyl- $\Delta^{2:4}$ -cyclohexadiene (6 g.) in dry chloroform (16 c.c.) until the copious evolution of hydrogen chloride had ceased. After removal of chloroform and standing in a vacuum, the residue solidified. Crystallisation from alcohol yielded 3:5-dichloro-3'-nitrodiphenyl, m. p. 162°.

The authors wish to express their indebtedness to Imperial Chemical Industries for a grant which partly defrayed the cost of this investigation.

UNIVERSITY COLLEGE, SWANSEA.

[Received, April 2nd, 1930.]

## CLXXX.—*The Alkaloids of Ergot. Part I.*

By SYDNEY SMITH and GEOFFREY MILLWARD TIMMIS.

It is probably true that no drug of vegetable origin has been more often investigated than ergot and this is not surprising in view of the importance of the drug in medical practice. The earlier researches, which extend backward for more than a century, dealt with undoubtedly impure preparations and the first important advance was made by Tanret (*Compt. rend.*, 1875, **81**, 896), who isolated a pure crystalline alkaloid, ergotinine, which he regarded

as the physiologically active principle. This view of ergotinine was not generally accepted, and for knowledge of the physiologically active alkaloid of ergot we are indebted to the researches of Barger, Carr, and Dale, who at the British Association meeting in 1906 announced the isolation of an amorphous alkaloid, ergotoxine, having the pharmacological effects characteristic of ergot, and to Kraft (*Arch. Pharm.*, 1906, **244**, 336), who independently and almost simultaneously described the same alkaloid under the name hydro-ergotinine. Barger and Carr (*J.*, 1907, **91**, 337) subsequently gave a detailed description of the chemical characteristics of ergotoxine and its salts, and the physiological effects of the alkaloid were fully described by Dale (*Biochem. J.*, 1907, **2**, 240 and elsewhere).

It was shown by Kraft and by Barger and Carr that ergotoxine and ergotinine are interconvertible and by Dale that ergotoxine has an intense physiological activity whereas ergotinine is comparatively inactive. It therefore created considerable interest when Spiro and Stoll (*Verh. Schweiz. Nat. Ges.*, 1920, abstracted in *Ber. ges. Physiol.*, 1921, **8**, 349 and *Chem. Zentr.*, 1921, III, 889—890) described two alkaloids, ergotamine and ergotaminine, which were also interconvertible and one of which, ergotamine, had a much greater biological activity than the other. Moreover, the methods which effected the interconversion of ergotoxine and ergotinine were the same as those which caused the interconversion of ergotamine and ergotaminine. It seemed probable, therefore, that ergotoxine and ergotamine, if not identical, must be closely related, a view which received support when it was shown by Dale and Spiro (*Arch. exp. Path. Pharmacol.*, 1922, **95**, 377) that ergotoxine and ergotamine had the same physiological action not only qualitatively but quantitatively. The identity of pharmacological action was fully confirmed by the subsequent work of Rothlin (*ibid.*, 1928, **138**, 115), Burn and Ellis (*Pharm. J.*, 1927, **64**, 384), and others.

Similarly, some years ago we began an investigation with the object of establishing the chemical identity of ergotoxine and ergotamine or alternatively of more clearly distinguishing the two alkaloids, since the recorded differences were not striking and might possibly be due to variations in the purity of the material used by the respective workers, particularly as ergotoxine had hitherto been obtained only in an amorphous condition.

Ergotoxine can now be obtained in beautifully crystalline form as an additive compound with benzene or its simple homologues (Wellcome Foundation Ltd., and G. M. Timmis, B.P. 286,400), or by crystallisation from carbon disulphide. Crystallisation from such solvents takes place very readily and affords an easy method of purification. The sharp definition of the crystals and the constant

specific rotation leave no doubt concerning the purity of the substance. Ergotoxine cannot according to our experience be crystallised from other solvents and in this respect shows a pronounced difference from ergotamine, which crystallises with great ease from a number of solvents. For the purpose of comparison we have prepared all four alkaloids in a state of purity. The evidence afforded by the crystalline form, specific rotation, solubilities and melting points shows quite clearly that the four alkaloids are definite and distinct substances.

Spiro and Stoll in their publications lay stress on the "protective" methods of extraction devised by Stoll (D.R.-P. 257,272), who suggests (*Naturwiss.*, 1923, **33**, 705) that the failure of other workers to obtain ergotamine may have been due to the use of commercial ergots containing little or no ergotamine either because they were old and deteriorated or because they were originally poor therein, but that the chief cause appeared to have been the use of insufficiently protective methods of extraction.

Our experience, on the contrary, has been that the isolation of the alkaloids may be effected satisfactorily by ordinary methods of alkaloid extraction such as that of Kraft (*loc. cit.*). Stoll's process consists essentially in treating the drug with a solution of a weakly acidic substance such as aluminium sulphate, ferrous sulphate, ferric chloride or copper sulphate. The acid material is freed from extractive matter by treatment with a solvent such as benzene or ether. The alkaloid is then set free by treatment with an alkali and extracted with ether or benzene or similar solvent. It is difficult to agree that such a process is less likely to cause decomposition of the alkaloids than the process of Kraft, which consists in extracting the drug with ether, extracting the alkaloids from the ethereal solution with a weak acid such as citric acid, and precipitating the alkaloids from the slightly acid extract by means of a base. In our experience it is immaterial as far as the nature of the alkaloid is concerned whether the alkaloids are prepared by the method of Kraft or by the processes described by Stoll.

During the past few years we have examined many commercial specimens of ergot from Spain, Portugal, Russia, Poland, Scandinavia, Hungary, and Czecho-Slovakia, all of which gave ergotoxine and ergotinine and these alkaloids only. These ergots were all obtained from rye which is the variety used traditionally in medicine and is officially specified by the pharmacopoeias.

Ergot grows on other *Gramineae* besides rye and we therefore examined some of the unofficial ergots. This part of the investigation is at present incomplete, as these varieties of ergot are difficult to procure. We have, however, been able to obtain three specimens

*Ergotinine.*

*Ergotoxine.*

*Ergotaminine.*

*Ergotamine.*

of the ergot growing on tall fescue (*Festuca*), which were collected in New Zealand in 1927, 1928 and 1929. Two of them gave excellent yields of ergotamine, but the third contained comparatively little alkaloid. These ergots were extracted by the method of Kraft.

These results suggest that the isolation of ergotamine and ergotaminine depends not on the special methods of extraction upon which Stoll lays so much stress but upon the nature of the ergot.

In our experience ergot of rye gives ergotoxine and ergotinine only and in this we confirm the results of Tanret, who isolated ergotinine, and of Barger and Carr and of Kraft, who isolated both alkaloids.

Barger and Carr suggested the formulæ  $C_{35}H_{41}O_6N_5$  and  $C_{35}H_{39}O_5N_5$  for ergotoxine and ergotinine, and Spiro and Stoll assigned the formula  $C_{33}H_{35}O_5N_5$  to ergotamine and ergotaminine. Although we have made many analyses of these alkaloids and their salts, we have not succeeded in finding conditions which give completely satisfactory results. Previous workers have experienced this difficulty also and we prefer to reserve a discussion of the composition and inter-relationship of the four alkaloids until these difficulties have been overcome or until we have been able to prepare degradation products which will throw light upon this question.

#### EXPERIMENTAL.

*Isolation of Ergotoxine and Ergotinine.*—The mixed crude alkaloids were prepared from ergot by the method of Kraft (*loc. cit.*), the average yield being 0.1 to 0.15%. The crude alkaloid is treated with methyl alcohol, which dissolves ergotoxine and leaves most of the ergotinine undissolved. The solution of ergotoxine with some ergotinine may then be purified by taking advantage of the different solubilities of the sulphates (Kraft), or purification may be effected by preparing the phosphate (Barger and Carr, *loc. cit.*). The ergotinine residue is readily purified by crystallisation from dilute alcohol.

Ergotoxine was usually prepared from the phosphate by triturating the salt with water and sodium bicarbonate. The mixture was extracted with ether, and the extract evaporated to dryness. The solid residue was dissolved in hot benzene, from which it readily crystallised on cooling in six-sided prisms containing 21% of benzene and having a specific rotation  $[\alpha]_{5461}^{19} = -179^\circ$  and  $[\alpha]_{5790}^{19} = -156^\circ$  ( $c = 1$  in chloroform). Ergotoxine can be crystallised from toluene, the xylenes and mesitylene and separates in each case associated with the solvent, which can be removed by very prolonged drying at  $90^\circ$  in a vacuum. The solvent-free residue has a specific rotation  $[\alpha]_{5461}^{18} = -226^\circ$  and  $[\alpha]_{5790}^{20} = -197^\circ$  ( $c = 1$  in chloroform). Ergot-

oxine is sparingly soluble in carbon disulphide and separates in stout prisms on the spontaneous evaporation of a solution in this solvent. It is insoluble in light petroleum, sparingly soluble in ether, and very soluble in methyl and ethyl alcohol, chloroform and acetone and ethyl acetate, but does not crystallise from these solvents. When an acetone solution is diluted with water, the base separates in an amorphous condition (distinction from ergotamine, which crystallises readily under these conditions). The amorphous base is hygroscopic. The dry substance when placed in a bath at 170° and slowly heated begins to soften at 180° (corr.) and melts very indefinitely between 190° and 200°. It is readily soluble in 1–3% aqueous sodium hydroxide solution but insoluble in sodium carbonate solution.

Ergotinine was most readily purified by crystallisation from hot alcohol containing from 10–50% of water. It crystallised in long, thin, glistening, colourless prisms, free from solvent. It has  $[\alpha]_{5461}^{19} = +513^\circ$ ,  $[\alpha]_{5790}^{19} = +435^\circ$  ( $c = 1$  in chloroform). It is insoluble in light petroleum, very sparingly soluble in pure ether, sparingly soluble in acetone and in methyl and ethyl alcohols, easily soluble in benzene and chloroform. The dry substance when placed in a bath at 200° and slowly heated melts and decomposes at 239° (corr.) after preliminary darkening. Barger and Carr (*loc. cit.*) record decomposition points up to 229° (corr.), but, as pointed out by these authors, the decomposition point is not very characteristic. Ergotinine is insoluble in solutions of alkaline hydroxides or carbonates.

*Isolation of Ergotamine and Ergotaminine.*—The mixed crude alkaloids were prepared from *Festuca ergot* in the same manner as ergotoxine and ergotinine from ergot of rye. The crude alkaloid was treated with three parts of methyl alcohol, which dissolved ergotamine and left a residue of ergotaminine. The methyl-alcoholic extract was diluted with five volumes of ether, and the solution extracted with aqueous citric acid. The acid extracts on basification with sodium carbonate gave a precipitate of ergotamine.

Ergotamine may be purified by preparing the phosphate. The base is dissolved in 10 parts of dry acetone and treated with a solution of phosphoric acid in acetone. The phosphate separates in a semi-crystalline condition and may be recrystallised or converted into the base by treatment with ether and sodium bicarbonate. Ergotamine crystallises readily from aqueous acetone in long rectangular plates containing solvent or less readily from benzene in small needles. It is insoluble in light petroleum, less soluble than ergotoxine in benzene, chloroform and ether, and easily soluble in nitrobenzene and pyridine. The dry substance has specific rotation

$[\alpha]_{5461}^{20} = -181^\circ$  and  $[\alpha]_{5790}^{20} = -159^\circ$  ( $c = 1$  in chloroform). When placed in a bath at  $205^\circ$  and slowly heated, the dry substance melts fairly sharply and decomposes at  $213\text{--}214^\circ$  (corr.) after softening and darkening. It is soluble in a dilute solution of sodium hydroxide but insoluble in aqueous sodium carbonate. Ergotamine isolated from commercial ergotamine tartrate crystallised in the same form as the alkaloid isolated from *Festuca ergot* and after recrystallisation had an identical specific rotation and m. p.

Ergotaminine was prepared by the crystallisation of the crude residue obtained as above. It crystallises from alcohol, acetone, nitrobenzene and ether, pyridine and water, chloroform, and light petroleum. It separates from alcohol in the characteristic thin triangular plates free from solvent as described by Spiro and Stoll or in five-sided plates as illustrated. It is practically insoluble in light petroleum, sparingly soluble in benzene, toluene, methyl and ethyl alcohols, acetone and ethyl acetate, fairly readily soluble in chloroform and nitrobenzene, and easily soluble in pyridine. It has specific rotation  $[\alpha]_{5461}^{18} = +450^\circ$  and  $[\alpha]_{5790}^{18} = +385^\circ$  ( $c = 0.5$  in chloroform). When placed in a bath at  $240^\circ$  and slowly heated, it melts and decomposes at  $252^\circ$  (corr.). It is insoluble in dilute solutions of alkaline hydroxides or carbonates.

Our thanks are due to Mr. A. C. McDougall, B.Sc., and Mr. E. L. Kendrick for the preparation of the photomicrographs which illustrate this paper.

[Received, April 30th, 1930.]

# CLXXXI.—*The Development of a Novel Form of Isomerism in the Sugar Series. Part II. The Third Variety of Tetra-acetyl Methylmannoside.*

By HAROLD GRAHAM BOTT, WALTER NORMAN HAWORTH, and EDMUND LANGLEY HIRST.

THE discussion opened in Part I of this series dealing with the third variety of triacetyl methylrhamnoside (Haworth, Hirst, and Miller, J., 1929, 2469) has now been extended to the anomalous or third variety of tetra-acetyl methylmannoside. The facts are that three forms of tetra-acetyl methylmannoside exist as crystalline substances, and have the following properties (Dale, J. Amer. Chem. Soc., 1924, 46, 1046):

	$\alpha$ -Form.	$\beta$ -Form.	" $\gamma$ "-Form.
M. p. ....	$65^\circ$	$161^\circ$	$105^\circ$
$[\alpha]_D$ in chloroform .....	$+49.1^\circ$	$-46.8^\circ$	$-26.6^\circ$

In discussing the three corresponding triacetyl methylrhannosides we were able to recognise all of them as six-atom ring forms of pyranosides. It will now be shown that the  $\alpha$ -,  $\beta$ -, and " $\gamma$ "-forms of tetra-acetyl methylmannoside are also six-atom ring forms, and there arises the question of how the existence of these three modifications can be reconciled with existing views on stereoisomerism in the sugar group. The proof of the constitution of tetra-acetyl  $\alpha$ -methylmannoside was developed in an earlier communication (Goodyear and Haworth, J., 1927, 3136), and a similar proof of the pyranose structure of tetra-acetyl  $\beta$ -methylmannoside has been completed and will be published soon.

The third or " $\gamma$ "-variety of tetra-acetyl methylmannoside possesses several unique features, the most important of which is that three of the acetyl groups are eliminated by contact with cold alkali but the fourth acetyl group is resistant to hydrolysis even with hot alkali. We have submitted the monoacetyl methylmannoside (prepared by an alternative procedure to that given by Levene and Sobotka, J. Biol. Chem., 1926, 67, 771) to a close investigation, and have found that it behaves in a similar manner to the monoacetyl methylrhannoside which has already been discussed in Part I of this series. On re-acetylation it passes again to the " $\gamma$ "-tetra-acetyl methylmannoside, so there can have been no profound change of structure during the partial de-acetylation process. The monoacetyl methylmannoside (I) gave on methylation *monoacetyl trimethyl methylmannoside* (II). The acetyl group in this substance also exhibits the same resistance towards alkaline reagents that was observed in the original tetra-acetate. It is evident that the monoacetyl trimethyl derivative retains the essential structure of the " $\gamma$ "-tetra-acetyl methylmannoside, a conclusion which is further supported by the ease of hydrolysis of the mannosidic methyl group in either compound with *N*/100-acid in the cold. The trimethyl derivative (II) loses both the mannosidic methyl group and the acetyl group with 2% acid at 100° and yields a crystalline trimethyl mannose which we have designated 3:4:6-*trimethyl mannopyranose* (III), a sugar which gives rise on oxidation to *d*-3:4:6-trimethyl  $\delta$ -mannonolactone (IV), m. p. 96–97°,  $[\alpha]_D + 167.5^\circ$  (in water)  $\rightarrow 110^\circ$ . The corresponding *l*-form (V) of this lactone has already been synthetically prepared by Haworth and Peat from *l*-trimethyl arabofuranose (VI) (J., 1929, 350), and has the same melting point, and the same magnitude of rotation but opposite in sign. From the *d*-lactone the phenylhydrazide of *d*-3:4:6-trimethyl mannonic acid was prepared, and this again has the same m. p. as that of the phenylhydrazide of the *l*-acid obtained by Haworth and Peat. Since the constitution of the

1-3 : 4 : 6-trimethyl  $\delta$ -mannonolactone has been proved both by the method of synthesis and by its conversion into the tetramethyl  $\delta$ -mannonolactone, it will be clear that the *d*-isomeride which has now been isolated must be a six-atom ring form and recognisable under the nomenclature assigned to it in this discussion.

A confirmation of the pyranose structure of the 3 : 4 : 6-trimethyl mannose was developed in the following way. By further methylation the sugar was converted into the crystalline 2 : 3 : 4 : 6-tetramethyl  $\beta$ -methylmannoside (VII) which, in a subsequent publication, will be shown to be capable of hydrolysis to 2 : 3 : 4 : 6-tetramethyl mannopyranose, yielding the characteristic crystalline anilide.

It may be added that the 3 : 4 : 6-trimethyl mannose was crystallised as an  $\alpha$ -form mutarotating from  $[\alpha]_D = +21^\circ \rightarrow 8.2^\circ$ . The rate of hydrolysis of the derived *d*-3 : 4 : 6-trimethyl  $\delta$ -mannonolactone (IV) was studied and was in full agreement with the values observed by Haworth and Peat (*loc. cit.*) for the *l*-isomeride, but with the sign of rotation reversed. Not only so, but the rate of hydrolysis is comparable with that of *d*-tetramethyl  $\delta$ -mannonolactone (Drew, Goodyear, and Haworth, J., 1927, 1237).

From these experiments it is inferred that the monoacetyl methyl-mannoside (I) has the constitution of a six-atom ring form, and that the acetyl group is situated at position 2 of the mannose ring. It is therefore to be formulated as a 2-acetyl derivative of methyl mannopyranoside, and not as a four-atom ring structure as represented by C. S. Hudson (*J. Amer. Chem. Soc.*, 1926, 48, 1434). The unique behaviour associated with this substance is, however, not explained by this simple formulation, since the tetra-acetyl mannoside from which it was derived differs widely in behaviour from the  $\beta$ -tetra-acetyl methylmannoside, in that from the latter the acetyl group at

position 2 is readily eliminated by hydrolysis along with the other three acetyl groups. There is, therefore, some special character associated with the acetyl group at position 2 in the third variety ("γ") of tetra-acetyl methylmannoside, and it is this remarkable feature which must now receive explanation.

When the above "γ"- or third variety of tetra-acetyl methylmannoside was submitted to methylation with silver oxide and methyl iodide, containing also sodium hydroxide, the product obtained was mainly monoacetyl trimethyl methylmannoside (II) which, on hydrolysis with dilute acid, gave a high yield of crystalline *d*-3 : 4 : 6-trimethyl mannopyranose (IV). On the other hand, the use of excessive quantities of methyl sulphate and alkali effected the replacement of all the acetyl residues by methyl groups, and yielded a mixture of α- and β-forms of tetramethyl methylmannopyranoside from which tetramethyl mannopyranose was afterwards isolated by hydrolysis, and characterised as the crystalline anilide of the latter sugar. The behaviour of the "γ"- or third variety of tetra-acetyl methylmannoside during methylation with these reagents was characteristic. The solution became very dark during the final heating at 100°, and the yield of product was only 40%. Under similar conditions the α- and β-forms of tetra-acetyl methylmannoside give yields which are practically theoretical.

It became evident that, although the replacement of all the four acetyl groups occurred when the "γ"-variety was submitted to this treatment, yet the darkening in colour of the solution was evidence of the intermediate formation of a free sugar, represented by the removal of the mannosidic methyl group simultaneously with the hydrolysis of the acetyl residues. This methyl residue appears to be labile also in contact with dimethylamine and methyl alcohol at 100°.

Still another characteristic feature which clearly differentiates the third or "γ"-variety of the tetra-acetyl or monoacetyl methylmannoside is the ease with which the mannosidic methyl group is hydrolysable with acids of extreme dilution. This property was also remarked upon in the earlier paper dealing with the corresponding rhamnoside. The conclusion there reached was that the resistant acetyl group, which is situated at carbon atom 2 of the pyranose ring, is obstructed by the β-methyl group of the mannoside, and by the proximity of the acetyl group at position 3. It was stated, in the case of the rhamnoside, that this phenomenon might be explicable on the view of the co-ordination of one of the acetoxyl residues with the neighbouring group, and that it was clearly evident that there was restricted movement of the groups attached to carbon atoms, 1, 2, and 3. We suggested as a tentative hypo-

thesis the existence of a strainless ring, which admitted of the interlocking of the groups at carbon atoms 1, 2, and 3.

Simultaneously with the work on this problem we have also been conducting an investigation on the transposition or wandering of acetyl residues in the glucose series, and the following paper illustrates the views which we have been led to adopt as an explanation of this phenomenon. The hypothesis introduced by Fischer that the wandering of acyl residues is accompanied by the intermediate formation of an ortho-carbonic ester type of grouping appears to receive confirmation in the case we have studied, and a similar conception of the existence of an ortho-carbonic ester linking seems to us to apply also to the examples of the third or " $\gamma$ "-varieties of triacetyl methylrhamnoside and tetra-acetyl methylmannoside. The adoption of this view involves both a structural and a stereochemical explanation. The existence of these anomalous compounds, and also the special properties associated with the resistant acetyl group at position 2 in both the rhamnoside and the mannoside, appear to receive a complete explanation from the conclusion that the interlocking of groups at this point in the structure is occasioned by the superposition on the pyranoside structure of a five-atom ring associated through the linking of the groups at carbon atoms 1 and 2.

It must be clearly recognised that the formation of these obstructed forms of methyl-rhamnoside and -mannoside occurs, so far as is at present known, only when the triacetyl rhamnosidyl bromide or tetra-acetyl mannosidyl bromide is submitted to the action of an alcohol in the presence of a base. They do not appear to be formed

by more direct methods. The following scheme may therefore be suggested to explain the mode of formation of these compounds.

(Since it is known that  $\alpha$ -glucosidyl bromides yield  $\beta$ -methylglucosides, a process involving a Walden inversion, the bromine atom is here formulated for the sake of clearness as a  $\beta$ -configuration.)

The alternative view that the resistant acetyl residue is located at position 5 of the rhamnose or mannose chain, and that the sugar ring attaches at positions 1 and 2, has not escaped our consideration. But this alternative is rendered very improbable if only for the fact that a mere change of reagent from quinoline to silver carbonate, in the transformation from the bromide to the rhamnoside, produces a substantial yield of the ordinary unobstructed form of triacetyl  $\beta$ -methylrhamnoside to which has been allocated the pyranose structure.

This formulation for the third varieties of the rhamnoside and mannoside as ortho-carbonic ester derivatives would seem also to provide a reason for the ease with which they undergo hydrolysis with dilute acid when compared with the much greater resistance of the  $\alpha$ - and  $\beta$ -forms to these reagents.

During the preparation of the present paper for the press a communication was received from Professor Freudenberg informing us that he had reached, independently, the same conclusion as ourselves as to the structure herein assigned to the " $\gamma$ "-triacetyl methylrhamnoside, and that a preliminary note by Freudenberg and Braun on this subject was to appear in *Naturwissenschaften*, May 1, 1930.

## EXPERIMENTAL.

*Preparation of "γ"-Monoacetyl Methylmannoside.*—Penta-acetyl mannose was obtained as a liquid containing both the α- and the β-form by treating mannose with acetic anhydride and pyridine at 0° for 4 days. The product was isolated by the method used by Haworth, Hirst, and Miller (*loc. cit.*) for rhamnose tetra-acetate. Tetra-acetyl mannosidyl bromide was then prepared from the liquid penta-acetyl mannose and was converted into "γ"-tetra-acetyl methylmannoside by Dale's method (*loc. cit.*). The latter substance was repeatedly crystallised from ether until it had m. p. 104°, and  $[\alpha]_D^{20} = 27^\circ$  in chloroform, in agreement with the constants recorded by Dale.

The following method was found to be more convenient than the one given by Levene and Sobotka (*loc. cit.*) for the transformation of "γ"-tetra-acetyl methylmannoside into monoacetyl methylmannoside. A solution of the former substance in an excess of *N*/2-alcoholic sodium hydroxide was kept at 0° for 16 hours. After neutralisation by carbon dioxide the solution was filtered and then evaporated to dryness under diminished pressure at 40°. The residue was extracted several times with cold ethyl acetate. Removal of the solvent under diminished pressure at 40° left a viscid syrup, which was obtained as a hygroscopic powder after prolonged drying in a vacuum (yield, 72% of the theoretical).  $[\alpha]_D^{20} = 6^\circ$  (c, 0.83 in water) (Found: C, 46.0; H, 7.1; OMe, 11.2. Calc. for  $C_9H_{16}O_7$ : C, 45.8; H, 6.8; OMe, 13.2%).

Monoacetyl γ-methylmannoside was non-reducing and the acetyl group resisted hydrolysis by 15% aqueous sodium hydroxide at 80°. The substance was, however, readily hydrolysed by dilute acids with loss of methyl and acetyl groups.

*Acetylation of Monoacetyl Methylmannoside.*—A solution of mono-acetyl methylmannoside (2 g.) in pyridine (15 c.c.) and acetic anhydride (21 c.c.) was kept at -5° for 50 hours, and then poured into water. The product was extracted by chloroform, the chloroform solution was neutralised by shaking with aqueous sodium bicarbonate and dried, and the solvent was then removed by distillation under diminished pressure at 35°. After removal of the pyridine by distillation in steam at 35°/11 mm., "γ"-tetra-acetyl methylmannoside was obtained as a colourless crystalline mass (3 g.), m. p. 100°. After recrystallisation from ether the m. p. was 102°. A mixed m. p. determination with an authentic specimen showed no depression.  $[\alpha]_D^{20} = 26.9^\circ$  (c, 1.11 in chloroform) (Found: C, 49.5; H, 6.2; OMe, 8.3. Calc. for  $C_{15}H_{22}O_{10}$ : C, 49.7; H, 6.1; OMe, 8.6%).

*Methylation of Monoacetyl Methylmannoside.*—(a) *By means of*

*silver oxide and methyl iodide.* A solution of monoacetyl methylmannoside (7 g.) in methyl alcohol (7 c.c.) and methyl iodide (70 c.c.) was heated at 30° with silver oxide (20 g.) until the reaction had commenced, and this proceeded for some time without further heating. Silver oxide was added from time to time (70 g. in all) and the temperature was gradually raised to 45°. At the end of 6 hours the product was extracted by chloroform and after isolation was remethylated in the usual way with silver oxide (30 g.) and methyl iodide (30 c.c.). It was then distilled, giving *monoacetyl trimethyl methylmannoside* (6.3 g.) as a colourless liquid, b. p. about 120°/0.1 mm.;  $n_D^{25}$  1.4594;  $[\alpha]_D^{25}$  -20° (c, 1.24 in water);  $[\alpha]_D^{25}$  -11° (c, 1.0 in chloroform) (Found: C, 51.8; H, 8.1; OMe, 42.0.  $C_{12}H_{22}O_7$  requires C, 51.8; H, 7.9; OMe, 44.7%).

(b) *By means of methyl sulphate.* Monoacetyl methylmannoside (5 g.), dissolved in acetone (30 c.c.) and water (10 c.c.), was treated at 50° with methyl sulphate (50 c.c.) and 30% aqueous sodium hydroxide (150 c.c.), the solution being maintained strongly alkaline throughout. (During the methylation there is a tendency for the formation of coloured decomposition products, and it is desirable to omit the usual heating for one hour at 90–100° at the end of the reaction.) The product (2.5 g.), which was isolated in the usual way, had b. p. about 120°/0.1 mm.,  $n_D^{25}$  1.4582,  $[\alpha]_D^{25}$  -23° (c, 1.0 in water). The identity of this material with the monoacetyl trimethyl methylmannoside described above was established by the conversion of both into the same crystalline trimethyl mannose, the yield in each case being over 90% of the theoretical.

The acetyl group in monoacetyl trimethyl "γ"-methylmannoside resisted hydrolysis by aqueous sodium hydroxide, no measurable amount of acetic acid being liberated during 50 hours when a solution of the substance in 3% aqueous alkali was kept at 15°. During this period the specific rotation remained unaltered. In hot aqueous alkali monoacetyl trimethyl "γ"-methylmannoside was slightly unstable, as was shown by the formation of coloured decomposition products. Fehling's solution was reduced to a small extent after prolonged boiling. The amount of decomposition was, however, minute even after treatment with 3% aqueous sodium hydroxide at 50° for 2 hours, since under these conditions 0.191 g. of substance accounted for only 0.2 c.c. of alkali. Further evidence of decomposition in the presence of alkali was provided by the marked development of colour during the simultaneous deacetylation and methylation of monoacetyl trimethyl "γ"-methylmannoside by means of methyl sulphate and strong alkali (see below).

Monoacetyl trimethyl methylmannoside was extremely sensitive to dilute hydrochloric acid. The specific rotation in *N*/100-acid at

20° changed in 60 minutes from  $[\alpha]_D^{20} - 25^\circ$  to the constant value  $+ 2^\circ$ . The liquid then vigorously reduced warm Fehling's solution.  $[\alpha]_D^{20} - 20^\circ$  (4 mins.);  $- 13^\circ$  (10 mins.);  $- 6.4^\circ$  (20 mins.);  $- 1.6^\circ$  (30 mins.);  $+ 0.4^\circ$  (45 mins.);  $2^\circ$  (60 mins.; constant value). No acetic acid was liberated during this period, since a solution of 0.1889 g. of substance in 26.8 c.c. of *N*/100-hydrochloric acid required for neutralisation after 60 minutes 27.0 c.c. of *N*/100-sodium hydroxide. Complete hydrolysis of the acetyl group would involve the liberation of acetic acid equivalent in this case to an additional 68.2 c.c. of *N*/100-alkali. The removal of the acetyl group was effected by the use of *N*/2-sulphuric acid at 90° for 60 minutes (Found:  $\text{CH}_3\text{CO}$ , 14.0. Calc., 15.5%).

3 : 4 : 6-Trimethyl Mannopyranose.—The following series of experiments was carried out in duplicate with material obtained respectively by methods (a) and (b) of the preceding section. The products were identical, and it is only necessary, therefore, to describe one set of experiments.

Monoacetyl trimethyl methylmannoside was dissolved in *N*/2-hydrochloric acid and heated on the water-bath for 90 minutes. The solution was neutralised with barium carbonate, filtered, and evaporated to dryness under diminished pressure. The product was extracted with chloroform and distilled, giving 3 : 4 : 6-trimethyl mannopyranose as a syrup, b. p. about 135°/0.04 mm.,  $n_D^{18}$  1.4734. This soon crystallised and, on recrystallisation from ether, d-3 : 4 : 6-trimethyl  $\alpha$ -mannopyranose was obtained, m. p. 101–102°,  $[\alpha]_D^{20} + 36^\circ$  (c, 0.8 in methyl alcohol),  $[\alpha]_D^{20} + 21^\circ$  (c, 1.04 in water; initial value). Yield, 90% of the theoretical (Found: C, 48.7; H, 8.3; OMe, 40.9.  $\text{C}_9\text{H}_{18}\text{O}_6$  requires C, 48.7; H, 8.1; OMe, 41.8%).

The mutarotation of 3 : 4 : 6-trimethyl mannopyranose in aqueous solution at 22° was complete in about 90 minutes, the equilibrium value being  $[\alpha]_D^{20} + 8.2^\circ$ :  $[\alpha]_D^{20} + 19^\circ$  (3 mins.);  $18.5^\circ$  (5 mins.);  $11.5^\circ$  (30 mins.);  $10^\circ$  (45 mins.);  $8.2^\circ$  (90 mins., constant value). From these figures the initial value was obtained by extrapolation.

3 : 4 : 6-Trimethyl mannopyranose (1.0 g.) was methylated by means of methyl iodide (30 c.c.) and silver oxide (10 g.), the addition of methyl alcohol (2 c.c.) being necessary to effect solution. The mixture was heated at 35° for 3 hours and then allowed to boil gently for an additional 4 hours. The product, after being remethylated in the usual way, crystallised (yield, 0.95 g.). On distillation crystalline tetramethyl  $\beta$ -methylmannopyranoside was obtained mixed with 12% of the  $\alpha$ -isomeride, b. p. about 90°/0.04 mm.,  $n_D^{18}$  1.4521 (supercooled liquid),  $[\alpha]_D^{20} - 65^\circ$  (c, 0.7 in water). Recrystallisation from light petroleum (b. p. 40–60°) gave pure tetramethyl  $\beta$ -methylmannopyranoside as long needles, m. p.

36—37°, alone or when mixed with an authentic specimen,  $[\alpha]_D^{25} - 78^\circ$  (c, 0.4 in water).

*d*-3 : 4 : 6-Trimethyl  $\delta$ -Mannonolactone.—3 : 4 : 6-Trimethyl manno-pyranose (3.7 g.) was dissolved in water (25 c.c.) and treated at 35—40° with bromine (4.5 c.c.) for 2 days; the solution was then found to be non-reducing. After removal of the remaining bromine by aeration the solution was neutralised with silver oxide, the organic acid liberated from its silver salt by titration with hydrochloric acid, the water removed by distillation under diminished pressure, and the product dissolved in ether in order to remove a small quantity of inorganic matter. Evaporation of the ether left crystalline *d*-3 : 4 : 6-trimethyl  $\delta$ -mannonolactone (3.2 g.) which, after recrystallisation from ether, had m. p. 96—97°,  $[\alpha]_D^{25} + 167.5^\circ$  (c, 0.7 in water). These constants are in excellent agreement with those recorded by Haworth and Peat for the corresponding *l*-3 : 4 : 6-trimethyl  $\delta$ -mannonolactone (*loc. cit.*), which has m. p. 96—97° and  $[\alpha]_D - 167^\circ$ .

The phenylhydrazide of *d*-3 : 4 : 6-trimethyl mannonic acid was prepared by heating the lactone (0.2 g.) with the calculated quantity of phenylhydrazine in benzene solution for 30 minutes on the water-bath. The product (0.3 g.) crystallised completely and had m. p. 137—139°, unaltered by recrystallisation from benzene. The m. p. of the *l*-isomeride is 137—139°.

The hydrolysis of the lactone in aqueous solution was followed polarimetrically:  $[\alpha]_D^{20} + 167.5^\circ$  (5 mins.); 167° (30 mins.); 162° (1.5 hrs.); 154° (4.5 hrs.); 147° (8 hrs.); 125° (24.5 hrs.); 118° (32 hrs.); 110° (74 hrs., constant value). If the sign of rotation be reversed, these figures are in excellent agreement with those recorded by Haworth and Peat for the *l*-isomeride.

The rotation of the acid in aqueous solution was measured in the manner described in previous papers:  $[\alpha]_D^{20} + 31^\circ$  (c, 0.7, calc. as lactone; initial value); 39° (1 hr.); 62° (4.5 hrs.); 103° (23 hrs.); 107° (30 hrs.); 111° (48 hrs., constant value). The proportion of lactone present at equilibrium was therefore 58%.

*Attempted Simultaneous Deacetylation and Methylation of "γ"-Tetra-acetyl Methylmannoside by Means of Methyl Iodide and Silver Oxide in the Presence of Solid Sodium Hydroxide.*—Silver oxide (70 g.) and solid sodium hydroxide (6 g.) were added to a solution of "γ"-tetra-acetyl methylmannoside (10 g.) in methyl iodide (50 c.c.). The mixture was heated at 45° for 8 hours. The product (9 g.) was extracted by chloroform and subjected to a second treatment under similar conditions, and was then distilled, giving a colourless viscid syrup (6 g.), b. p. about 120°/0.1 mm.,  $n_D^{25}$  1.4601,  $[\alpha]_D^{25} - 16^\circ$  in chloroform (Found: C, 51.8; H, 8.5; OMe, 45.1%). The material

was therefore mainly monoacetyl trimethyl methylmannoside, and the correctness of this view was proved by hydrolysis with *N*/5-hydrochloric acid at 95°. During 2 hours the specific rotation altered from  $[\alpha]_D^{20} - 7^\circ$  to  $+ 4^\circ$ . The product, which was isolated in the usual way, was 3:4:6-trimethyl mannopyranose, m. p. 101° (yield, 90%).

Similar experiments with silver oxide and solid sodium hydroxide were carried out on monoacetyl trimethyl methylmannoside, but in no case could the acetyl group be removed, and the monoacetyl trimethyl methylmannoside was recovered unchanged.

*Simultaneous Deacetylation and Methylation by Means of Methyl Sulphate and Alkali.*—“ $\gamma$ ”-Tetra-acetyl methylmannoside (5.5 g.), dissolved in acetone (15 c.c.), was treated at 50° with a large excess of methyl sulphate (55 c.c.) and 30% aqueous sodium hydroxide (140 c.c.). During the final heating at 100° for 1 hour the solution became very dark. The product was methylated three times by Purdie's reagents and distilled, giving a colourless liquid, b. p. about 85°/0.03 mm.,  $n_D^{20}$  1.4530,  $[\alpha]_D^{20} - 15^\circ$  (c, 0.9 in water),  $[\alpha]_D^{20} - 7^\circ$  (c, 0.7 in chloroform). Yield, 40% (Found: OMe, 58.2. Calc. for the tetramethyl methylmannoside, 62%). During hydrolysis with 6% hydrochloric acid at 80° the specific rotation altered from  $[\alpha]_D^{20} - 15^\circ$  to the constant value  $[\alpha]_D^{20} + 14^\circ$ . The product was a syrup which, when boiled with aniline in ethyl-alcoholic solution, gave tetramethyl mannopyranose anilide, m. p. 140–142°, alone or in admixture with an authentic specimen. The overall yield of syrupy tetramethyl mannopyranose from “ $\gamma$ ”-tetra-acetyl methylmannoside was 25% of the theoretical, and the minimum yield of crystalline anilide from the tetramethyl mannopyranose was 70%.

## CLXXXII.—*The Conversion of 1:2:3:4-Tetra-acetyl $\beta$ -D-Glucose into 2:3:4:6-Tetra-acetyl $\beta$ -Methylglucoside.*

By WALTER NORMAN HAWORTH, EDMUND LANGLEY HIRST, and  
ETHEL GERTRUDE TEECE.

VARIOUS examples are known of the wandering of acyl groups linked with polyhydric alcohol residues. One of the first to observe this change was Fischer (*Ber.*, 1920, 53, 1624), who suggested that the mechanism of the wandering of acyl groups might be explained

by the intermediate formation of an ortho-carbonic ester group of the type shown below :

This view may be expanded by including the assumption that the addition and elimination of water takes place in the following way :

Similar instances of acyl wandering are known in the glycerides of higher fatty acids (Grün, *Ber.*, 1921, 54, 290; Fairbourn and Cowdrey, J., 1929, 129; Fairbourn, *ibid.*, pp. 1151, 2232; Hibbert and Carter, *J. Amer. Chem. Soc.*, 1929, 51, 1607) and also in the sugar group (Ohle, *Ber.*, 1924, 57, 403; Ohle and Dickhäuser, *Ber.*, 1925, 58, 2593). A benzoyl or acetyl residue at position 3 in glucose is shown to be capable of translation to position 6, especially under the influence of faintly alkaline solutions, and the conditions under which this change is effected have been studied (Josephson, *Annalen*, 1929, 472, 217).

If the above mechanism be admitted, it would appear that the cases studied by the last author may be expressed as follows, where positions 1 and 2 are linked by an acetone group in glucofuranose.

The spatial proximity of the hydroxyls at positions 3 and 6 which are situated at the same side of the plane constituting the glucose ring apparently facilitates this interchange, and these stereochemical considerations are probably of importance also in other cases. In the course of our work on the properties of 1:2:3:4-tetra-acetyl  $\beta$ -glucose (I) (Oldham, J., 1925, 127, 2840; Helferich and Klein, *Annalen*, 1926, 450, 219) we were impressed by the similar

melting points of this substance, of the 2 : 3 : 4 : 6-tetra-acetyl  $\beta$ -glucose (II) (Fischer and Delbrück, *Ber.*, 1909, 42, 2778), and of the supposed 1 : 2 : 3 : 6-tetra-acetyl glucose (III) of Helferich and Klein (*Annalen*, 1927, 455, 173), and by the statement that the pyridine derivative of the supposed 1 : 2 : 3 : 6-tetra-acetyl glucose (III) mutarotates in water from the value  $[\alpha]_D - 22^\circ$  to about that of *D*-glucose ( $+ 53^\circ$ ). Since the simple mutarotation of a compound acetylated in position 1 may be considered unusual, the possibility arose that this last-named compound (III) was structurally closely related to the 2 : 3 : 4 : 6-tetra-acetyl  $\beta$ -glucose (II), which mutarotates from a negative value, in ethyl alcohol, to  $+ 81^\circ$ , and has a melting point almost identical with that of Helferich's supposed 1 : 2 : 3 : 6-tetra-acetyl glucose (III). We have confirmed, by mixed melting-point determinations, the statement that these two substances are not identical, and another explanation must therefore be provided for the properties of (III). It has been shown already that compound (III) passes by methylation into 2 : 3 : 4 : 6-tetra-acetyl  $\beta$ -methylglucoside (Helferich and Klein, *loc. cit.*) and that the acetylated sugar (III) exists in equilibrium with 1 : 2 : 3 : 4-tetra-acetyl  $\beta$ -glucose (I) in very dilute alkali, and is prepared from the latter by this reaction. Helferich has tentatively suggested that the acetyl group which wanders is that at position 4 in the latter compound (I), but has recognised that a further transposition of acetyl residues must occur when (III) undergoes conversion, although in indifferent yield, into tetra-acetyl  $\beta$ -methylglucoside.

It is seen, however, that position 4 is remote from position 6 in that these hydroxyl groups are situated in different planes in the  $\beta$ -glucopyranose configuration given below.

The possibility that the exchange of acetyl groups may occur from position 3 to 6 has been considered and rejected by Helferich, since the *p*-toluene-sulphonyl derivative of (III) is different from that prepared by Freudenberg and Ivers (*Ber.*, 1922, 55, 929).

Experiments which we have carried out lead definitely to the view that, in the isomerisation of (I) to give (III), the hydroxyls involved are those at positions 1 and 6. We have submitted both 1 : 2 : 3 : 4-tetra-acetyl  $\beta$ -glucose (I) and 2 : 3 : 4 : 6-tetra-acetyl  $\beta$ -glucose (II) to methylation with methyl iodide and silver oxide and have obtained in both cases 2 : 3 : 4 : 6-tetra-acetyl  $\beta$ -methylglucoside (IV) as our product. It is important to note that the migration is not in any way connected with the actual process of

methylation, but is an example of that type of isomerisation which has been referred to above as taking place in certain partially acylated substances under the influence of alkali. Our observations support the result recorded by Helferich, who has obtained the same product (IV) by methylation of the converted tetra-acetyl glucose (III), and we are therefore of opinion that this evidence points to the formulation of (III) as a derivative of ortho-acetic acid originating from (I) in the following way.

Helferich has demonstrated that the pyranose ring remains undisturbed during the change from (I) to (III), since both give rise on acetylation to the usual penta-acetyl glucose.

At present the evidence of the *p*-toluenesulphonyl derivatives of (I) and (III) throws little light on this view of the structure allocated to (III), although it is not inconsistent with it. Before the problem is finally decided, the toluenesulphonyl derivative of (III) will require further study.

#### EXPERIMENTAL.

**1:2:3:4-Tetra-acetyl  $\beta$ -D-Glucose.**—This substance was prepared by the action of hydrogen bromide, dissolved in glacial acetic acid, on 6-trityl 1:2:3:4-tetra-acetyl  $\beta$ -D-glucose (Helferich and Klein, *Annalen*, 1926, 450, 219). Crystallisation from ether gave colourless needles, m. p. 127°,  $[\alpha]_D^{20} + 13^\circ$  (*c*, 2.95 in chloroform). These constants and the properties of the substance are in complete agreement with those given by Helferich and Klein, but the m. p. and rotation are very close also to those of 2:3:4:6-tetra-acetyl  $\beta$ -D-glucose, which, when prepared from tetra-acetyl glucosidyl bromide by the method of Fischer and Delbrück (*Ber.*, 1909, 42, 2778), has m. p. 135°,  $[\alpha]_D^{20} + 16^\circ$  (*c*, 0.87 in chloroform);  $[\alpha]_D^{20} - 1.5^\circ$  (in ethyl alcohol; *c*, 1.17)  $\longrightarrow + 81^\circ$  in 10 days. The two substances are not, however, identical, since the m. p. of a mixture showed a depression of 20–25°. A similar depression was observed when either 1:2:3:4-tetra-acetyl  $\beta$ -D-glucose or 2:3:4:6-tetra-acetyl  $\beta$ -D-glucose (m. p. 135°) was mixed with Helferich's supposed 1:2:3:6-tetra-acetyl  $\beta$ -D-glucose, prepared from the 1:2:3:4-compound by the action of very dilute alkali.

*Methylation of 1:2:3:4-Tetra-acetyl β-d-Glucose.*—A solution of 1:2:3:4-tetra-acetyl β-*d*-glucose (3 g.) in methyl iodide (8 c.c.) was boiled for 8 hours during the gradual addition of dry silver oxide (15 g.) which had been prepared from silver nitrate and barium hydroxide and very thoroughly washed. The product was extracted by boiling chloroform and, on removal of the solvent under diminished pressure, was obtained as a pale yellow viscid syrup (2.8 g.). After being kept for some weeks, this began to crystallise, the rate of crystallisation being increased when the syrup was rubbed with alcohol. The solid was then recrystallised from absolute alcohol, giving colourless needles, m. p. 104–106° (yield, 0.6 g.);  $[\alpha]_D^{22} - 18.5^\circ$  (c, 1.62 in chloroform). The substance did not reduce boiling Fehling's solution. It was identified by a mixed m. p. determination as tetra-acetyl β-methylglucoside, which has m. p. 104–105°;  $[\alpha]_D^{20} - 18.2^\circ$  in chloroform (Found: C, 49.8; H, 6.5; OMe, 9.1. Calc. for C<sub>15</sub>H<sub>22</sub>O<sub>10</sub>: C, 49.7; H, 6.1; OMe, 8.6%).

The syrup left after removal of the tetra-acetyl β-methylglucoside gave OMe, 14.5%, from which it appeared that the methylation process had been accompanied by simultaneous deacetylation.

*Methylation of 2:3:4:6-Tetra-acetyl β-d-Glucose.*—2:3:4:6-Tetra-acetyl β-*d*-glucose (4.2 g.) was dissolved by gentle heating in methyl iodide (15 c.c.). The solution was heated with silver oxide (10 g.) for 6 hours at 45°. The product (4.3 g.), which crystallised spontaneously, m. p. 96°, was mainly 2:3:4:6-tetra-acetyl β-methylglucoside. One crystallisation from alcohol gave pure material, m. p. 105° alone or when mixed with authentic 2:3:4:6-tetra-acetyl β-methylglucoside which had been prepared by the acetylation of β-methylglucoside.

## CLXXXIII.—*The Hydrolysis of Diacetyl-o-diamines.*

By MONTAGUE ALEXANDRA PHILLIPS.

THE view that *o*-diamines are produced as intermediates in the formation of benziminazoles by the hydrolysis of diacetyl-*o*-diamines (J., 1928, 2393) has now been shown to be only partly correct. The acid hydrolysis of 4-nitro-1:2-diacetamidobenzene and of 5-nitro-1:2:4-triacetamidobenzene proceeds in two directions with the formation of the benziminazole and, to a less extent, of 4-nitro-1:2-diaminobenzene and 5-nitro-1:2:4-triaminobenzene respectively.

If the reaction is stopped when the acetyl compound is largely unchanged, a considerable quantity of the benziminazole, mixed with some diamine (or triamine) can be isolated; at the completion of the hydrolysis, the proportion of ring compound to amine is unchanged, although the amounts are greater. When the reaction is continued, the amount of amine decreases at a rate independent of the concentration of the mineral acid and corresponding with the rate of reaction between the *o*-diamine and acetic acid in the presence of mineral acid; a corresponding increase in the amount of cyclic compound occurs.

Although the rate of hydrolysis in the first stage depends on the concentration of mineral acid, the proportion of *o*-diamine to the ring compound is independent of this. It is possible that the first stage involves hydrolysis to the monoacetyl derivative, especially as it has been shown (Phillips, J., 1928, 172) that *o*-aminoacetanilide is formed together with 2-methylbenziminazole by acid hydrolysis of diacetyl-*o*-phenylenediamine. Although no monoacetyl derivative was isolated in the hydrolysis of 4-nitro-1:2-diacetamidobenzene, owing possibly to its lability, it was found that 4-nitro- and 5-nitro-2-aminoacetanilides behave with boiling hydrochloric acid as does 4-nitro-1:2-diacetamidobenzene, *i.e.*, 4-nitro-1:2-diaminobenzene and 5-nitro-2-methylbenziminazole are both produced and the latter increases in amount at the expense of the former as the reaction proceeds.

When methyl-alcoholic hydrogen chloride is used as the hydrolysing agent, acetic acid is removed as methyl acetate as it is formed, and the cyclic compound obtained must be produced from the diacetyl derivative (possibly, however, with the transient formation of monoacetyl derivatives). It is known that the ring compounds are stable to hot concentrated hydrochloric acid, hence the diamine also is formed from the diacetyl compound. At 80°, with 4-nitro-1:2-diacetamidobenzene, the proportion of 4-nitro-1:2-diaminobenzene to the benziminazole was greater than that found in a similar hydrolysis with aqueous hydrochloric acid, and was unchanged after several hours; at 160°, the yield of the diamine was 96%. Analogous results were obtained with 5-nitro-1:2:4-triacetamidobenzene.

The use of methyl alcohol and the formation of methyl acetate would account for the formation of amino-ketones from diacyl-diaminoethylenes (Windaus, Dorries, and Jensen, *Ber.*, 1921, 54, 2754); in the absence of the alcohol, it is probable that a glyoxaline would be formed.

With diacetyl-*o*-phenylenediamine and hot hydrochloric acid, the reaction proceeds rapidly to give the benziminazole, no diamine

being found even with limited hydrolysis. However, by the use of methyl-alcoholic hydrogen chloride at 160°, *NN'*-dimethyl-*o*-phenylenediamine was obtained, no ring compound being detected.

Taking into consideration all these facts, it is probable that the hydrolysis of diacetyl-*o*-diamines follows the course

The action of caustic alkali on the nitrodiacetyl-*o*-diamines proceeds in the same way, except that the proportion of nitro-diamine to cyclic compound is independent of the time of heating, since 4-nitro-1 : 2-diaminobenzene is unchanged by sodium acetate and sodium hydroxide at 100°. With diacetyl-*o*-phenylenediamine and 25% caustic alkali solution, the ring compound only was detected.

The reduction of 2 : 4-dinitroacetanilide, giving 4-nitro-2-aminoacetanilide, was accompanied by the formation of 5-nitro-2-methylbenziminazole; monoacetylation of 4-nitro-1 : 2-diaminobenzene yielded, in addition to 5-nitro-2-aminoacetanilide, the same cyclic compound. Since the solution was alkaline (ammonia) in the former case and acid (acetic acid only) in the latter, it seems that the ring compound in both cases is formed directly from the initial material.

In the 1-methylbenziminazole series, similar principles probably apply. Treatment of 4-nitro-2-acetamidomethylaniline with methyl-alcoholic hydrogen chloride gave a mixture of 5-nitro-1 : 2-dimethylbenziminazole and 4-nitro-2-aminomethylaniline; as before, both compounds must have been formed independently from the initial material. With hot aqueous hydrochloric acid, no estimation of the rate of disappearance of the methylaniline derivative was recorded; the time after which the *pure* cyclic compound was obtained, however, corresponded with the time after which the *pure* cyclic compound was formed from the methylaniline derivative and acetic acid in the presence of a mineral acid. Shorter periods of heating gave a mixture of the cyclic compound and 4-nitro-2-aminomethylaniline.

The nitration of 5(or 6)-acetamido-2-methylbenziminazole gives 6(or 5)-nitro-5(or 6)-acetamido-2-methylbenziminazole, which was oriented by deamination of the corresponding *amino*-compound, 5(or 6)-nitro-2-methylbenziminazole being formed in good yield. 1 : 2 : 4-Triacetamidobenzene on nitration gives the 5-nitro-derivative, which was oriented by conversion into 6(or 5)-nitro-5(or 6)-amino-2-methylbenziminazole. The orientation of 5-nitro-1 : 2 : 4-triaminobenzene follows from this and also from its reduction to 1 : 2 : 4 : 5-tetra-aminobenzene (compare Nietzki and Hagenbach,

*Ber.*, 1887, 20, 329). Reduction of 5(or 6)-nitro-6(or 5)-acetamido-2-methylbenziminazole gives 5(or 6)-amino-6(or 5)-acetamido-2-methylbenziminazole; this compound and 5(or 6)-diacetamido-2-methylbenziminazole on treatment with boiling dilute mineral acids pass rapidly into  $\alpha$ -2 : 2'-dimethylbenzbisiminazole (compare Nietski and Hagenbach, *loc. cit.*), which is also obtained readily from 1 : 2 : 4 : 5-tetra-aminobenzene or 5 : 6-diamino-2-methylbenziminazole (compare Kym and Ratner, *Ber.*, 1912, 45, 3249) by treatment with acetic and hydrochloric acids. In the presence of formic and hydrochloric acids,  $\alpha$ -2-methylbenzbisiminazole is obtained from 5 : 6-diamino-2-methylbenziminazole, and  $\alpha$ -benzbisiminazole from the tetra-aminobenzene.

5(or 6)-Nitro-2-methylbenziminazole-6(or 5)-arsinic acid, prepared from 5(or 6)-nitro-6(or 5)-amino-2-methylbenziminazole by the Bart reaction, gives the amino-derivative on reduction.

#### EXPERIMENTAL.

4-Nitro-2-aminoacetanilide.—2 : 4-Dinitroacetanilide (10 g.) was boiled for 15 minutes with ammonium sulphide solution (6%, 50 c.c.); on acidification to Congo-red with hydrochloric acid and addition of excess of sodium acetate to the filtered solution, 7 g. of mixed bases were obtained. By digestion with 2*N*-caustic soda solution, 5-nitro-2-methylbenziminazole (3.8 g., m. p. 221°, crystallised from alcohol. Found: N, 23.6. Calc.: N, 23.7%) was extracted; it was precipitated from the alkaline solution with acetic acid. The residue, after crystallisation from alcohol (80%), melted at 205° and was shown to be 4-nitro-2-aminoacetanilide (1.8 g.). It was completely soluble in excess of dilute mineral acids, readily soluble in alcohol or acetic acid, and insoluble in water (Found: N, 21.5.  $C_8H_9O_3N_3$  requires N, 21.5%).

5-Nitro-2-aminoacetanilide.—4-Nitro-1 : 2-diaminobenzene (5.4 g.) was dissolved in 20 c.c. of water with 5 c.c. of hydrochloric acid (*d* 1.16). On addition of acetic anhydride (10 c.c.), followed rapidly by excess of solid sodium acetate (until acidity to Congo-red was removed), the nitro-diamine was reprecipitated as a red solid; this rapidly became yellow as it was acetylated. After 15 minutes, the solid was collected and digested with 2*N*-caustic soda solution; this removed 2.6 g. of 5-nitro-2-methylbenziminazole (m. p. 221° after crystallisation from alcohol. Found: N, 23.7%). The residue (1.6 g.) was crystallised from alcohol until it melted at 195°; it was shown to be 5-nitro-2-aminoacetanilide by the solubility in mineral acids (excess), insolubility in alkalis, and analysis (Found: N, 21.4%). It is sparingly soluble in cold alcohol and insoluble in water or ether, and is a much weaker base than the isomeric 4-nitro-derivative.

5(or 6)-Nitro-6(or 5)-acetamido-2-methylbenziminazole.—5(or 6)-Acetamido-2-methylbenziminazole (9 g.), mixed with potassium nitrate (5 g.), was added at 0–5° to sulphuric acid (60 c.c.); after 1 hour, the mixture was poured into ice-water (1 l.) and basified at 50° with 15% aqueous ammonia. The voluminous yellow mass was collected, washed with water, and crystallised from 50% alcohol (yield, 7.7 g. or 70%). No trace of isomerides was detected in the liquors. 5(or 6)-Nitro-6(or 5)-acetamido-2-methylbenziminazole forms orange-yellow needles, m. p. 235°, insoluble in boiling alcohol or cold water, soluble in about 10 parts of boiling 50% aqueous alcohol. It is readily soluble in caustic alkalis, mineral acids, and in dilute acetic acid, from which it is reprecipitated by bases (Found: N, 23.7.  $C_{10}H_{10}O_3N_4$  requires N, 23.9%).

5(or 6)-Amino-6(or 5)-acetamido-2-methylbenziminazole, obtained by reduction of the above nitro-compound with iron and boiling dilute acetic acid (see J., 1928, 174), consists of white needles, m. p. above 300°, moderately easily soluble in boiling water (Found: N, 27.8.  $C_{10}H_{12}ON_4$  requires N, 27.4%). The dihydrochloride is sparingly soluble in cold water (Found: Cl, 25.2.  $C_{10}H_{12}ON_4 \cdot 2HCl$  requires Cl, 25.6%), and the triazole (Found: N, 33.0.  $C_{10}H_9ON_5$  requires N, 32.6%) forms prisms from boiling water, not molten at 300°.

5:6-Diacetamido-2-methylbenziminazole (compare Kym and Ratner, *loc. cit.*), obtained by the action of acetic anhydride on the above amino-compound, formed colourless needles, m. p. above 300°, from boiling water (Found: N, 22.7. Calc.: N, 22.8%).

5-Nitro-1:2:4-triacetamidobenzene.—1:2:4-Triacetamidobenzene (15 g.) was mixed with potassium nitrate (6.6 g.) and added at 5–10° to sulphuric acid (75 c.c.); after remaining for 1 hour at 10°, the mixture was poured on ice, and the nitro-compound collected and washed; it crystallised from glacial acetic acid in yellow prisms (9 g.), m. p. 261°. The mother-liquor on concentration gave a further 2 g. of fairly pure nitro-compound, making the total yield 65%. This compound is sparingly soluble in hot alcohol and insoluble in water (Found: N, 19.1.  $C_{12}H_{14}O_5N_4$  requires N, 19.0%).

5-Nitro-1:2:4-triaminobenzene, obtained, together with 5(or 6)-nitro-6(or 5)-amino-2-methylbenziminazole (see Table VI, p. 1417) by hydrolysis of the triacetyl derivative, crystallised in deep red needles, m. p. 210°, from aqueous alcohol. It is insoluble in alkalis and only slightly soluble in ether.

5(or 6)-Nitro-6(or 5)-amino-2-methylbenziminazole, obtained by hydrolysis of its acetyl derivative, by the action of hydrochloric acid (Table VI) on 5-nitro-1:2:4-triacetamidobenzene, or by the action of acetic anhydride and boiling dilute mineral acids on 5-nitro-

1 : 2 : 4-triaminobenzene, crystallised in red prisms, m. p.  $292^{\circ}$ , from alcohol. It is soluble in *excess* of caustic alkalis and readily soluble in mineral acids (compare Biedermann and Ledoux, *Ber.*, 1874, 7, 1532; Nietzki and Hagenbach, *loc. cit.*) (Found : N, 28.8. Calc. : N, 29.2%). The *hydrochloride* consists of brown needles, sparingly soluble in water (Found : Cl, 15.3.  $C_6H_3O_2N_4 \cdot HCl$  requires Cl, 15.5%). The amino-group in this compound is very stable to hot concentrated aqueous alkalis.

5(or 6)-Nitro-2-methylbenziminazole (yield, 70%) was obtained from 5(or 6)-nitro-6(or 5)-amino-2-methylbenziminazole by treatment of its diazo-compound with excess of boiling alcohol.

5 : 6-Diamino-2-methylbenziminazole (Kym and Ratner, *loc. cit.*) was obtained as its *dihydrochloride* (Found : Cl, 29.9; N, 23.9.  $C_8H_{10}N_4 \cdot 2HCl$  requires Cl, 30.2; N, 23.9%) by reduction of 5(6)-nitro-6(5)-amino-2-methylbenziminazole (3 g.) with boiling 5*N*-hydrochloric acid (30 c.c.) and tin (8 g.). After removal of tin by hydrogen sulphide, the filtrate was evaporated to dryness under reduced pressure (yield, 70%). The *triazole* melted above  $300^{\circ}$  (Found : N, 40.5.  $C_8H_7N_5$  requires N, 40.5%).

5(6)-Nitro-2-methylbenziminazole-6(5)-*arsinic Acid*.—5(6)-Nitro-6(5)-amino-2-methylbenziminazole (7.5 g.) in 30 c.c. of water and 30 g. of ice with 12 c.c. of 10*N*-hydrochloric acid was diazotised at  $0^{\circ}$  with 3 g. of sodium nitrite. The diazo-solution was added at  $50^{\circ}$  to a sodium arsenite mixture prepared from arsenious oxide (5.4 g.) and sodium hydroxide (8.0 g.) in water (15 c.c.) to which 7 c.c. of 2*N*-copper sulphate solution had been added. After remaining for 30 minutes at  $60^{\circ}$ , the reaction mixture was submitted to filtration and the filtrate was acidified to litmus, again filtered, and acidified faintly to Congo-red. The *arsinic acid*, obtained in 60% yield, formed pale yellow, hexagonal plates, not molten at  $300^{\circ}$ , from glacial acetic acid, in which it was sparingly soluble (Found : As, 24.75; N, 13.7.  $C_8H_8O_5N_3As$  requires As, 24.9; N, 13.9%). The calcium and magnesium salts are amorphous but the barium salt forms fine needles. The acid can be recovered unchanged after several hours' boiling with 20% caustic alkali solution.

On reduction of the nitro-acid by freshly precipitated ferrous hydroxide at  $60^{\circ}$ , a 65% yield of 5(6)-*amino-2-methylbenziminazole-6(5)-arsinic acid* is obtained. The acid forms white needles, is amphoteric, and is remarkably stable towards boiling 5*N*-hydrochloric acid (Found : As, 27.8; N, 15.5.  $C_8H_{10}O_3N_3As$  requires As, 27.6; N, 15.5%). The *acetyl* derivative forms colourless prisms, readily soluble in alkalis and mineral acids (Found : As, 23.7; N, 13.2.  $C_{10}H_{10}O_4N_3As$  requires As, 24.0; N, 13.4%).

1 : 2 : 4 : 5-Tetra-aminobenzene tetrahydrochloride (compare

Nietzki and Hagenbach, *loc. cit.*) was obtained by reduction of 5-nitro-1:2:4-triaminobenzene with tin and boiling 5*N*-hydrochloric acid. It is sparingly soluble in cold water and on treatment of its aqueous solution with ammonia and acetic anhydride gives 1:2:4:5-tetra-acetamidobenzene (Found: N, 18.2. Calc.: N, 18.3%).

$\alpha$ -Benzbisiminazole was obtained as an amorphous white solid, not molten at 300°, when 1:2:4:5-tetra-aminobenzene hydrochloride was treated with formic acid (1 part) and 5*N*-hydrochloric acid (5 parts) for  $\frac{1}{2}$  hour at the boiling point, and the solution made alkaline with ammonia (Found: N, 35.0.  $C_8H_8N_4$  requires N, 35.4%).

$\alpha$ -2-Methylbenzbisiminazole.—5:6-Diamino-2-methylbenziminazole dihydrochloride (2 g.) was refluxed for 30 minutes with 6 c.c. of 5*N*-hydrochloric acid and 2 c.c. of formic acid; on basification with ammonia the cyclic compound was precipitated. It is an amorphous solid, not molten at 300°, readily soluble in acids but not in caustic alkali (Found: N, 32.2.  $C_9H_8N_4$  requires N, 32.6%).

$\alpha$ -2:2'-Dimethylbenzbisiminazole was obtained (a) from 5:6-diamino-2-methylbenziminazole by the action of acetic and 5*N*-hydrochloric acids, (b) by the action of boiling 5*N*-hydrochloric acid (5 parts) on 5:6-diacetamido-2-methyl- or 5(6)-amino-6(5)-acetamido-2-methyl-benziminazole, and (c) by the action of acetic anhydride (2 parts) and boiling 5*N*-hydrochloric acid (3 parts) on 1:2:4:5-tetra-aminobenzene hydrochloride. It is an amorphous white solid resembling its lower homologues in solubility, and is unmelted at 300° (Found: N, 30.3. Calc.: N, 30.1%).

4-Nitro-2-aminomethylaniline was obtained in 60% yield by reduction of 2:4-dinitromethylaniline with aqueous ammonium sulphide solution. By the action of acetic anhydride on the dry solid or of sodium acetate on an aqueous solution of its hydrochloride, was obtained 4-nitro-2-acetamidomethylaniline, which crystallised from acetone in yellow rhombs, m.p. 185° (Found: N, 20.1.  $C_9H_{11}O_3N_3$  requires N, 20.1%); no trace of 4-nitro-2-acetamidomethylacetanilide was formed even when a large excess of acetic anhydride was used. The difficulty of acetylating a methylamino-group in the *o*- or *p*-position with respect to a nitro-group is also shown in the case of 2:4-dinitromethylaniline, which cannot be acetylated with acetic anhydride even in the presence of fused sodium acetate.

*Formation of 5-Nitro-2-methylbenziminazole.*—Before the quantitative work was undertaken, it was shown that the cyclic compound was stable to 10*N*-hydrochloric acid at 160° and to boiling 50% sodium hydroxide solution, the recovery of unchanged material after many hours being almost quantitative in both cases.

*General method of estimation.* Aliquot portions of the reaction

mixture were withdrawn after various times, cooled rapidly, and treated with sodium acetate. The solids obtained were digested with excess of 2*N*-caustic soda, and the nitro-diamine collected. The filtrate was acidified with acetic acid, and the cyclic compound filtered off. The combined mother-liquors were evaporated to dryness, and the residual solids extracted with acetone. The substance obtained by evaporation of the acetone was redigested with caustic alkali and separated into the same two compounds.

## CLXXXIV.—*The Sulphonation of m-Chlorophenol and Some New Halogenophenols.*

By HERBERT HENRY HODGSON and ARNOLD KERSHAW.

THE monosulphonation of *m*-chlorophenol, whether hot or cold, gives almost entirely 3-chlorophenol-6-sulphonic acid. On the current electronic theory this result was to be anticipated, since the normally less intensely activated 4-position is deactivated by the general effect of the 3-chloro-substituent (compare Hodgson and Jenkinson, J., 1929, 469). With the more powerful kationoid reagent, oleum, disulphonation takes place in the 4- and 6-positions.

The solubilities of the salts of 3-chlorophenol-6-sulphonic acid resemble those of the corresponding sulphates, *viz.*,  $\text{Ca} > \text{Sr} > \text{Ba}$ , and  $\text{Na} > \text{K}$ , and the calcium salt is unique in forming a hydrate.

The tetrahydrated barium salts of the 4:6-disulphonic acid and of its 2-halogeno-derivatives are of interest from the co-ordination standpoint, and it is suggested that two of the molecules of water are co-ordinated with the barium atom by means of oxygen atoms and that each sulphonic acid group is co-ordinated by means of its negatively charged oxygen atoms with the hydrogen atoms of a molecule of water (compare Sidgwick, "Electronic Theory of Valency," 1927, pp. 192 and 195).

3-Chloro-2:4-dibromo-6-nitrophenol is obtained in two crystalline forms according to the method of preparation, *viz.*, elongated needles by the dibromination of 6-nitro-3-chlorophenol, and stout prisms by the nitration of 3-chloro-2:4-dibromophenol. Though interconvertible, each form could be recrystallised from alcohol without change of habit. It is tentatively suggested that the two forms are an example of Kekulé's ortho-isomerism.

## EXPERIMENTAL.

*Monosulphonation of 3-Chlorophenol at 100° and at the Ordinary Temperature.*—3-Chlorophenol (12 g.) and concentrated sulphuric acid (20 g.) were heated together for 8 hours on the water-bath, the mixture was then poured into water (1000 c.c.), and the solution was heated on the water-bath while it was being made neutral to Congo-red by addition of barium carbonate. The residue after filtration was extracted several times with boiling water (1000 c.c. in all) and the solution obtained, combined with the filtrate above, was evaporated to dryness, leaving the barium salt (26 g.) of the sulphonic acid (yield, theoretical). The salt was decomposed by dilute sulphuric acid, the solution evaporated to small bulk, and the remainder of the water removed in a vacuum desiccator containing calcium chloride; colourless prisms of 3-chlorophenol-6-sulphonic acid were obtained containing a variable quantity of water of hydration. The constitution of the acid has already been deduced by the authors (J., 1929, 2923). The same results were also obtained when the sulphonation was conducted at room temperature.

The following salts are prepared by adding the corresponding carbonates to solutions of the acid until these are neutral to Congo-red: The *potassium* salt forms anhydrous prisms (Found: C, 28.9; H, 1.7; Cl, 14.4; K, 16.0.  $C_6H_4O_4ClSK$  requires C, 29.2; H, 1.7; Cl, 14.4; K, 15.9%). The *sodium* salt is much more soluble in water than the potassium salt, and separates from this solvent in anhydrous, minute, elongated prisms (Found: Cl, 15.6; Na, 10.2.  $C_6H_4O_4ClSNa$  requires Cl, 15.4; Na, 10.0%). The *ammonium* salt crystallises in large stout prisms (Found: Cl, 15.9; S, 14.5.  $C_6H_4O_4ClSNH_4$  requires Cl, 15.7; S, 14.2%). The *barium* salt forms anhydrous, short, stout prisms which are sparingly soluble in water [Found: C, 26.2; H, 1.6; Ba, 24.6.  $(C_6H_4O_4ClS)_2Ba$  requires C, 26.1; H, 1.4; Ba, 24.8%]. The *strontium* salt separates from water, in which it is more soluble than the barium salt, in anhydrous flat prisms [Found: Sr, 17.1.  $(C_6H_4O_4ClS)_2Sr$  requires Sr, 17.3%. 0.2195 G. gave 0.3339 g. of mixed silver chloride and strontium sulphate; required, 0.3291 g.). The *lead* salt crystallises in anhydrous prisms which are easily soluble in water [0.2490 g. gave 0.2991 g. of mixed precipitates (see below); required, 0.3016 g.]. The monohydrated *calcium* salt separates from water, in which it is readily soluble, in flat rectangular prisms [Found: C, 30.0; H, 2.4; Cl, 15.0; Ca, 8.6.  $(C_6H_4O_4ClS)_2Ca \cdot H_2O$  requires C, 30.4; H, 2.1; Cl, 15.0; Ca, 8.5%].

*Analytical Note.*—The above salts were analysed for carbon and hydrogen by admixture with lead chromate and combustion in a stream of oxygen in a tube packed with lead chromate. Very few

gave stoicheiometric results, but those obtained are recorded. In other cases the amounts of mixed silver halides and insoluble sulphates obtained by the Carius method are given, and also the percentage of metal estimated as sulphate.

*Halogenation of 3-Chlorophenol-6-sulphonic Acid.*—(a) *Dichlorination.* Barium 3-chlorophenol-6-sulphonate (14 g.) was dissolved in water (1000 c.c.), and the theoretical amount of a freshly prepared solution of barium hypochlorite added. After 12 hours, the mixture was neutralised with sulphuric acid, and the filtered liquid evaporated to small bulk; *barium 2 : 3 : 4-trichlorophenol-6-sulphonate* then separated in good yield as flat rhombs sparingly soluble in water [Found: Ba, 20.1.  $(C_6H_2O_4Cl_3S)_2Ba$  requires Ba, 20.2%]. The *dihydrate* of this salt separated on one occasion in very long prisms [Found: Ba, 19.25.  $(C_6H_2O_4Cl_3S)_2Ba \cdot 2H_2O$  requires Ba, 19.0%. 0.1225 G. gave 0.1849 g. of mixed precipitates (see above); required, 0.1849 g.].

*2 : 3 : 4-Trichlorophenol* is obtained by heating the above salt in aqueous sulphuric acid (80%) during the passage of steam, in which it is volatile; it crystallises from light petroleum in elongated needle-like prisms, m. p. 79° (Found: Cl, 53.7.  $C_6H_3OCl_3$  requires Cl, 53.9%).

*2 : 3 : 4-Trichloroanisole*, obtained from the phenol by the action of methyl sulphate and sodium hydroxide solution, crystallises from alcohol in long, flat, rectangular prisms, m. p. 69.5° (Found: Cl, 50.3.  $C_7H_5OCl_3$  requires Cl, 50.3%).

(b) *Dibromination.* Barium 3-chloro-2 : 4-dibromo-6-sulphonate *dihydrate* was obtained by the action of bromine (2.5 c.c.; 8 g.) on barium 3-chlorophenol-6-sulphonate (7 g.) dissolved in water (500 c.c.). The solution obtained was made neutral to Congo-red with barium carbonate, filtered, and evaporated to small bulk; the product then crystallised in very long prisms sparingly soluble in water [Found: Ba, 15.1.  $(C_6H_2O_4ClBr_2S)_2Ba \cdot 2H_2O$  requires Ba, 15.2%. 0.1225 G. gave 0.2260 g. of mixed precipitates; required, 0.2338 g.].

The *potassium* salt separates from water, in which it is sparingly soluble, in anhydrous, thin, flat plates (Found: C, 17.8.  $C_6H_2O_4ClBr_2SK$  requires C, 17.8%. 0.1116 G. gave 0.1430 g. of mixed silver halides; required, 0.1432 g.).

The *sodium* salt was obtained in clusters of anhydrous flat plates (Found: Na, 6.0.  $C_6H_2O_4ClBr_2SNa$  requires Na, 5.9%. 0.2542 G. gave 0.3400 g. of mixed silver halides; required, 0.3320 g.).

The above salts are extremely stable and very difficult to hydrolyse, as they crystallise unchanged from hot concentrated sulphuric acid; the free acid, however, is easily hydrolysed under the same conditions.

*3-Chloro-2 : 4-dibromophenol* was prepared by heating for 8 hours on the water-bath a mixture of 3-chlorophenol (65 g.) and concentrated sulphuric acid (12 g.), then pouring it on ice (30 g.) and adding bromine (16 g.). After 4 hours, a small quantity (less than 1 g.) of 3-chloro-2 : 4 : 6-tribromophenol which had separated was removed and the filtrate was hydrolysed in steam; the 3-chloro-2 : 4-dibromophenol (9.5 g.) which passed over crystallised from light petroleum in long colourless prisms, m. p.  $88^{\circ}$  (0.2228 g. gave 0.4062 g. of mixed silver halides; required, 0.4039 g.). Its constitution was established by nitration to *3-chloro-2 : 4-dibromo-6-nitrophenol* as follows: the phenol (9 g.), dissolved in glacial acetic acid (20 c.c.), was treated gradually, whilst ice-cold, with a solution of nitric acid (1.8 c.c.;  $d$  1.5) in glacial acetic acid (7 c.c.). The mixture was kept over-night and the 3-chloro-2 : 4-dibromo-6-nitrophenol was then precipitated by the addition of water (500 c.c.), and crystallised from alcohol (yield, 8.0 g.; 76%); m. p.  $90^{\circ}$  (0.2143 g. gave 0.3470 g. of mixed silver halides; required, 0.3504 g.). The product was identical (m. p. and mixed m. p.) with that obtained by treating 3-chloro-6-nitrophenol (3 g.), dissolved in glacial acetic acid (15 c.c.), with bromine (2.4 g.).

*3-Chloro-2 : 4-dibromoanisole*, prepared by the usual method, crystallises from alcohol in very long, flat prisms, m. p.  $92^{\circ}$  (0.2312 g. gave 0.4019 g. of mixed silver halides; required, 0.3996 g.).

*3-Chloro-2 : 4 : 6-tribromoanisole* is obtained by bromination of the previous product in glacial acetic acid, and also by methylation of the corresponding phenol (see above). It crystallises from alcohol or acetic acid in long needles, m. p.  $92^{\circ}$  (0.1409 g. gave 0.2643 g. of mixed silver halides; required, 0.2620 g.).

(c) *Di-iodination.* *3-Chloro-2 : 4-di-iodophenol-6-sulphonic acid trihydrate* is obtained from the corresponding barium salt (see below) by treatment with dilute sulphuric acid, the solution being then evaporated to small bulk and the acid precipitated by means of concentrated hydrochloric acid; it forms long flat prisms, m. p.  $167^{\circ}$  (slight decomp.) (Found: S, 6.7.  $C_6H_3O_4ClI_2S \cdot 3H_2O$  requires S, 6.2%. 0.2328 G. gave 0.2764 g. of mixed silver halides; required, 0.2774 g.).

The tetrahydrated *barium* salt was obtained when barium 3-chlorophenol-6-sulphonate (10 g.), powdered iodine (20 g.), precipitated mercuric oxide (8 g.), alcohol (60 c.c.), and water (20 c.c.) were shaken together for 30 minutes. After removal of the excess iodine by the gradual addition of sodium bisulphite solution, the whole mixture was evaporated to dryness, the residue extracted with boiling water (300 c.c.), and barium chloride (2 g.) added to the filtered extract; when this was then evaporated to 100 c.c., the sparingly soluble salt was obtained in long thin prisms. Any mercuric iodide which

separate with the product may be removed by extraction with boiling alcohol [Found: Ba, 12.1. ( $\text{C}_6\text{H}_2\text{O}_4\text{ClI}_2\text{S}$ )<sub>2</sub>.Ba, 4H<sub>2</sub>O requires Ba, 12.17%]. (Mercuric iodide is definitely soluble in hot water, and may be steam-distilled from hot sulphuric acid, passing over in the yellow form which subsequently becomes red.)

*3-Chloro-2:4-di-iodophenol*, obtained from its 6-sulphonic acid (above) by hydrolysis, crystallises from light petroleum in long prisms, m. p. 111.5° (0.1329 g. gave 0.2161 g. of mixed silver halides; required, 0.2144 g.).

*3-Chloro-2:4-di-iodoanisole*, readily obtained in the usual way, crystallises from alcohol in somewhat stout prisms, m. p. 105° (0.1715 g. gave 0.2701 g. of mixed silver halides; required, 0.2667 g.).

*Disulphonation of 3-Chlorophenol*.—*Barium 3-chlorophenol-4:6-disulphonate tetrahydrate* is obtained when 3-chlorophenol (12.8 g.) is added gradually to oleum (75 g.; 27% SO<sub>3</sub>) with cooling, the mixture kept over-night, then heated for 2 hours on the water-bath, poured into water (1000 c.c.), rendered neutral to Congo-red by addition of barium carbonate (about 10 g.), and the filtered solution evaporated to dryness. It is a white powder, which, like the salts of the other sulphonic acids described later, is very soluble in water, in marked contrast to the sparing solubility of the barium salts of the 6-monosulphonic acids described above. The product crystallises from water in clusters of minute short prisms (Found: Ba, 27.4.  $\text{C}_6\text{H}_3\text{O}_7\text{ClS}_2\text{Ba}, 4\text{H}_2\text{O}$  requires Ba, 27.7%).

*Halogenation of the above Barium Salt and Preparation of the 2-Halogeno-3-chlorophenols*.—(a) *Chlorination*. *Barium 2:3-dichlorophenol-4:6-disulphonate tetrahydrate* is obtained when the foregoing barium salt (24 g.), dissolved in water (500 c.c.), is treated with the theoretical quantity of freshly prepared barium hypochlorite solution, the mixture kept over-night and neutralised with sulphuric acid, and the solution filtered and evaporated to dryness. It crystallises from water in clusters of long prisms (Found: Ba, 26.2.  $\text{C}_6\text{H}_2\text{O}_7\text{Cl}_2\text{S}_2\text{Ba}, 4\text{H}_2\text{O}$  requires Ba, 25.9%).

*2:3-Dichlorophenol*, prepared from the above product in 70% yield by the usual procedure for the elimination of sulphonic acid groups, forms a mass of prisms on solidification after distillation, m. p. 58°, b. p. 206° (Found: Cl, 43.5. Calc.: Cl, 43.6%).

*2:3-Dichloro-4:6-dibromophenol* is readily obtained by direct dibromination of the above phenol and separates from glacial acetic acid in colourless needles which rapidly become opaque; m. p. 90° (0.1581 g. gave 0.3230 g. of mixed silver halides; required, 0.3266 g.).

*2:3-Dichloro-4:6-dibromoanisole* crystallises from alcohol in long needle-like prisms, m. p. 82° (0.1324 g. gave 0.2623 g. of mixed silver halides; required, 0.2621 g.).

(b) *Bromination*. 3-Chlorophenol (12.8 g.) was disulphonated as above, the solution diluted with water (100 c.c.) and treated with bromine (16 g.), and the resulting solution hydrolysed to give the corresponding phenol or diluted to 1000 c.c. and neutralised with barium carbonate, etc., as above.

*Barium 3-chloro-2-bromophenol-4 : 6-disulphonate tetrahydrate* crystallises from water in small prisms (Found: Ba, 24.0.  $C_6H_2O_7ClBrS_2Ba \cdot 4H_2O$  requires Ba, 23.8%. 0.1615 G. gave 0.1541 g. of mixed precipitates; required, 0.1558 g.).

3-Chloro-2-bromophenol is obtained in 75% yield as above and crystallises from light petroleum in large stout prisms, m. p. 55.5°, b. p. 225° (0.2438 g. gave 0.3892 g. of mixed silver halides; required, 0.3910 g.).

3-Chloro-2-bromoanisole, obtained by the action of methyl sulphate and sodium hydroxide on the above phenol, crystallises from alcohol in long colourless plates, m. p. and mixed m. p. with a specimen prepared from 3-chloro-2-aminoanisole (Hodgson and Kershaw, *loc. cit.*), 50°.

A solution of 3-chloro-2-bromophenol (7 g.) in ice-cold glacial acetic acid (7 c.c.) was treated with nitric acid (3.5 c.c.; *d* 1.5) in glacial acetic acid (4 c.c.). After 12 hours, steam distillation removed the volatile 3-chloro-2-bromo-6-nitrophenol, which crystallised from light petroleum in small yellow prisms, m. p. 98.5° (0.0755 g. gave 0.0990 g. of mixed silver halides; required, 0.0991 g.), leaving behind the non-volatile 3-chloro-2-bromo-4-nitrophenol, which crystallised from dilute alcohol in fine, almost colourless, needles, m. p. 136° (0.1949 g. gave 0.2601 g. of mixed silver halides; required, 0.2569 g.).

(c) *Iodination*. *Barium 3-chloro-2-iodophenol-4 : 6-disulphonate tetrahydrate* was prepared by stirring for 1 hour a mixture of barium 3-chlorophenol-4 : 6-disulphonate (13 g.), finely powdered iodine (7.6 g.), precipitated mercuric oxide (3.3 g.), alcohol (50 c.c.), and water (50 c.c.), during which period most of the iodine disappeared. The alcohol was then boiled off, and the residue extracted with boiling water (200 c.c.); the filtered extract on slow evaporation gave the product in small rectangular prisms (Found: Ba, 22.4.  $C_6H_2O_7ClIS_2Ba \cdot 4H_2O$  requires Ba, 22.1%. 0.1814 G. gave 0.1745 g. of mixed precipitates; required, 0.1783 g.).

3-Chloro-2-iodophenol was prepared by hydrolysis of the above disulphonate and also by the action of potassium iodide on diazotised 3-chloro-2-aminophenol. It crystallises from light petroleum in colourless needles, m. p. 56° (Found: 0.1107 g. gave 0.1692 g. of mixed silver halides, required, 0.1646 g.).

*Colour Reactions of the Sulphonic Acids with Ferric Chloride.*—An aqueous solution of 3-chlorophenol-6-sulphonic acid gives a violet

colour with ferric chloride, and the salts give similar but deeper colours. The colours are not produced in concentrated acid solutions.

The halogeno-derivatives of the above acid give bluer colours than the parent acid, all the halogens having approximately the same effect: the nitro-derivatives give brownish-red colours.

3-Chlorophenol-4:6-disulphonic acid and its salts give red colours: the halogeno- and nitro-derivatives have similar effects on the shades as in the case of the monosulphonic acids and salts.

The authors desire to thank the Department of Scientific and Industrial Research for a grant to one of them (A. K.), and the British Dyestuffs Corporation for gifts of chemicals.

## CLXXXV.—*A General (Exact) Equation to the Potentiometric-titration Curve.*

By BERNARD CAVANAGH.

### *Section 1.*

IN a previous paper (Part II; J., 1928, 855) an exact equation was obtained, on thermodynamic grounds, representing the whole potentiometric-titration curve in all cases where (a) the analytical reaction consists in the combination of two ions of like valency to form a substance of constant activity such as a precipitate, and (b) the indicator electrode behaves as a "soluble electrode" towards either of these ions. Essentially of the tractable form,

$$X = \sinh U \quad . \quad . \quad . \quad . \quad . \quad (1)$$

(where  $U$  and  $X$  represent distance from the equivalence point in terms of potential and of quantity of reagent, respectively), this equation was used in developing certain highly refined methods of titration. It will now be shown that both the equation and the methods arising out of it can be generalised. A system involving both analytical and electrode reactions of the most general type yields, under equilibrium conditions, a titration curve exactly represented by an equation of the form

$$X = \sinh_{\alpha\beta} U \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where

$$\sinh_{\alpha\beta} U = \frac{1}{2}(e^{\alpha U} - e^{-\beta U}) \quad . \quad . \quad . \quad . \quad . \quad (3)^*$$

\* This equation could be written in the form  $\sinh U = e^{\frac{\alpha-\beta}{2}U} \sinh \frac{\alpha+\beta}{2}U$ , and similarly for other hyperbolic functions of  $U$ , but the formulæ would be, not only cumbersome, but less direct in their physicochemical significance.

Fig. 1.  
Typical forms of the curve represented by the general titration-curve equation. (Graphs of the function  $X = \frac{\sinh U}{\alpha\beta}$  for various assigned values of the parameters  $\alpha$  and  $\beta$ .)

The origin represents the point of exact equivalence. Abscissae ( $X$ ) represent distance from the equivalence point in terms of quantity of reagent solution, the unit being  $H$  c.c. (see Section 2). Ordinates ( $U$ ) represent distance from the equivalence point in terms of potential, the unit being  $RT/F$  (i.e., about 25 millivolts). Three kinds of broken line are used to distinguish the curves.

and  $\alpha$  and  $\beta$  are two simple numbers characteristic of the system (see Section 3; and Fig. 1).

Between the function defined in (3) and the corresponding cosine and other functions (see Section 4) many of the inter-relations of the ordinary hyperbolic functions hold good (for fixed values of  $\alpha$  and  $\beta$ ), while others assume a more general form. These relations facilitate the derivation of methods of refined titration essentially

FIG. 2.  
 Derived curves, corresponding with those of Fig. 1. [*Graphs of the function*  $h^{-1} \operatorname{sech} \frac{g}{\alpha\beta}$  ( $g + \operatorname{arcsinh} X$ ), i.e., of  $h^{-1} \operatorname{sech} (g + U)$ .]

Abscissae ( $X$ ) correspond exactly with those of Fig. 1. Ordinates represent rate of change of potential,  $dU/dX$  (i.e., the slope of the corresponding curve in Fig. 1), the unit being  $RT/FH$ , or about  $25/H$  millivolts/c.c.

similar to those already described, but with the advantage of general applicability.

By means of these methods, not only is the sensitivity, or absolute precision, obtainable from the accepted reactions very much increased, but also other reactions should become available for analytical purposes which otherwise would not be sufficiently sensitive. Incidentally the same methods also provide an accurate

means of determining equivalence-point potentials and reaction constants (compare Part II, p. 870).

The rigorous deduction of the general titration-curve equation appears to be especially useful in providing a sound basis for the quantitative study of all the various analytical and electrode reactions that are now available or may yet be discovered. In so far as such study is to be anything more than mere empiricism, it must rest upon the assumption and the attempted realisation of equilibrium conditions, and this is the only assumption on which the following deduction is based.

### *Section 2. Deduction of the Equation.*

This deduction may be effected concisely and yet with strict generality by adopting the device of writing the chemical and thermodynamic equations in an algebraic manner, such that no formal distinction need be made between products of the reactions and reactants other than the two principal reactants. Four abstract or typical molecular symbols will then suffice to represent all possibilities, whereas otherwise eight at least would be necessary. The procedure at this stage may be illustrated by a concrete case.

The reduction of iodate ion by (aqueous) sulphur dioxide in strongly acid solution has recently been studied potentiometrically (Hendrixson, *J. Amer. Chem. Soc.*, 1925, 47, 1319; the author actually used a solution of sodium sulphite, but in effect this was the same as adding aqueous sulphur dioxide, since a large excess of acid was present), and shown to proceed in two clearly separated stages. Considering only the first of these, the analytical reaction is

Iodate ion and sulphur dioxide are the two principal reactants; the latter, being the added substance, may conveniently be called the "reagent," and the former the "titrated substance." In order to avoid needless repetition, the word "substance" will be taken to include ionic or molecular species throughout this paper, and similarly the expression "g.-mol." will cover "g.-ion."

Before the first addition of reagent, the only electrode reaction is

(where the symbol  $\ominus$  represents one faraday of negative electricity), but when once the titration has commenced there is the alternative electrode reaction

obtained by subtracting (5) from (4). These equations must now

be re-written in the algebraic manner convenient for the present purpose by transferring the symbols of the "subsidiary reactants," *i.e.*, all save the two principal reactants, to the right-hand sides with change of sign, thus:

and the corresponding thermodynamic equations (for equilibrium) can be written logarithmically in an entirely parallel manner, the algebraic signs being retained.

We now revert to the general treatment. Representing the molecular or ionic symbols (in the abstract) by capital letters, and taking A as the titrated substance, and B as the reagent, we express the alternative electrode reactions quite generally by the equations

$$\pm \nu \ominus + aA = \Sigma pP \quad . \quad . \quad . \quad (10)$$

$$\mp \nu \ominus + bB = \Sigma qQ \quad . \quad . \quad . \quad (11)$$

the small letters representing numerical coefficients, of which those on the right, typified by  $p$  and  $q$ , may be either positive or negative as in equations (7) and (8). From the latter it is also seen that the symbols represented by P, Q, etc., are not necessarily all different. The equation for the analytical reaction is obtained from (10) and (11) by addition, giving

$$aA + bB = \Sigma pP + \Sigma qQ \quad . \quad . \quad . \quad (12)$$

and the three thermodynamic equations corresponding to (10), (11), (12), respectively, are then written in terms of the equivalent concentrations  $C_A$ ,  $C_B$ , etc., the activity coefficients  $\gamma_A$ ,  $\gamma_B$ , etc., and the measured potential  $E$ . It is convenient to adopt the convention that the direction in which  $E$  changes during titration is taken as the negative direction, thus avoiding alternative signs, and we have

$$\nu F/RT \cdot (E_0 - E) + a \log C_A \gamma_A = \Sigma p \log C_P \gamma_P \quad . \quad . \quad (13)$$

$$- \nu F/RT \cdot (E'_0 - E) + b \log C_B \gamma_B = \Sigma q \log C_Q \gamma_Q \quad . \quad . \quad (14)$$

$$- \log K + a \log C_A \gamma_A + b \log C_B \gamma_B = \Sigma p \log C_P \gamma_P + \Sigma q \log C_Q \gamma_Q \quad . \quad . \quad (15)$$

in which logarithms (as throughout this paper) are to the base  $e$ ;  $F$ ,  $R$ , and  $T$  have their usual significance; and the three constants,  $E_0$ ,  $E'_0$ , and  $K$ , are connected by the relation

$$\log K = \nu F/RT \cdot (E'_0 - E_0) \quad . \quad . \quad . \quad (16)$$

These equations express the assumption of equilibrium conditions.

Now suppose (as in Part I, J., 1928, 843, and Part II, *loc. cit.*) that at any given stage of the titration,  $M$  c.c. of the reagent solution are

still required in order to reach the exact equivalence point. Thus  $M$  may be positive or negative, but in any case, to know  $M$  is, from the experimental point of view, to know the result of the titration. If  $n$  is the normality of the reagent solution (which may or may not be known) then the excess of the titrated substance at this stage is evidently  $Mn$  mg.-equivs.\*

In order to show how adsorption by precipitates (if any) would affect the titration curve, a coefficient,  $\theta_A$ , is now introduced, representing the ratio of the amount of A present in solution (*i.e.*, not adsorbed) to the total amount present (compare Part I, p. 848); a similar coefficient,  $\theta_B$ , relates to B.

Then if  $V$  c.c. is the volume of the solution at this stage, the total amount (mg.-equivs.) of A in the vessel is  $VC_A/\theta_A$ , and similarly that of B is  $VC_B/\theta_B$ , and since the excess of A is  $Mn$  mg.-equivs.,

$$Mn = VC_A/\theta_A - VC_B/\theta_B \quad (17)$$

The remaining steps, by which  $C_A$  and  $C_B$  are eliminated and the result is reduced to a tractable form, will be plain if three constants  $\alpha$ ,  $\beta$ ,  $\bar{E}_0$ , and two other quantities,  $H$  and  $G$  (not in general constant, but independent of  $C_A$  and  $C_B$ ), are first defined by the equations

$$\alpha\alpha = \beta\beta = \nu$$

$$(\alpha + \beta)\bar{E}_0 = \alpha E'_0 + \beta E'_0 \quad (18)$$

$$(\alpha + \beta)G = \log(\gamma_B\theta_B/\gamma_A\theta_A) + \sum \frac{p}{a} \log C_F\gamma_F - \sum \frac{q}{b} \log C_Q\gamma_Q \quad (19)$$

$$(a + b) \log(nH/2V) = \log K - a \log \gamma_A\theta_A - b \log \gamma_B\theta_B + \sum p \log C_F\gamma_F + \sum q \log C_Q\gamma_Q \quad (20)$$

Then, from equations (13), (14), (15), and (17), the general titration-curve equation connecting  $M$  and  $E$  is obtained in the form

$$M/H = \sinh_{\alpha\beta}[(F/RT)(E - \bar{E}_0) + G] \quad (21)$$

and, since this is identical with equation (2),

$$X = M/H \quad (22)$$

$$U = (F/RT) \cdot (E - \bar{E}_0) + G \quad (23)$$

From equations (19) and (20),  $G$  and  $H$  are seen to depend on the concentrations of the products and subsidiary reactants (if any), the adsorption and activity coefficients, and (in the case of  $H$ ) the volume of the solution. Their complexity and probable variation might appear, at first sight, to render impracticable the general

\* Ordinary usages have been adhered to as far as possible, but it is plain that the reagent might be measured in other units—in g. of solution, or of the pure substance B, or of some compound of B, etc.—so long as  $n$  is defined as the number of mg.-equivs. of B per unit.

application of the equation and of the methods of titration based upon it, but this is not the case. In using these methods, variation in  $H$  and  $G$  can be accurately allowed for by applying a predetermined additive correction to the measured potentials (see Section 7), after which the procedure is exactly as if  $H$  and  $G$  were strictly constant during a titration.

The volume  $H$  c.c. is, as it were, a "natural" unit-quantity of the reagent solution, in terms of which  $X$  represents distance from the equivalence point. Since  $U$  vanishes with  $X$  (i.e., at the equivalence point),

$$E_e = \bar{E}_0 - RTG_e/F \quad . \quad . \quad . \quad . \quad . \quad . \quad (24)$$

$$U = F(E - E_c)/RT + (G - G_c) \quad . \quad . \quad . \quad (25)$$

where  $E_e$  and  $G_e$  are the equivalence-point values of  $E$  and  $G$ . But the difference  $(G - G_e)$  is either negligible or is made so by the application of the corrections just mentioned, so that essentially  $U$  represents distance from the equivalence point in terms of the unit  $RT/F$  ( $= 25.00$  millivolts at  $17.0^\circ$ ).

### Section 3. Characteristic Forms of the Titration Curve.

*The Electrode-valencies.*—Some examples of the curves represented by the general equation (2), are exhibited in Fig. 1. The intersection of the axes represents the point of exact equivalence, and the positive direction of  $X$  is towards the left, so that the progressive addition of the reagent is represented by moving from left to right, as is customary in titration diagrams.

The forms of the curves will be better appreciated when considered in conjunction with the corresponding curves (Fig. 2), in which  $dU/dX$  is plotted against  $X$ . It is noticeable that the maxima in Fig. 2, and correspondingly the points of inflexion in Fig. 1, do not occur at the equivalence point except in the symmetrical cases where  $\alpha = \beta$ . Actually (see Section 4) they occur where  $(\alpha + \beta)U = 2 \log (\beta/\alpha)$ . Any one of the curves in Fig. 1, when rotated about the origin through  $180^\circ$ , coincides with the curve obtained by interchanging  $\alpha$  and  $\beta$ .

The parameters  $\alpha$  and  $\beta$ , which characterise the curves, are by definition equal to the ratios  $v/a$  and  $v/b$  respectively, and from (13) and (14) it is seen that 1 g.-mol. of the titrated substance "reacts" with  $v/a$  faradays of electricity in one of the electrode reactions, while in the other, 1 g.-mol. of the reagent reacts with  $v/b$  faradays.

For instance, in a precipitation reaction, with an indicator electrode behaving as a "soluble" electrode towards either of the precipitated ions,  $\alpha$  and  $\beta$  would be the valencies of the two ions.

More generally, therefore, the term "electrode-valency" may be used to signify the number of faradays of electricity reacting with 1 g.-mol. of a given substance in a particular electrode-reaction. Thus  $\alpha$  and  $\beta$  are the electrode-valencies of A and B in this system.

In many cases, though not all, the electrode-valency is simply the ratio of the molecular weight to the equivalent weight ordinarily used in volumetric analysis. For instance, it is 5 for the permanganate ion and 1 for the ferrous ion, with a platinum electrode, the electrode reactions being

Similarly, in the iodate titration (p. 1429), equations (7) and (8) show that the electrode-valencies of the two principal reactants, iodate ion and sulphur dioxide, are respectively 5 and 2. On the other hand in Greeff's titration of fluoride ion by ferric ion, as applied potentiometrically by Treadwell and Köhl (*Helv. Chim. Acta*, 1925, 8, 500), the electrode-valency would not be equal to the ratio of the molecular weight to the ordinarily accepted equivalent weight, for here the alternative electrode reactions are

whence the electrode-valencies of ferric and fluoride ions would be 1 and  $\frac{1}{6}$ , respectively.

#### Section 4. Some Mathematical Properties of the Curves.

The curves in Fig. 1 are graphs of the function  $\sinh U$  for various assigned values of the parameters  $\alpha$  and  $\beta$ . If the positive directions of both axes of co-ordinates are reversed, the curves then represent the complementary function  $\sinh U$ , for

$$-\sinh(-U) = \frac{1}{2}(e^{\beta U} - e^{-\alpha U}) = \sinh U \quad (27)$$

Correspondingly, there are two complementary cosine functions,

$$\cosh U = \cosh(-U) = \frac{1}{2}(e^{\alpha U} + e^{-\beta U}) \quad (28)$$

and the other functions are obtained from these according to the usual conventions, e.g.,  $\tanh U = \sinh U / \cosh U$ , and  $\text{sech } U = 1 / \cosh U$ .

If, now, the purely numerical constants,  $(\alpha\beta\beta\alpha)^{1/(\alpha+\beta)}$  and  $\frac{1}{\alpha+\beta} \log\left(\frac{\alpha}{\beta}\right)$ , are represented by  $h$  and  $g$  respectively, the first

derivative of  $\frac{dU}{dX}$   $U$  (or  $dX/dU$ ) can be written in the form  $\frac{1}{\cosh(U+g)}$ , and it is the reciprocal of this, i.e.,  $dU/dX$  or  $\frac{1}{\cosh(U+g)}$ , which is plotted against  $X$  in Fig. 2. Similarly, the first derivative of  $\cosh U$  is  $\sinh(U+g)$ , and it follows that the second derivative of  $\sinh U$  is  $\cosh(U+2g)$ . Thus each curve in Fig. 1 has a point of inflexion where  $U = -2g$  and  $X = -\sinh 2g$ . This is the point of maximal slope and sensitivity (see Section 9), the maximal value of  $dU/dX$  being  $\cosh g$ . The following table shows the values of these characteristic constants for several types of curve. In the last column the quantity  $50g$  is tabulated, being the distance of the point of inflexion from the equivalence point in millivolts at  $17^\circ$  (i.e.,  $RT/F \cdot 2g$ ).

$\alpha.$	$\beta.$	$h.$	$g.$	$-X_{\text{infl.}}$	$\left(\frac{dX}{dU}\right)_{\text{min.}}$	$\left(\frac{dU}{dX}\right)_{\text{max.}}$	$E_e - E_{\text{infl.}}$
1	1	1	0	0	1	1	0
2	1	1.26	0.231	0.59 <sub>6</sub>	1.19 <sub>2</sub>	0.83 <sub>8</sub>	11.5 <sub>5</sub>
3	1	1.31 <sub>4</sub>	0.274 <sub>7</sub>	0.77	1.15 <sub>5</sub>	0.86 <sub>5</sub>	13.7 <sub>3</sub>
5	1	1.30 <sub>8</sub>	0.268 <sub>2</sub>	0.82 <sub>2</sub>	1.02 <sub>5</sub>	0.97 <sub>5</sub>	13.4
6	1	1.29 <sub>2</sub>	0.256	0.81 <sub>2</sub>	0.97 <sub>5</sub>	1.02 <sub>5</sub>	12.8
2	2	2	0	0	2	0.5	0
3	2	2.35 <sub>2</sub>	0.081 <sub>1</sub>	0.38 <sub>4</sub>	2.30 <sub>1</sub>	0.434	4.0 <sub>3</sub>
5	2	2.59 <sub>8</sub>	0.131	0.70 <sub>9</sub>	2.36	0.424	6.5 <sub>5</sub>
1	$\frac{1}{2}$	0.215 <sub>3</sub>	1.535 <sub>8</sub>	0.81 <sub>2</sub>	0.162 <sub>5</sub>	6.16	76.7 <sub>9</sub>

Interchange of the values of  $\alpha$  and  $\beta$  in any case alters the sign of  $X_{\text{ind}}$ ,  $g$ , and of  $E_e - E_{\text{ind}}$ , but makes no other difference. It is noticeable that  $\left(\frac{dX}{dU}\right)_{\min.}$ , or  $h \cosh g$ , always approximates  $\beta_\alpha$  in value to the smaller of the two electrode-valencies.

### Section 5. General Application of Method I.

Equation (2) has two limiting forms,

$$X = \frac{1}{2} e^{aU} \quad . \quad . \quad . \quad . \quad . \quad . \quad (29)$$

$$-X = \frac{1}{\beta} e^{-\beta U} \quad . \quad . \quad . \quad . \quad . \quad . \quad (30)$$

valid respectively for large positive and large negative values of  $U$ . One or other of these will be accurate to 1% as regards  $X$ , unless  $U$  lies between the limits  $\pm (\log 100)/(\alpha + \beta)$ ; and the region defined by these limits, some  $230/(\alpha + \beta)$  millivolts in extent, within which the incompleteness of the analytical reaction exceeds 1%, may be referred to as the "equivalence region." Outside this region Method I is applicable and the result of the titration

can be determined from a single change of the potential  $E$ , without knowledge of  $E_e$ ,  $\bar{E}_0$ ,  $G$ , or  $H$ , as follows.

Fully written, equation (29) is equivalent to

$$E = E_0 + \frac{RT}{\alpha F} \log \frac{nM}{V} \gamma_A \theta_A - \frac{RT}{\alpha F} \Sigma \frac{p}{a} \log C_F \gamma_F. \quad (31)$$

which is therefore valid at all points or stages outside and *before* the equivalence region. Consider two such points,  $(E, M)$  and  $(E', M')$ , separated by  $\epsilon$  millivolts and  $m$  c.c. of reagent solution (compare Part I, Section 4). Suppose that at the earlier stage,  $(E', M')$ , the amount of the (typical) subsidiary substance P in the titrated solution is  $nM_P$  mg.-equivs. [all equivalents being reckoned according to the chemical equation (12)], then if the volume of the solution is  $V'$  c.c.,

$$E' = E_0 + \frac{RT}{\alpha F} \log \frac{nM'}{V'} \gamma_A \theta_A - \frac{RT}{\alpha F} \Sigma \frac{p}{a} \log \frac{nM_P}{V'} \gamma_F. \quad (32)$$

Now, on the addition of  $m$  c.c. of the reagent solution, not only is the amount of the titrated substance diminished to  $nM$  mg.-equivs., but the volume of the solution is increased to  $V$  c.c., and also the amount of the subsidiary substance, P, is either increased or decreased by  $mn$  mg.-equivs., according as this substance is, on the whole, a product or a reactant in the analytical reaction (*i.e.*, not merely according as  $p$  is positive or negative).

At the later stage, therefore, assuming for the present (see Part I, Sections 2 and 7) that change in the adsorption and activity coefficients can be neglected,

$$E = E_0 + \frac{RT}{\alpha F} \log \frac{nM}{V} \gamma_A \theta_A - \frac{RT}{\alpha F} \Sigma \frac{p}{a} \log n \frac{M_P \pm m}{V} \gamma_F. \quad (33)$$

where  $E = (E' - \epsilon)$ ,  $M = (M' - m)$ , and  $V = (V' + m)$ . Then, by subtraction,

$$\epsilon = \epsilon_m + \epsilon_v \left( 1 - \Sigma \frac{p}{a} \right) + \Sigma \frac{p}{a} \epsilon_P \quad (34)$$

where

$$\alpha \epsilon_m = RT/F \cdot \log (1 + m/M) \quad (35)$$

$$\alpha \epsilon_v = RT/F \cdot \log (1 + m/V') = -RT/F \cdot \log (1 - m/V) \quad (36)$$

$$\alpha \epsilon_P = RT/F \cdot \log (1 \pm m/M_P) \quad (37)$$

The effect of the change in the amount of A is represented by  $\epsilon_m$ , while the effects of the simultaneous changes in the "subsidiary conditions" (the volume of the solution and the amounts of the

subsidiary substances) are represented by the remaining terms on the right of equation (34). In this sense  $\epsilon_m$  is the value of the measured potential change "corrected to constant subsidiary conditions," and the correction terms,  $\epsilon_v$ ,  $\epsilon_P$ , etc., are to be found from the tables provided in Part I (*loc. cit.*). It is obvious that, as indicated in Part I, changes in the adsorption and activity coefficients (if not negligible, as assumed) could be corrected for in an entirely similar manner. The result of the titration then follows from the relation

$$M = m \cdot f(\alpha\epsilon_m) \quad (38)$$

[see Part I, Table I and equations (22) and (26)].

In Part I, the use of the dilution term  $\epsilon_v$  is fully demonstrated, a convenient procedure being indicated in Section 12, and a type of case being discussed in Section 8, in which this correction is eliminated owing to the fact that  $\Sigma p/a$  is equal to unity. The latter section includes an example of a correction of the  $\epsilon_P$  type, P being a product of the reaction (ferrie or titanic ion). In this case, on the assumption that P is absent at the commencement of the titration,  $M_P$  is accurately known, being simply the number of c.c. of reagent solution already added before the further addition of the  $m$  c.c.

On the other hand, in many cases P will be a substance present in considerable excess,  $M_P$  will be large in comparison with  $m$ , and therefore only a rough estimate (if any) of its magnitude will be required in order to determine the very small correction,  $\epsilon_P$ . An example of this would be hydrogen ion as a subsidiary substance in most oxidation-reduction titrations. In short, it is plain that in any particular case, under suitable conditions, the correction of the measured potential changes will readily be reduced to a simple routine.

One special advantage of Method I is that it makes use of less than one half or side of the titration curve, being independent of the equivalence region as well as of all that part of the curve beyond it. This is notably useful in the titration of mixed solutions (*e.g.*, a mixture of halides), where the curves corresponding to the successive reactions overlap and truncate one another. Nevertheless, if the second half of the curve happens to be available, it may be utilised in essentially the same way, the full form of equation (30), valid here, being

$$-E = -E'_0 + \frac{RT}{\beta F} \log \frac{nM}{V} \gamma_B \theta_B - \frac{RT}{\beta F} \Sigma \frac{q}{b} \log C_c \gamma_c \quad (39)$$

If ( $E$ ,  $M$ ) and ( $E''$ ,  $M''$ ) are the two successive stages, both beyond the equivalence region, and separated by  $\epsilon'$  millivolts and  $m'$  c.c.

of reagent solution, so that  $E'' = (E - \varepsilon')$ ,  $M'' = (M - m')$ , and  $M$  is negative, we find

$$\varepsilon' = \varepsilon'_m - \varepsilon'_v (1 - \Sigma q/b) \quad . \quad . \quad . \quad (40)$$

where  $\beta \varepsilon'_v = RT/F \cdot \log (1 + m'/V) \quad . \quad . \quad . \quad (41)$

$$\beta \varepsilon'_m = RT/F \cdot \log \left( 1 + \frac{m'}{-M} \right) \quad . \quad . \quad . \quad (42)$$

and therefore  $-M = m' \cdot f(\beta \varepsilon'_m) \quad . \quad . \quad . \quad (43)$

No correction term of the  $\varepsilon_p$  (or  $\varepsilon_q$ ) type occurs here, because the chemical reaction has ceased and the *quantities* of the subsidiary substances are not changing.

It has been assumed, so far, that B is the only significant substance (apart from the solvent) introduced by means of the reagent solution. If, however, the latter contains also appreciable quantities of any of the subsidiary substances, or of compounds capable of reacting with the latter (for examples, see Section II), this merely involves obvious modifications in the form of the subsidiary-conditions correction, for it remains true, in general, that the changes in these conditions are proportional to the quantities of reagent solution added.

In using Method I, should the stage ( $E$ ,  $M$ ) be allowed to fall within the equivalence region, the result of the titration will be too high if obtained from the first half of the curve, and too low if from the second half. If  $M_{app.}$  is the erroneous value of  $M$  so found, the error in the former case is approximately  $(H/2)^{1+\beta/\alpha} / M_{app.}^{\beta/\alpha}$ , and the same with  $\alpha$  and  $\beta$  interchanged in the latter case. In either case, an alternative formulation of the error is  $M_{app.} \cdot f[(\alpha + \beta)(E \sim E_e)]$ .

Thus, approximate knowledge of *either*  $H$  or  $E_e$  would permit the correction of this error if not too large. Such procedure, of course, would really constitute a crude form of Method II.

### Section 6. General Forms of Methods II and III.

Apart from its special advantages, the absolute precision of Method I is higher than that attainable under the most favourable conditions by the customary potentiometric methods. Sometimes, however (as when dealing with unusually dilute solutions or with an analytical reaction of low inherent sensitivity), it may be desirable to seek the appreciable increase of precision which is, in general, to be obtained by making use of a stage nearer to the point of inflexion than is permissible in Method I. Of the two distinct methods of so doing, Method II makes use of only one half or side of the titration curve, but requires some knowledge of the unit  $H$ , whereas Method III requires no knowledge of  $H$  but utilises both halves of the curve. Properly applied, either method yields the highest absolute precision

obtainable with a given experimental system. Potentiometric methods of the "absolute" type (see introductory remarks in Part I) should theoretically yield the same maximal precision, but in practice this is not realised because the absolute values of the measured potential are not nearly so accurately reproducible as are the differences or changes on which alone the differential methods depend.

*Method II.*—Consider, as in the last section, two successive stages ( $E'$ ,  $M'$ ) and ( $E$ ,  $M$ ), separated by  $\epsilon$  millivolts and  $m$  c.c. of reagent solution; but suppose, now, that the second stage lies within the equivalence region, so that the limiting form (31) is not valid at this stage. Applying, instead, the general equation, we may write

$$M/H = \sinh_{\alpha\beta} U \quad . \quad . \quad . \quad (44)$$

where  $U$  is defined by equation (23).

At the earlier stage the measured potential has the value  $E'$ , or ( $E + \epsilon$ ), but this is, in effect, "corrected" to a value ( $E + \epsilon_m$ ), in the manner to be explained in the following section, whereupon both  $H$  and  $G$  may be treated as constants; hence, using the same value of  $H$  as in (44),

$$(M + m)/H = \sinh_{\alpha\beta} (U + u) \quad . \quad . \quad . \quad (45)$$

where

$$u = F/RT \cdot \epsilon_m \quad . \quad . \quad . \quad (46)$$

Now the following identity can easily be verified,

$$\sinh_{\alpha\beta} (U + u) - \sinh_{\alpha\beta} U = \sinh_{\alpha\beta} u \cdot \cosh_{\alpha\beta} (U + \phi) \cdot \operatorname{sech}_{\alpha\beta} \phi \quad (47)$$

where  $(\alpha + \beta)\phi = \log \frac{1 + f(\beta\epsilon_m)}{f(\alpha\epsilon_m)} \quad . \quad . \quad . \quad (48)$

or, for large values of  $\epsilon_m$ ,

$$(\alpha + \beta)\phi \approx \alpha u + f(\beta\epsilon_m) - f(\alpha\epsilon_m) \quad . \quad . \quad (49)$$

$$\approx \alpha u \quad . \quad . \quad . \quad (50)$$

Thus, if equation (48) is written in the form

$$\operatorname{sech}_{\alpha\beta} (U + \phi) = (H/m) \sinh_{\alpha\beta} u \cdot \operatorname{sech}_{\alpha\beta} \phi \quad . \quad (51)$$

and coupled with equation (44), it is apparent that when  $m$  and  $\epsilon$  have been measured and  $H$  is known,  $M$  may be obtained by the use of a parallel table of the functions  $\sinh_{\alpha\beta}$  and  $\operatorname{sech}_{\alpha\beta}$  in a manner essentially similar to that described in Part II (pp. 862, 863). The corresponding curves shown in Figs. 1 and 2 would be a (less accurate) substitute for such tables since there is no objection to dividing both sides of equation (51) by  $h$ . Alternatively, of course, suitable

diagrams, after the manner of those shown in Part II (Figs. 1 and 2), could be constructed.

*Method III.*—Introducing a third and later stage ( $E''$ ,  $M''$ ) beyond the equivalence region and separated from the second stage by  $\epsilon'$  millivolts and  $m'$  c.c. of reagent solution, and supposing as before that the correction of Section 7 is applied, the measured potential ( $E - \epsilon'$ ) being corrected to ( $E - \epsilon'_m$ ), then we have

$$(M - m')/H = \sinh \frac{(U - u')}{\alpha\beta} \quad . \quad . \quad . \quad (52)$$

where

$$u' = F/RT \cdot \epsilon'_m \quad . \quad . \quad . \quad (53)$$

Between the three equations (44), (46), and (53), both  $H$  and  $U$  can be eliminated, and the following exact equation obtained,

$$M = \frac{m \operatorname{cosech} \frac{u}{\alpha\beta} - m' \operatorname{cosech} \frac{u'}{\beta\alpha}}{\coth \frac{u}{\alpha\beta} + \coth \frac{u'}{\alpha\beta} - \operatorname{cosech} \frac{u}{\alpha\beta} - \operatorname{cosech} \frac{u'}{\beta\alpha}} \quad . \quad (54)$$

For large values of  $u$  and  $u'$ , such as will in practice be used, equation (54) can be reduced to the much more convenient approximate form

$$M_{app} = m \cdot f(\alpha\epsilon_m) - m' \cdot f(\beta\epsilon'_m) \quad . \quad . \quad . \quad (55)$$

The error involved in this approximation is of the order of magnitude of

$$(m - m' + 2M_{app}) \cdot f(\alpha\epsilon_m + \beta\epsilon'_m) \quad . \quad . \quad . \quad (56)$$

and so is negligible when  $\epsilon_m$  and  $\epsilon'_m$  are both large.

Equations (29) and (30) of Part II are complicated by the terms involving  $V$  which there represent (approximate) allowance for volume change, but on omitting these terms and (in compensation) altering  $\epsilon$  and  $\epsilon'$  to  $\epsilon_m$  and  $\epsilon'_m$ , we see that these equations represent the special case where  $\alpha = \beta = 1$  (see examples in Section 7).

### Section 7. Correction for Variation in $H$ and $G$ .

It is essential to the increased precision of Methods II and III, as compared with Method I, that the stage ( $E$ ,  $M$ ) should lie within the equivalence region, so that equation (33), for example, no longer holds good. Nevertheless, the additive corrections (described in Section 5) for change in the subsidiary conditions are still essentially valid, being equivalent in effect to making  $H$  and  $G$  constant, with the values they attain at the stage ( $E$ ,  $M$ ). For, consider again the stage ( $E'$ ,  $M'$ ) which is outside and before the equivalence region, so that equation (32) still applies. If, now, without altering the amount ( $nM$  mg.-equivs.) of the titrated substance, we could alter the subsidiary conditions, the volume from  $V'$  to  $V$ , and the amount

of the subsidiary substance P from  $nM_P$  to  $n(M_P \pm m)$  mg.-equivs., etc., it is obvious that  $E'$  would be altered to

$$E'(\text{corr.}) = E' - \varepsilon_v \left(1 - \frac{\Sigma p}{a}\right) - \frac{\Sigma p}{a} \varepsilon_P \quad . \quad . \quad (57)$$

where  $\varepsilon_v$  and  $\varepsilon_P$  are defined by equations (36) and (37). Now, at the stage ( $E, M$ ) the subsidiary conditions *actually* are  $V$ , and, to a close approximation,  $n(M_P \pm m)$ , etc., the error of the latter approximation (due to the incompleteness of the analytical reaction) being only  $\frac{1}{2}nH\epsilon^{\beta U}$ , which may be neglected in comparison with  $nM_P$ . In other words,  $E'(\text{corr.})$  is the value the potential would possess at the stage ( $E', M'$ ) *if the subsidiary conditions (and therefore H and G) had those values which they actually attain at the stage ( $E, M$ )*.

Since  $E' = (E + \varepsilon)$ , we may write

$$E'(\text{corr.}) = (E + \varepsilon_m) \quad . \quad . \quad . \quad (58)$$

where  $\varepsilon_m$  is defined by equation (34). In an exactly similar manner, it can be shown that if  $\varepsilon'_m$  is defined by equations (40) and (41), the value which the potential would possess at the stage ( $E'', M''$ ) (which is *beyond* the equivalence region), if  $H$  and  $G$  still had those values which they actually attained at the stage ( $E, M$ ), is

$$E''(\text{corr.}) = (E - \varepsilon'_m) \quad . \quad . \quad . \quad (59)$$

In applying these corrections, it is usually convenient to adopt the procedure indicated in Part I, Section 12, correcting the measured potentials to some simple round value of each subsidiary condition. It is true that such correction is artificial as applied to the stage ( $E, M$ ) because the latter is in the equivalence region, and the corrected value of  $E$  will not be the value it would attain if the subsidiary conditions were altered to the stated round values. Nevertheless, if  $E$  is corrected in the same manner as  $E'$ , the difference between these corrected values will be  $\varepsilon_m$ , as defined above. And similarly, if  $E$  is corrected in the same manner as  $E''$ , *i.e.*, as if it were *beyond* the equivalence region, then the difference between the corrected  $E$  and  $E''$  will be  $\varepsilon'_m$  as defined above.

For example, take the simple case of the chloride titrations recorded in Part II (p. 868). As explained there, the *E.M.F.* of the silver chloride-quinhydrone cell used is doubly affected by dilution when the chloride is in marked excess, and is unaffected by dilution when the silver ion is in excess. In this case, therefore, equations (34) and (40) assume the special forms

$$\begin{aligned}\varepsilon_m &= \varepsilon - (2RT/F) \cdot \log V/V' \\ \varepsilon'_m &= \varepsilon'\end{aligned}$$

Now if  $E'$  is corrected to some convenient volume, such as 100 c.c., it becomes (say)  $E'_a$  by addition of a correction of the first form,

$$\text{Corr. (a)} = (2RT/F) \cdot \log V'/100 \quad (60)$$

$$E'_a = E' + (2RT/F) \cdot \log V'/100 \quad (61)$$

and if  $E$  is "corrected" in the same manner,

$$E_a = E + (2RT/F) \cdot \log V/100$$

then, by subtraction,

$$E'_a - E_a = \varepsilon - (2RT/F) \cdot \log V/V' = \varepsilon_m.$$

On the other hand,  $E''$  is corrected to any convenient volume by the addition of a different form of correction, which in this particular case is zero,

$$\text{Corr. (b)} = 0 \quad (62)$$

$$E''_b = E'' \quad (63)$$

and, of course, on "correcting"  $E$  in the same way and subtracting,

$$E_b - E''_b = \varepsilon' = \varepsilon'_m.$$

For the sake of comparison, two of the titrations recorded in Part II (Examples 1 and 2, p. 868) are worked out below according to the newer and generally applicable procedure, which will be seen to be also much simpler arithmetically. In order to make the examples more generally illustrative, the second form of correction [Corr. (b)] is explicitly stated and applied, although in this special case it happens to be zero throughout.

*Example 1.* 1000 C.c. of  $N/1000\text{-KCl}$  titrated by  $N/100\text{-AgNO}_3$  (actually known to be equivalent to 98.5 c.c. of  $\text{AgNO}_3$ , but titrated as if only known to be stronger than  $N/2000$ ); temp.  $\approx 14.5^\circ$ .

The application of Method III begins at Stage II, when 85 c.c. of silver nitrate have already been added in applying Method I. The latter method having shown that between 13 and 14 c.c. are still required to reach equivalence, two successive additions of 13 c.c. and 12 c.c. respectively are made, and the potentials at Stages III and IV measured. The three measured potentials are corrected to  $17^\circ$ , and then the first and second are corrected to 1000 c.c. volume in the manner (a) [see equations (60) and (61)], and the second and third to any convenient volume in the manner (b) [see equations (62) and (63)], and  $\varepsilon_m$  and  $\varepsilon'_m$  are obtained by subtraction.

Stage.	$V$ 1000	Corr. (a).	Corr. (b).	$E$ (expt.).	$E_{17^\circ}$ .	$E_a$ .	$E_b$ .
II	1.085	4.0 <sub>5</sub>		172.2	173.6 <sub>5</sub>	177.7	
III	1.098	4.6 <sub>5</sub>	0	118.1	119.1	123.7 <sub>5</sub>	119.1
IV			0	58.3	58.8		58.8
				By subtraction		53.9 <sub>5</sub>	60.3

Then, to find  $M$  at Stage III, and hence  $M_0$  :

$$\begin{array}{llll} m = 13 & \epsilon_m = 53.9_5 & f(\epsilon_m) = 0.130_2 & m \cdot f(\epsilon_m) = 1.69_3 \\ m' = 12 & \epsilon'_m = 60.3 & f(\epsilon'_m) = 0.098_8 & m' \cdot f(\epsilon'_m) = 1.18_3 \end{array}$$

By subtraction,  $M = 0.51$   
and by addition of 98.0,  $M_0 = 98.51$

*Example 2.* 100 C.c. of  $N/1000\text{-KCl}$  titrated by  $N/1000\text{-AgNO}_3$  (actually known to be equivalent to 98.5 c.c. of  $\text{AgNO}_3$ , but titrated as if only known to be stronger than  $N/4000$ ); temp.  $\sim 20^\circ$ .

The procedure is essentially as in Example 1, except that two stages (III and IV) within the equivalence region are used, in turn, as the stage ( $E$ ,  $M$ ), so that two results are obtained which are then averaged.

For the purpose of the dilution correction, 100 c.c. is taken as a convenient round value of the volume.

Stage.	$\frac{V}{100}$	Corr. (a).	Corr. (b).	$E$ (expt.).	$E_{17.5}$	$E_a$	$E_b$
II	1.75	28.0		190.4	188.5	216.5	
III	1.96	33.6 <sub>5</sub>	0	139.8	138.4	172.0 <sub>5</sub>	138.4
IV	2.00	34.6 <sub>5</sub>	0	120.5	119.3	153.9 <sub>5</sub>	119.3
V			0	68.4	67.7		67.7
By subtraction							
						$\begin{cases} 44.4_5 \\ 62.5_5 \end{cases}$	$\begin{cases} 70.7 \\ 51.6 \end{cases}$

(i) To find  $M$  at Stage III, and hence  $M_0$  :

$$\begin{array}{llll} m = 21 & \epsilon_m = 44.4_5 & f(\epsilon_m) = 0.2034 & m \cdot f(\epsilon_m) = 4.27_1 \\ m' = 29 & \epsilon'_m = 70.7 & f(\epsilon'_m) = 0.0629 & m' \cdot f(\epsilon'_m) = 1.82_4 \end{array}$$

By subtraction,  $M = 2.45$   
By adding 96.0,  $M_0 = 98.45$

(ii) To find  $M$  at Stage IV, and hence  $M_0$  :

$$\begin{array}{llll} m = 25 & \epsilon_m = 62.5_5 & f(\epsilon_m) = 0.0892_8 & m \cdot f(\epsilon_m) = 2.23_1 \\ m' = 25 & \epsilon'_m = 51.6 & f(\epsilon'_m) = 0.1454 & m' \cdot f(\epsilon'_m) = 3.63_5 \end{array}$$

By subtraction,  $M = -1.40$   
By adding 100.0,  $M_0 = 98.60$   
Average of two results in Example 2,  $M_0 = 98.52_5$ .

In Example 2, the values of Corr. (a) are seen to be large, but this does not mean that it will be liable to introduce appreciable errors into the result of the titration, or that the subsidiary condition  $V$  needs to be very accurately known, for it is only the *change* in Corr. (a)—amounting to 6.65 millivolts in all—which affects the corrected difference  $\epsilon_m$ .

### Section 8. Complete Temperature Correction.

If, as in the above examples, the measured potentials are multiplied by  $(290/T)$ , this has the effect of multiplying the differences  $\epsilon$  and  $\epsilon'$  by the same factor, which makes allowance for the fact that the unit  $(RT/F)$  is proportional to the absolute temperature.

This is all that is required so long as the temperature does not vary much during a titration.

In working at temperatures other than "room temperature," however, considerable fluctuations are not easily avoided under practical conditions for titration. Even if a thermostat is used it is very troublesome to keep the reagent at the same temperature, while, if it is not so kept, time is lost after each addition in waiting for temperature equilibrium. It is therefore quicker and simpler to make no attempt to maintain a fixed temperature, but to read the thermometer at each stage and apply a complete temperature correction in the following manner.

For such variation as will occur during a titration both  $E_0$  and  $E'_0$  may be assumed to depend linearly on the temperature. This means that if the temperature coefficient of the potential  $E$  is measured at *any* stage outside the equivalence region, the quantity  $(E - T \cdot dE/dT)$  will be found to possess one or other of two values, say  $E_{00}$  and  $E'_{00}$ —the former at any stage *before* the equivalence region, the latter at any *beyond* it. Two such measurements will therefore suffice to determine these two constants, which are all that we require for the purpose of the complete temperature correction.

If  $T'$ ,  $T$ , and  $T''$  are the temperatures of the system at the successive stages  $(E', M')$ ,  $(E, M)$ , and  $(E'', M'')$  in Method III, it is easily shown that when the potential changes,  $\epsilon$  and  $\epsilon'$ , are corrected for the *variation* of temperature during titration, as well as for the value of the unit,  $RT/F$ , they become

$$\epsilon_{17} = 290(E' - E_{00})/T' - 290(E - E_{00})/T \quad . \quad (64)$$

$$\epsilon'_{17} = 290(E - E'_{00})/T - 290(E'' - E'_{00})/T'' \quad . \quad (65)$$

so that for differential purposes  $290(E' - E_{00})/T'$  and  $290(E'' - E'_{00})/T''$  may be used as temperature-corrected values of  $E'$  and  $E''$  respectively, while  $E$  has two such values—one  $290(E - E_{00})/T$ , as if it were *before* the equivalence region, and the other  $290(E - E'_{00})/T$ , as if it were *beyond* that region. There is here an obvious analogy in principle with the procedure discussed in the latter part of Section 7. If  $\epsilon_{17}$  is re-written in the form

$$\epsilon_{17} = \frac{290}{T} \left[ \left\{ \frac{T}{T'} (E' - E_{00}) + E_{00} \right\} - E \right] \quad . \quad (66)$$

its derivation will be obvious, and it will be seen that the accuracy of the correction depends on the assumption that  $(E' - E_{00})$  is proportional to the absolute temperature over some range including  $T$  and  $T'$  *but not necessarily including*  $290^\circ$  Abs. That it does not

depend on accurate knowledge of  $E_{00}$  will be seen if  $\varepsilon_{17}$  is again re-written as

$$\varepsilon_{17} = \frac{290}{T'} E' - \frac{290}{T} E + \left( \frac{290}{T} - \frac{290}{T'} \right) E_{00} \quad (67)$$

since the coefficient of  $E_{00}$  is small. Similar considerations apply to  $\varepsilon'_{17}$ .

### Section 9. Precision of the Generalised Method.

Writing  $U'$  for  $(U + u)$ , and using the abbreviations  $\Delta \operatorname{sech}$  and  $\Delta \tanh$  for the positive differences  $[\operatorname{sech}_{\alpha\beta}(U + g) - \operatorname{sech}_{\alpha\beta}(U' + g)]$  and  $[\tanh_{\alpha\beta}(U' + g) - \tanh_{\alpha\beta}(U + g)]$  respectively, we may formulate the error  $dM$  of a titration by Method II as follows :

$$-dM = \frac{Hh}{\Delta \operatorname{sech}} du + \frac{\Delta \tanh}{\Delta \operatorname{sech}} (\cosh g)_{\beta\alpha} dH \quad (68)$$

where  $du$  and  $dH$  represent (small) errors in  $u$  and  $H$ . Under the conditions of highest sensitivity, when  $U \approx -2g$  and  $u$  is large, this reduces to

$$-\frac{dM}{h \cdot \cosh g}_{\beta\alpha} \approx H \cdot du + \frac{dH}{\beta} \quad (69)$$

and it has been seen (Section 4) that  $h \cdot \cosh g$  is approximately equal to the smaller of the two electrode-valencies.

Similarly, writing  $U''$  for  $(U - u')$ , and  $\Delta' \operatorname{sech}$  and  $\Delta' \tanh$  for the analogous positive differences, due regard being paid to the fact that  $u$  and  $u'$  have opposite signs, we derive the following equation for the error of a titration by Method III :

$$\frac{dM}{Hh} \left[ \frac{\Delta \operatorname{sech}}{\Delta \tanh} + \frac{\Delta' \operatorname{sech}}{\Delta' \tanh} \right] = \frac{du'}{\Delta' \tanh} - \frac{du}{\Delta \tanh} \quad (70)$$

which is the generalised form of equation (37) of Part II.

Under optimum conditions, when  $U \approx -2g$  and both  $u$  and  $u'$  are large, equation (70) reduces to

$$\frac{dM}{Hh \cosh g} \approx \frac{\alpha du' - \beta du}{\alpha + \beta} \quad (71)$$

showing that (under these conditions) equal and opposite errors in  $u$  and  $u'$  will have the same effect as a single error of the same magnitude as either in  $u$  in Method II. The precision of Method II, however, depends also on the correctness of the value assigned to  $H$ . Thus from equation (69),  $-\partial M / \partial H$  would be approximately equal to either unity or  $\alpha/\beta$  according as  $\alpha$  is greater or less than  $\beta$ , i.e., it would not be greater than unity and might be much less.

Of course, Method II, like Method I, can be applied to the second half of the curve if this is available. For this case equation (68) would be modified in an obvious manner, and instead of equation (69) we should have

$$\frac{dM}{h \cosh g_{\beta a}} \approx H \cdot du' + \frac{dH}{\alpha} \quad (72)$$

showing that the maximal sensitivity is the same, but  $\partial M / \partial H$  is now (approximately) equal to either unity or  $\beta / \alpha$ .

### Section 10. An Alternative Geometrical Form of Method I.

*The Straight-line Method.*—If, as in Section 7,  $E_a$  represents the value of the measured potential when “corrected” in the manner proper to any stage before the equivalence region, then equation (31) is equivalent to  $E_a = \text{constant} + RT / \alpha F \cdot \log M$ . The (unknown) constant may be written in the form  $-RT / \alpha F \cdot \log k$ , and  $E_a$  in the substituted form  $RT / \alpha F \cdot \log y$ , whereupon the equation reduces to  $ky = M = M_0 - (M_0 - M)$ , where  $y$  is equal to  $e^{(\alpha F / RT) E_a}$ .

If, then, the corrected potential at each stage is plotted on a suitable *exponential scale*, against the number of c.c. of reagent present, the successive points *will lie on a straight line*, which cuts the axis at a point indicating the result of the titration. Thus two points or stages suffice to determine the result (the more accurately if they are well separated), but also, owing to the exponential scale, it will be found that the determination becomes very much more certain as the final measurement more nearly approaches the equivalence point, provided always that it do not fall within the equivalence region. All this corresponds exactly with the conditions of precision in the ordinary or algebraic form of the method.

The geometrical form, however, provides a useful general method for investigating new or uncertain systems, since if a number of points are plotted (instead of merely two) their adherence to a straight line is a strong indication, amounting almost to conclusive proof, that equilibrium conditions are being realised.

A suitably graduated scale is easily constructed. The distances being proportional to  $e^x$ , the graduations are placed at convenient intervals of  $(RT / \alpha F)x$  [or, for  $17^\circ$ ,  $(25 / \alpha)x$ ] and numbered consecutively in millivolts, *commencing with any convenient number*. The test and the certainty of the result can be improved if the second half of the titration curve is available, for, corresponding to this, a second straight line should be obtainable, passing through the same end-point, the equation being  $k'y' = (M_0 - M) - M_0$ , where  $y' = e^{-(\beta F / RT) E_b}$ .

Section 11. *Importance of the Symmetrical Case.*

*Application in Acidimetry and Alkalimetry.*—It will be noticed that, even in the symmetrical case where  $\alpha = \beta$ , the titration-curve equation and the methods dependent on it are now much more general in application than those obtained in Part II, since the latter took no account of subsidiary reactants and products. For example, with the new equation, and the general form of subsidiary-conditions correction described in Section 7, the following important cases can be dealt with in a simple manner.

*Case (1).* In the titration of a *weak base* (such as ammonia) against a strong acid, the former being the added substance, the equation for the analytical reaction is properly written

( $K$  being *ca.*  $5 \times 10^{-10}$ , *i.e.*,  $10^{-14}/2 \times 10^{-5}$  or  $K_w/K_b$ ) and if a hydrogen electrode or its equivalent is used as indicator electrode, the alternative electrode reactions are

The principal reactants are, in effect, hydrogen ion and the base, the amount of hydroxyl ion present being relatively quite negligible until far beyond the equivalence region, unless excessively dilute solutions are being used.

*Case (2).* Exactly the same equations are applicable to the titration of a *strong base* against a strong acid *in the presence of an appreciable amount of a salt of a weak base*, for in that case, owing to the weakness of the base, the addition of hydroxyl ions (*i.e.*, the strong base) is exactly the same in effect as adding an equivalent quantity of the *weak base* and, at the same time, withdrawing an equivalent quantity of the positive ion of its salt, thus

The additional molecule of water makes no difference, while the withdrawal of the positive ion only affects the form of the subsidiary-conditions correction.

*Case (3).* The titration of a *salt of a weak acid* against a strong acid is really entirely analogous to Case (1), the negative ion of the salt behaving essentially like the weak base. For example, with borax (which in solution is essentially  $\text{NaH}_2\text{BO}_3$  mixed with an equimolar quantity of free boric acid) the analytical reaction is

( $K$  being *ca.*  $10^{-9}$ ) and the electrode reactions are

The principal reactants are hydrogen ion and the dihydrogen-borate ion, and it is only an incidental matter affecting the form of the subsidiary-conditions correction that, in this particular case, an equivalent amount of free boric acid accompanies the added substance.

*Case 4.* From the same analogy, it follows that the equations of Case (3) are applicable to the titration of a strong base against a strong acid *in the presence of an appreciable amount of a weak acid*. The addition of the hydroxyl ion is exactly the same in effect as adding an equivalent quantity of the negative ion of the weak acid, and at the same time withdrawing an equivalent quantity of the weak acid itself :

and the latter withdrawal merely modifies the subsidiary-conditions correction.

Finally, four cases analogous to the above are obtained on interchanging the words "acid" and "base," making obvious equivalent alterations with regard to the ions, and adopting as indicator electrode either the hydrogen electrode or any other which behaves *in alkaline solution* as a "hydroxyl electrode." Treated in this manner, the eight cases are seen to be essentially one and the same, and the equations of this section, taken in conjunction with the preceding general theory, show how these common titrations of acidimetry and alkalimetry may be made to yield the highest possible precision.

#### *Summary.*

It is shown that both the titration-curve equation and the new methods of titration given in two previous papers can be fully generalised, *i.e.*, made applicable to a system involving both analytical and electrode reactions of the most general type.

The characteristic forms of the curves represented by the generalised equation, and of the derived curves, are indicated with the aid of diagrams, and some concrete examples cited. The more important mathematical properties of the curves are exhibited, the generalised methods of titration deduced, and their precision formulated, in terms of certain bin-exponential functions, regarded as generalised hyperbolic functions. Methods I and III, however, still involve only the single function, *f*, tabulated in the first of this series of papers.

A routine procedure previously indicated is now more fully developed, whereby, in connexion with all three methods, accurate allowance is made for unavoidable variations in the subsidiary conditions, *i.e.*, the volume of the solution and the concentrations

of subsidiary reactants and products. A simple mode of correction is also provided for any unavoidable *fluctuations* of temperature.

In Section 10, a *geometrical* form of Method I is outlined (a "straight-line method"), suitable for the investigation of new and uncertain systems, since it provides a stringent test as to the attainment of equilibrium in the system.

Finally, the advantage of the more general form of the titration-curve equation, even in the symmetrical case, is pointed out and exemplified by its application to the titrations of acidimetry and alkalimetry involving weak acids, weak bases, and their salts.

I have pleasure in thanking Messrs. F. H. Brooks and A. H. Richards for assistance in the construction of the diagrams which accompany this paper.

# CLXXXVI.—*Colloidal Platinum. Part VII. The Effect of Electrolytes upon the Cataphoretic Velocity of Platinum Particles, and its Bearing on Stability.*

By STUART W. PENNYCUICK.

THE electric charge is being increasingly recognised as the controlling factor in the stability of hydrophobic sols. In this paper a comparative study is made of the effect of various electrolytes upon the cataphoretic velocity of platinum particles, and upon the corresponding changes in stability. Owing to the remarkable influence of traces of certain electrolytes, it is necessary to have trustworthy details regarding, first, the purity of the preparation, and secondly, the constitution of the surface ionogen whose ionisation confers the stabilising charge. From this point of view colloidal platinum is seen, from the author's previous work, to be particularly suitable. As will be shown, the velocity measurements confirm the conclusions already drawn regarding the action of acids (J., 1929, 618) and of bases (*ibid.*, p. 623) on this colloid.

The methods of obtaining the colloid charge and the electrokinetic potential are limited to observations of the electrokinetic phenomena. Of these, cataphoresis is outstanding, and accordingly considerable attention has been paid in recent years to the accurate measurement of cataphoretic velocities (see reviews by Tuorila, *Kolloid-Z.*, 1928, 44, 11, and by Pauli and Valkó, "Elektrochemie der Kolloide," Wien, 1929, pp. 149 and 202).

In this work, the author has utilised the macroscopic moving-

boundary method, as developed by Burton (*Phil. Mag.*, 1906, **11**, 436) and improved by Landsteiner and Pauli (*Verh. d. Kongr. f. innere Medizin*, XXV Kongress, Wien, 1908) and by Mukherjee (*Proc. Roy. Soc.*, 1923, *A*, **103**, 102). The technical errors arising from this method have been discussed by Mukherjee and by Kruyt and van der Willigen (*Kolloid-Z.*, 1928, **44**, 22), who have shown that extreme precautions are necessary if trustworthy results are to be obtained, and that the common practice of using, as the overlying liquid, any electrolyte having the same conductivity as the sol, is by no means satisfactory. During migration, if the colloid particles move into a slightly different environment, important changes occur which result in velocity fluctuations. It is obvious that the ideal overlying liquid would be the intermicellar fluid; Kruyt and van der Willigen (*loc. cit.*) have attempted to isolate such a liquid by subjecting portions of the sol to centrifuging and ultra-filtration, whereas Powis (J., 1916, **109**, 734) used the clear solution obtained by filtering a coagulated sol. The majority of workers, however, have been satisfied to use comparable solutions of potassium chloride or of hydrochloric acid. The author has shown (J., 1928, 2108) that, in the case of colloidal platinum, the intermicellar liquid can be isolated by freezing out the colloid particles. If this liquid is used as the overlying fluid, therefore, these particles suffer no material change in environment during the whole of their movement, and it is believed that by this device and by the exercise of the precautions now outlined, the nearest approach yet recorded to the ideal conditions has been made.

The moving boundary between the dark brown platinum sol and the clear overlying liquid is well defined, and can be followed with accuracy.

#### EXPERIMENTAL.

The mode of preparation of a sol has a direct influence on its charge and on its cataphoretic velocity. Accordingly, the various samples of colloidal platinum were prepared in exactly the same way (*Australian J. Exp. Biol. Med. Sci.*, 1927, **4**, 99), the following being the details: voltage 200, current 3.5 amps., sparking time (continuous) 18 minutes per 500 c.c. of water. After preparation, the sol was boiled for 25 minutes and stored for two days. The samples used had specific conductivities ( $\kappa$ ) ranging from 10 to 15 gemmhos (see Table I).

For the measurement of cataphoretic velocities, a modified Landsteiner-Pauli apparatus was used throughout. It was thoroughly cleaned before each determination. As the results with sodium hydroxide are of great importance, and as measurements with bases are often avoided, the method of making cataphoretic

measurements in the absence of carbon dioxide is described. Samples of the platinum sol and of the intermicellar fluid (frozen sol) are brought into two conductivity cells of low cell constant. The intermicellar fluid, which has the higher conductivity (owing to previous boiling and evaporation), is diluted with conductivity water until it shows the same specific conductivity as the platinum sol. The required amount of sodium or barium hydroxide is introduced into each cell in the absence of carbon dioxide (J., 1927, 2600), and the conductivities are brought to exactly the same values: as the platinum particles remove some of the base, the colloid solution requires more alkali than the sample of intermicellar fluid, and hence it is not sufficiently accurate simply to add equal quantities of base to the two solutions. The solutions are then introduced into the cataphoresis tube shown in Fig. 1. To keep the solutions carbon-dioxide free, the air-tight connexions *A*, *B*, *C*, and *D* are fitted. The apparatus, previously washed with conductivity water, is dried by passing a warm carbon dioxide-free air stream in at *E* and out through bubblers at *F* and *G*. The conductivity cells are fitted with tubes so that the solutions can be blown into the cataphoresis apparatus under a small head of carbon dioxide-free air. The platinum sol is introduced at *G*, until it rises 1 mm. or so above the taps, whilst the overlying solution is introduced at *E*. By careful manipulation the transference may be accomplished without any contamination whatsoever with carbon dioxide.

When acids and salts are to be used, simplifying modifications at once suggest themselves. In preparing comparable solutions in the presence of salts, the knowledge of the surface actions as previously developed (J., 1929, 618) was always utilised with the object of providing a perfectly uniform environment for the

TABLE I.

moving particles. In all cases the solutions were prepared in the conductivity cells, and then transferred to the apparatus.

*Results.*—The distance between the electrodes was 74 cm., and the voltage 135 (less in a few cases). Each result is the average of several determinations. The error is of the order 6–7%, which is considered satisfactory for this type of measurement. Unless

FIG. 2.

otherwise stated, all velocity values recorded are negative, this sign being omitted for the sake of convenience.

The results for the pure platinum sols are set out in Table I, and curves for sols containing this and other electrolytes appear in Fig. 2.

*Interpretation of Results.*—The criticisms of McBain (*J. Physical Chem.*, 1924, 28, 706), Burton (*Colloid Symposium Monographs*, 1926, 4, 132), and Kruyt and van der Willigen (*Z. physikal. Chem.*,

1927, 130, 170) undoubtedly show that the theoretical relation between cataphoretic velocity and electrokinetic potential, which was developed some 30 years ago, rests upon very insecure grounds. Nevertheless, because of convenience and long usage, practically every investigator in this field prefers to interpret cataphoretic results in terms of electrokinetic potential  $\zeta$ .

In this paper the cataphoretic velocities ( $u$ ) themselves are recorded, and it is these which are stressed, but for the sake of comparison the  $\zeta$  values also are recorded. As colloidal platinum particles are spherical (Diesselhorst and Freundlich, *Physikal. Z.*, 1916, 17, 117), the usual Helmholtz-Smoluchowski equation,  $\zeta = 4\pi\eta u/DH$ , must be replaced by the corrected equation  $\zeta = 6\pi\eta u/DH$  (Debye and Hückel, *ibid.*, 1924, 25, 49). For the dilute solutions of electrolytes used,  $\eta$  may be taken as the viscosity of water (0.00893 at 25°), and  $D$  as 81, the dielectric constant of water;  $\zeta$  and  $u/H$  then become proportional and the equation may be written  $\zeta = (6\pi\eta/D) (u/H) = ku/H$ . In this paper  $u$  is always given as the velocity (cm. per sec.) for a potential gradient of 1 volt per cm., whence  $H = 1$ , and  $\zeta = ku$ . The value of the proportionality factor  $k$  is 187.1. The  $\zeta$  values so calculated are shown in Fig. 2 and in the table.

### Discussion of Results.

*The Pure Sols.*—The cataphoretic velocities of the pure sols, as shown in Table I, exhibit variations in spite of the similarity of the method of preparation. For the boiled sols,  $u \times 10^5$  ranges from 27.8 to 37.0 cm./sec./volt/cm. The free acid content, as obtained from the specific conductivity [assumed all to be due to  $\text{H}_2\text{Pt}(\text{OH})_6$ ], ranges from  $28 \times 10^{-6}$  to  $43 \times 10^{-6}$  equiv. The source of charge is undoubtedly the platinic acid, but it is evident from the irregularity of the figures that no simple relationship holds between cataphoretic velocity and concentration of free acid. The unboiled sols have the smallest acid content but the greatest velocities; and as the acid content increases (by boiling or ageing), the charge as revealed by cataphoretic velocity decreases. The absence of the simple relation between velocity and acid concentration which will be shown to hold for the surface-inactive acids, such as hydrochloric and nitric, is evidently due to the surface activity of the  $\text{Pt}(\text{OH})_6$  anion. An increase in the  $\text{H}_2\text{Pt}(\text{OH})_6$  concentration then has a double effect: the hydrogen ion decreases the surface ionisation, whilst the  $\text{Pt}(\text{OH})_6$  ion increases the number of surface ionogens and hence the charge. The total action is complicated by the changes in surface area, state of aggregation, etc., which must occur when the sol is boiled or aged.

The results recorded for  $u \times 10^5$  by other workers with pure platinum (Bredig) sols are 30 (Whitney and Blake, *J. Amer. Chem. Soc.*, 1904, **26**, 1339), 21 (Burton, *Phil. Mag.*, 1906, **11**, 425), 24 (Svedberg, *Nova Acta Upsala*, 1907, [IV, 2] 190), and 20–40 (Cotton and Mouton, *Compt. rend.*, 1904, **138**, 1692). Although all the results are very roughly of the same order of magnitude, variations would be expected for the reasons outlined above. (For comparison with other sols, see Pauli and Valkó, *op. cit.*)

*The Critical Potential.*—The idea that all coagulations occur at a critical potential (critical velocity) was developed by Powis (*loc. cit.*; *Z. physikal. Chem.*, 1915, **89**, 186), using oil drops and arsenious sulphide sols. The negative results of Mukherjee (*Nature*, 1928, **122**, 960), the confirmatory results of Kruyt and Briggs (*Proc. K. Akad. Wetensch. Amsterdam*, 1929, **32**, 384) and of Ghosh (J., 1929, 2693), and the indefinite conclusions of Tuorila (*Koll.-Chem. Beih.*, 1928, **27**, 44) and of Kruyt and van der Willigen (*loc. cit.*) leave the question open as to whether the critical potential has any general significance.

From the results now recorded, it is evident (i) that coagulation always occurs before the cataphoretic velocity has been depressed to zero, and (ii) that with hydrochloric acid, barium hydroxide, barium chloride, ferric chloride, and calcium chloride (not shown), coagulation occurs at a velocity between  $10 \times 10^{-5}$  and  $15 \times 10^{-5}$ . Hence with these electrolytes we may speak of a critical velocity (or potential). On the other hand, sodium chloride and hydroxide and potassium chloride (not shown) show coagulation velocities of quite a different order. These conclusions are in general accord with those of Powis and of Ghosh (*loc. cit.*) on arsenious sulphide, and of Freundlich and Zeh (*Z. physikal. Chem.*, 1925, **114**, 65) on both arsenious sulphide and ferric hydroxide sols. There appears to be strong evidence for the view that, with electrolytes which coagulate at low concentrations, a critical potential exists below which the sols are unstable, but that where a large concentration of electrolyte is required, coagulation occurs at a much higher potential.

*Hydrochloric Acid.*—It has been established that colloidal platinum is an acidoid sol, and that the ionisation of the surface hexahydroxyplatonic acid is the source of charge and of stability. Coagulation by surface-inactive acids, such as the common inorganic acids, is then interpreted as due to the repression of the surface ionisation or of the ionic double layer. The slope of the hydrochloric acid curve (Fig. 2) is in keeping with this view. Further confirmation is at hand, for, by the application of the Debye-Hückel theory (*Physikal. Z.*, 1923, **24**, 185), it follows that

if no abnormalities occur, the addition of an electrolyte should cause a decrease in the velocity which is directly proportional to the square root of the concentration, and actually when these two variables are plotted against one another, the curve (Fig. 3) shows that the linear relationship holds.

These conclusions are in agreement with the results obtained with the acidoid mastic sol, where it has been shown that coagulation by inorganic acids is a plain case of ionic repression (Michaelis, "The Effect of Ions in Colloidal Systems," 1925, 67).

FIG. 3.

*Barium Chloride.*—On the addition of this salt, the cataphoretic velocity decreases rapidly, and coagulation occurs at a relatively low concentration. Here the outstanding action, and the one which ultimately leads to coagulation, is the ionic exchange of hydrogen contra-ions for barium ions from solution. Because of this interfering action, the velocity- $\sqrt{\text{concentration}}$  curve does not yield a straight line.

The critical potential for this and comparable salts lies between  $-0.020$  and  $-0.030$  volt. The corresponding value of  $\zeta$  recorded by Powis for oil drops and arsenious sulphide is  $-0.025$  volt.

*Sodium Hydroxide.*—From a study of the reactions of colloidal platinum in basic solutions (J., 1929, 623), the author has concluded that univalent bases have the important property of reacting with surface non-ionogenic groups (probably oxides) to form further stabilising ionogens. It was, in fact, in order to test this conclusion that the present experiments were undertaken. The remarkable increase in the cataphoretic velocity on the addition of sodium hydroxide completely confirms the view that fresh surface ionogens are formed. From the curve in Fig. 2 (where, for convenience, the concentration is replaced by its square root),

it is seen that when  $5.3 \times 10^{-6}$  equiv. of base has been added (free sodium hydroxide =  $33 \times 10^{-6}$  equiv.), the cataphoretic velocity is more than doubled; on further addition of base, the velocity remains practically constant over a considerable range; and at higher concentrations it begins to decrease. The important stabilising and peptising action of univalent bases is undoubtedly connected with this increase in charge. The flat maximum in the curve is probably related to the view (Hevesy, *Kolloid-Z.*, 1917, 21, 129) that the electrokinetic potential of colloid particles cannot exceed a certain maximum, viz., approx. 0.105 volt ( $0.070 \times 3/2$ ). At all events the very high value of  $\zeta$  here obtained, 0.120 volt, is not exceeded by any other colloid system.

The important charging action of the hydroxyl ion was first emphasised by Perrin (*J. Chim. physique*, 1904, 2, 601), and has since been demonstrated for various negative suspensions—for emulsions by Ellis (*Z. physikal. Chem.*, 1912, 78, 321; 80, 597), and for kaolin by von Buzágh (*Kolloid-Z.*, 1929, 48, 33) and Dubrissay, Trillat, and Astier (*Compt. rend.*, 1929, 189, 41). These workers all find an increase in  $\zeta$  on the addition of univalent bases. The explanation in terms of an increase in surface ionogens can be extended to include all the known observations. The streaming potential against ordinary glass shows no such maximum (Ellis, *loc. cit.*; Powis, *Z. physikal. Chem.*, 1915, 89, 91; Elissafoff, *Z. physikal. Chem.*, 1912, 79, 385): the high initial  $\zeta$  indicates that the sodium hydroxide from the hydrolysis of the sodium silicate has already given the glass its maximum charge.

The cataphoretic velocity of the platinum particles at the coagulation point (in the case of sodium hydroxide) is remarkably high, viz.,  $36.8 \times 10^{-5}$  ( $\zeta = 0.069$ ), i.e., higher than the initial velocity of the particles. Sodium hydroxide coagulation figures for other acidoid sols have not yet been recorded.

*Barium Hydroxide.*—On the addition of barium hydroxide, the cataphoretic velocity shows an extremely small initial increase, in striking contrast to the results obtained with univalent bases. This small increase cannot be ascribed to the lack of formation of surface ionogens, for it has been shown that platinum sols take up 4 or 5 times as much barium hydroxide as sodium hydroxide. There is little doubt that both the low value of the maximum and the subsequent rapid decrease in the cataphoretic velocity are intimately connected with the strong inter-attractive forces between the colloid particle and the ion of higher valency. This, in fact, is the interpretation of the "valency rule."

The shape and the position of the curve show that the charging

and stabilising action of the hydroxyl ion are here very soon outweighed by the coagulating action of the bivalent barium ion. Barium hydroxide will therefore have no pronounced action as a peptising agent.

The only example in the literature where a similar maximum for a bivalent base is recorded is that of Dubrissay, Trillat, and Astier (*loc. cit.*) for kaolin.

*Sodium Chloride.*—Sodium chloride and also potassium chloride show two interesting features: a definite maximum in the velocity-concentration curve, and an abnormally high velocity at coagulation. Similar maxima for univalent salts are recorded by Ivanitzkaja and Proskurnin for colloidal arsenious sulphide and vanadium pentoxide (*Kolloid-Z.*, 1926, **39**, 15), by Thiessen and Heumann for gold (*Z. anorg. Chem.*, 1929, **181**, 379), and by Powis for oil emulsions (*loc. cit.*). They are generally interpreted in terms of the charging action (adsorption) of the negative ion, usually the chlorine ion. In the case of colloidal platinum, the results with hydrochloric acid show that this ion is not surface-active, and there is no reason to believe that such activity would develop in the case of its salts. The author considers that the explanation of the initial increase in the cataphoretic velocity is to be found in the hydrolytic cleavage of the salt. The collective evidence for this view is shortly to be presented elsewhere.

The high velocity at coagulation, *viz.*,  $25 \times 10^{-5}$  ( $\zeta = 0.050$ ), is not unique. Similar high values for univalent salts have been recorded with colloidal arsenious sulphide (Freundlich and Zeh; Powis; Kruyt and van der Willigen; *loc. cit.*), and also for oil emulsions (Limburg, Dissertation, 1924). Owing to the low platinum content, the salting-out effect suggested by Powis has in this case little significance; and there is nothing in the records to indicate, as suggested by Kruyt and van der Willigen, that variations in the dielectric constant of such a weak electrolyte as 0.005*N*-sodium chloride would play an interfering part.

*Potassium Cyanide.*—The potassium cyanide curve corresponds very closely to that of a univalent base. Owing to the very high hydrolysis of this salt the result is not surprising. The hydrolysis is doubtless increased by the removal of some potassium hydroxide by the platinum surface, and here we have a rather obvious, but extreme case of hydrolytic cleavage. The well-known surface activity of the cyanide ion may also play some part. It will be noticed that the maximum electrokinetic potential for sodium hydroxide (0.120 volt) is not exceeded.

*Ferric Chloride.*—Ferric chloride shows a first coagulating zone when the negative velocity is decreased to about  $-12 \times 10^{-5}$

cm. per sec., and the sol then remains unstable over a range of ferric chloride concentration, but when this reaches  $0.00004M$ , and the velocity becomes  $+15 \times 10^{-5}$ , the charge is reversed and the sol again becomes stable. For higher saline concentration, well above  $0.004M$ , the sol behaves as a typical positive sol. The existence of an unstable zone and of a negative and a positive critical potential are clearly shown by the curve.

*Coagulation Zones.*—The shaded portions of the various curves represent the coagulation zones, i.e., the concentrations between slow and rapid coagulation. It has been usual to distinguish between two critical potentials, one for slow and one for rapid coagulation, and to assume that, whilst the former may have a relatively large value, the latter is approximately zero. The slopes of the curves at and near coagulation show that this is not the case, but that the potential at rapid coagulation is only slightly less than that at slow. This is confirmed by the actual measurements. The velocity at slow coagulation is obtained in the normal manner, the experiment being completed before the particles have had time to coalesce; and that at rapid coagulation can also be directly measured if the necessary amount of salt, and no more, is added. For example, if a sol is made  $101 \times 10^{-6}M$  with respect to barium chloride, an extremely fine but quite definite precipitate can be noticed with a magnifying glass. This settles so very slowly that its cataphoretic velocity may be measured in the normal manner. The final point on the barium chloride curve was obtained with such a coagulated sol. The settling cannot altogether be neglected, and therefore such values are, if anything, a little too low. The fact that such points fall in the continuation of the curves brings out the interesting feature, viz., that the coagulated agglomerates move with the same velocity (and therefore have the same potential) as the individual particles immediately before coalescence.

*The Cause of Coagulation.*—The recognition of colloid particles as great multivalent ions was first emphasised by Billiter (*Z. physikal. Chem.*, 1903, 45, 307) and Duclaux (*J. Chim. physique*, 1907, 5, 29); but the practical demonstration that colloid systems are strong electrolytes is due to the work of Pauli and of Bjerrum (*Z. physikal. Chem.*, 1924, 110, 656). In the light of this view, the condensed double layer of Helmholtz, Lamb, and Smoluchowski has become replaced by the diffuse double layer or ionic atmosphere of Gouy (*J. Physique*, 1910, 9, 457) and of Debye and Hückel (*loc. cit.*). Accordingly, the source of colloid stability is the ionisation of the surface ionogens, whose contra-ions ("gegenionen") extend into the solution as an ionic atmosphere. Any

increase in the ionic concentration, *e.g.*, on addition of acids to acidoid sols, causes an attenuation of the ionic atmosphere, or a displacement of the "electrical centre of gravity" of the contractions towards the colloid surface. The cataphoretic velocity and the electrokinetic potential are accordingly decreased, and at some critical value coagulation ensues. If there be no interfering reactions, the Debye-Hückel theory requires that the average density of the ionic atmosphere be proportional to the square root of the concentration of coagulating ion, and in the simplest cases this has been confirmed. With all salts, however, the kationic interchange is superimposed on the above relation, and the simple linear law does not hold. With univalent bases the production of fresh surface ionogens acts in the opposite direction to the effect due to the increase in concentration of the contra-ions; hence the maximum in the curve. For these cases the complete relation between cataphoretic velocity and electrolyte concentration is still lacking. The valency rule is also directly interpreted in terms of the theory.

Any decrease in the cataphoretic velocity leading to coagulation has usually been explained in terms of the "adsorption" of the oppositely charged ion, but, although this hypothesis has been of service, ultimately it will have to be abandoned, for it fails to explain even the simplest case, *viz.*, the coagulation of an acidoid sol by an acid, the work with platinum (and also with mastic) having shown that the colloid particles do not remove (or adsorb) any of the coagulating acid. Where other ions, *e.g.*,  $\text{Ba}^{++}$ ,  $\text{Al}^{+++}$ , are the active coagulating agents, the more definite explanation in terms of ionic interchange is to be preferred.

In spite of numerous speculations, we have no complete answer to the question, "Why does coagulation ensue before the colloid is completely discharged?" The work with colloidal platinum shows that there are no abrupt changes (beyond instability) at the coagulation point. This has also been emphasised by Ellis and by Powis with oil emulsions. We can only assume that, when the ionic atmosphere has been sufficiently attenuated, the repulsion which existed when the two particles approached under their Brownian movement is no longer sufficient to keep them from adhering. The latter effect is probably largely a capillary one, and is not solely due to changes in interfacial tension, as is often supposed. Perrin's work with mastic and gamboge, and that of Ellis and of Powis with oil emulsions, shows that at coagulation the droplets do not run together but adhere in clusters. Peptisation experiments with platinum are in accord, for on addition of sodium hydroxide to a sol which has been coagulated

with sodium chloride, peptisation follows readily, and no severe treatment is necessary to draw the adhering particles apart.

### *Conclusion and Summary.*

Colloidal platinum is a typical hydrophobic acidoid sol. In the presence of air, the surface appears to contain oxide and acid only.

The changes in the cataphoretic velocity of the particles have been measured in the presence of certain electrolytes.

The effect of inorganic acids is interpreted as a direct repression of the diffuse ionic atmosphere, and the linear relation of Debye and Hückel is found to hold.

Univalent bases react with the surface oxide to form fresh stabilising ionogens, and the cataphoretic velocity accordingly passes through a maximum. Bivalent bases show a very weak maximum.

Hydrochloric acid, barium hydroxide, and barium, calcium, and ferric chlorides show a critical velocity and critical potential.

Poor coagulants, such as univalent salts and univalent bases, show a maximum in the velocity-concentration curve, and an abnormally high velocity (and potential) at coagulation.

Ferric chloride shows two critical velocities, one negative and the other positive.

The coagulation process in the presence of electrolytes is discussed in terms of the results obtained.

The author wishes to record his indebtedness to the Trustees of the Endowment Fund of the Council for Scientific and Industrial Research of the Commonwealth of Australia for grants towards the purchase of platinum used in this series of investigations.

## CLXXXVII.—*A Simple Electrically Controlled Thermostat.*

By JOHN ARNOLD CRANSTON.

THIS thermostat is of a type that has been in use for a number of years in this laboratory, and as it has certain advantages in respect of compactness and economy in use of electric current, a description of it seems desirable.

The vessel (Fig. 1) consists of a glass accumulator jar,  $40 \times 28 \times 22$  cm., of 25 litres capacity; it is divided into two approxi-

mately equal portions by a glass plate, *E*, which is suspended from its sides and serves to improve the efficiency of stirring by directing the flow of the water from the stirrer into a one-way stream round the tank. Water is kept in the vessel to a level some 2 cm. above this plate.

The rear portion of the vessel contains (i) a heating lamp *D*, of the Robertson radiator type consuming 1 amp. at 250 volts,

FIG. 1.

FIG. 2.

FIG. 3.

(ii) a stirrer *B*, consisting of a monel metal propeller mounted on a shaft which is connected to a bicycle hub and driven by an electric motor or hot-air engine *A*, (iii) a thermoregulator *C*, consisting of a bulb with a capillary stem. A piece of platinum wire, sealed into the bulb, enables electrical contact to be made with the mercury within. A piece of nichrome wire, *W* (Fig. 2), acts as the other terminal of the circuit and makes and breaks contact with the surface of the mercury *M* in the capillary tube. The wire is soldered to the base of the screw *S*, which is in electrical

contact with the lead-in wire *L*. The screw is mounted in a vulcanite cap *V*, supported by a glass tube *G* and rubber cork *C*. By means of this screw, contacts may be set to operate at any desired temperature.

The thermoregulator circuit includes a coil of wire *E* (Fig. 3) of the electric-bell type, above which is suspended a piece of soft iron attached to the lever arm of a balance; when expansion of mercury in the capillary tube closes this circuit, the current flowing through the coil attracts the soft iron and so draws the other lever arm out of a trough of mercury *G*, thus breaking the main circuit of the heating lamp. The regulator circuit requires a low-voltage current, which is obtained by inserting a piece of nichrome wire of about 7 ohms resistance in the main circuit driving the motor stirrer, and by tapping the current from the ends of this wire. A convenient form of resistance is the wireless rheostat.

If it is desired to maintain the temperature constant for an experiment lasting several weeks, and the circumstances are such that a single failure in the make-and-break system, with its consequent rise in temperature, would ruin the experiment, the following precaution can be adopted. A second thermoregulator can be inserted in parallel with the first, but set to operate at a slightly higher temperature than the desired one.

Since a continuous flow of electric current is necessary to operate the thermoregulator, economy of current is effected by using it to drive the motor instead of having a lamp in circuit providing useless illumination.

The electrical connexions are shown diagrammatically in Fig. 3; an ordinary electrical wall block, 9"  $\times$  9", is used for mounting (i) all the required terminals, (ii) the make-and-break of the heating circuit, (iii) the shunt for the low-voltage current supply, and (iv) two condensers of about 0.5 microfarad capacity each. These are inserted to minimise the sparks in the two make-and-break circuits.

A test with a Beckmann thermometer showed the variation of temperature at 25° to be 0.03°.

THE ROYAL TECHNICAL COLLEGE,  
GLASGOW.

[Received, April 29th, 1930.]

CLXXXVIII.—*The Constitution of Some Organic Derivatives of Thallium.*

By NEVIL VINCENT SIDGWICK and LESLIE ERNEST SUTTON.

THE majority of the known metallic alcoholates are salt-like substances; they are non-volatile, insoluble in organic solvents such as benzene, and they often combine with the parent alcohol. Examples of this type are the alcoholates of the alkali metals, the alkaline-earth metals (Chablay, *Compt. rend.*, 1911, **153**, 953; de Forcrand, *ibid.*, 1912, **154**, 1441; Doby, *Z. anorg. Chem.*, 1903, **35**, 93), zinc, magnesium (Tolkatscheff, *J. Russ. Phys. Chem. Soc.*, 1901, **33**, 469; Szarvasy, *Ber.*, 1897, **30**, 806), and lead (Chablay, *loc. cit.*). Aluminium is exceptional in that, though its methoxide decomposes on heating, its ethoxide melts at 135° and boils at 234—235°/23 mm., the propoxide and the amyloxyde being similar (Hillyer, *Amer. Chem. J.*, 1897, **19**, 597; Hillyer and Crooker, *ibid.*, p. 37). With the exception of the methoxide these may be regarded as esters of aluminic acid and as being analogous to the esters of boric acid.

Thallos ethoxide belongs to neither of these types; it is a colourless oil at room temperature (m. p. -3°) which is miscible with benzene, only partially with ethyl alcohol, but has no appreciable vapour pressure at temperatures up to 80°, where it decomposes. It is readily decomposed by water or carbon dioxide. The *n*-propoxide, the *n*-butoxide, and the isobutoxide have also been made and appear to be of the same type (Lamy, *Ann. Chim. Phys.*, 1863, **67**, 395; 1864, **3**, 373; Kahlbaum, Roth, and Siedler, *Z. anorg. Chem.*, 1902, **29**, 177), but the methoxide and cyclohexanyloxyde (Lamy, *loc. cit.*; de Forcrand, *Compt. rend.*, 1923, **176**, 20) are white microcrystalline solids which do not melt, but decompose above 110°. The phenoxide (de Forcrand, *loc. cit.*) and some of the substituted phenoxides (Christie and Menzies, *J.*, 1925, **127**, 2373) are stable white solids which can be recrystallised from water and have definite melting-points, but are soluble in benzene (see later), while the ethylene glycolate and glycerate (de Forcrand, *loc. cit.*) are yellow crystalline solids. It therefore seemed that some, at least, of these alcoholates were covalent, but, from their non-volatility, were associated.

In the present investigation, the molecular weights of the methoxide, the ethoxide, the cyclohexanyloxyde and the benzyloxyde in benzene solution were determined at the freezing point, those of the methoxide and the ethoxide also being determined in their parent alcohols at the boiling points. In addition, the molecular weights of several phenoxides and of ethyl thalioacetoacetate were measured

in boiling benzene, while finally the solubilities of the ethoxide in ethyl alcohol and of the methoxide in methyl alcohol and in benzene were determined.

### EXPERIMENTAL.

*Preparation of Materials.*—*Thallous ethoxide.* This was the starting material for all the thallium derivatives used. Some of it was very kindly supplied to us by Dr. R. C. Menzies and more was made by Lamy's method in an apparatus similar to one described to us by Dr. Menzies, wherein thallium, rolled into ribbon, was subjected to the combined action of boiling, dry ethyl alcohol and dry oxygen. The thallous ethoxide dropped into the ethyl alcohol as it was formed, being subsequently withdrawn and filtered through a plug of cotton-wool into a receptacle. It kept best if a layer of alcohol was allowed to remain over it but, in any case, it decomposed in time with the formation of a black colloidal precipitate which could not be removed by filtration. We found that it could then readily be purified by dissolving it in boiling, dry ethyl alcohol, filtering the solution and allowing it to cool, and separating the two liquid layers. Specimens so purified kept considerably better than the crude ones. Ethyl alcohol is soluble in the ethoxide, though only to a small extent (Lamy, *loc. cit.*), so the last traces of it were removed from small quantities of ethoxide, as required, by keeping them for 24 hours over metallic sodium in a vacuum desiccator.

*Thallous methoxide.* This was prepared as described by de Forcrand (*loc. cit.*) by double decomposition between the ethoxide and an excess of dry acetone-free methyl alcohol (kindly supplied by the Balliol and Trinity College Laboratories). Owing to its instability, small quantities were made as required and purified by recrystallisation from dry benzene. The time during which the filtered solutions were exposed to the air was kept as short as possible, and, with care, specimens could be obtained which gave very clear benzene solutions in the molecular-weight determinations. When quite free from methyl alcohol, the methoxide was very unstable; these solutions would begin to deposit a black precipitate even at 25–30°.

Thallous methoxide has no melting point; the solid begins to decompose above 120°.

*Thallous cyclohexanyloxide.* This was prepared in a similar way, thallous ethoxide being added to an excess of a dry, ethereal solution of cyclohexanol which had twice been distilled in a vacuum to remove most of the water in it. It was washed with a small quantity of pure dry ether and recrystallised from benzene. It has no melting point, but begins to decompose above 110°.

*Thallous benzyloxyde* was also prepared in this way, but, owing to its greater solubility in ether, the reaction mixture was well cooled in a freezing-bath. The product crystallised in colourless shining plates, which were filtered off, washed with a small quantity of well-cooled ether, and kept over potash. It was finally recrystallised from ligroin (b. p. 60—80°). The removal of the last traces of benzyl alcohol from small samples of this substance was difficult, owing to the limited solubility in ligroin of the alcohol and the relatively great solubility of the benzyloxyde.

This compound, m. p. 74—78°, has not been previously described. It decomposes slowly on keeping, is very sensitive to moisture, and is readily soluble in benzene or ether [Found: Tl, estimated as iodide, (1) 65.9, (2) 65.1.  $C_7H_7OTl$  requires Tl, 65.6%].

Dr. T. V. Barker and Mr. R. C. Spiller kindly made a micro-crystallographic examination of this substance. The crystals were regular octagonal plates which, under crossed Nicols, exhibited straight extinction. Normal to the plate was the acute bisectrix of a positive biaxial figure with medium axial angle. The system was possibly orthorhombic, certainly not cubic, tetragonal, hexagonal or rhombohedral.

*Thallous phenoxide, m-tolyloxyde, o-methoxyphenoxide, m-methoxyphenoxide, thallous salicylaldehyde, and the thallous derivative of o-vanillin.* These were all made by double decomposition of the ethoxide with an excess of an ethereal solution of the appropriate phenol. They were filtered off, washed with ether, and recrystallised by solution in either boiling benzene or pyridine and precipitation with ligroin (b. p. 60—80°). The m. p.'s of the first five substances were higher than those reported by Menzies and Wilkins (J., 1924, 125, 1148) and Christie and Menzies (*loc. cit.*), who recrystallised them from alcohol or water.

Thallous phenoxide .....	M. p. 233—235° (C. & M., 231—235°)	
„ <i>m</i> -tolyloxyde .....	196°	(187°)
„ <i>o</i> -methoxyphenoxide .....	164°	(160°)
„ <i>m</i> -methoxyphenoxide .....	148°	(146—148°)
„ salicylaldehyde .....	197° decomp.	(186°)
„ <i>o</i> -vanillin ..	142° decomp.	

The last compound is new. After purification it was obtained as fine yellow crystals which kept well (Found: Tl, determined as iodide, 58.2.  $C_8H_7O_3Tl$  requires Tl, 57.5%); the crude product eventually turned brown or black. It was sufficiently soluble in boiling benzene for its molecular weight to be determined (thallous salicylaldehyde is not).

*Determination of Molecular Weights in Benzene by the Beckmann Freezing-point Method.*

For these determinations the solvent had to be thoroughly dry and the solutions had to be protected against wet air during the course of the experiments, owing to the ease of hydrolysis of the solutes.

The benzene was purified in the usual manner, by repeated fractional freezing and by shaking with sulphuric acid. It was distilled, in a stream of dry air, into a reservoir from which, by the closing of an air by-pass tap, it could be blown direct into the Beckmann tube. Throughout the experiment a slow stream of dry air was passed. It left the apparatus through the stirrer sleeve, which was provided with the usual buffer space to prevent wet air being drawn in by the movement of the stirrer. The air appeared to be sufficiently saturated with benzene in passing through the distilling flask, for no drift of readings, which could be ascribed to evaporation of benzene from the Beckmann tube, was observed. The efficiency of the apparatus in this form was once tested by observing the freezing point of some benzene over a period of 6 hours. The first and the last reading differed by  $0.003^{\circ}$ , the former being  $0.001^{\circ}$  above and the latter  $0.002^{\circ}$  below the mean of the whole series. In view of this and the fact that the alcoholates gave perfectly clear solutions, the drying was considered satisfactory.

Since the methoxide and the *cyclohexanyloxyde* gave maximum lowerings of only  $0.08^{\circ}$  and  $0.05^{\circ}$  respectively, considerable care was necessary in working with them. Whenever possible, freezing-point readings were taken until four successive values differing by not more than  $0.005^{\circ}$  had been obtained, and the mean value taken. If greater fluctuations persisted, the mean of six readings was taken.

We confirmed the observation of Jones and Bury (J., 1925, 127, 1947) that dry benzene is difficult to supercool, and, moreover, at first we experienced difficulty in avoiding caking of the fine benzene crystals on the walls of the tube. This occurred less in the case of the solutions than with the pure solvent, so the conditions under which the "convergence temperatures" (Wildermann, *Proc. Roy. Soc.*, 1896, 59, 251) were reached were different in the two cases, and a zero error resulted. This difficulty was overcome by using an air space round the Beckmann tube of at least 8 mm. and by supercooling about  $1^{\circ}$  for all readings.

The methoxide, ethoxide, or *cyclohexanyloxyde* was introduced through the side tube of the Beckmann apparatus, and, after the readings had been taken, some of the solution was withdrawn through a curved tube which was passed through the side tube,

filtered through a plug of cotton-wool, weighed, and then shaken with a definite volume of water, which was shown to remove the whole of the thallium. The concentration of the solution in the Beckmann tube was altered by adding more benzene from the reservoir to make it up roughly to its original volume, and the cycle of operations repeated. The thallous hydroxide in the aqueous layers was titrated with *N*/50-hydrochloric acid (methyl-red indicator) and the concentration of the original benzene solution could then be calculated. The benzyloxyde was weighed into the Beckmann tube.

The degrees of association of the thallous compounds were calculated (the cryoscopic constant of the benzene being taken as 53.1

from the results of calibration experiments with naphthalene as solute) and plotted against the "simple molecular concentrations," *i.e.*, the quotient of the weight of solute per 100 g. of solvent divided by its simple molecular weight. The curves obtained are shown in Fig. 1 and the data from which they are constructed are tabulated below. The error in the associations of the sparingly soluble substances could be expected to be 5%, allowing an error of 0.002° in the depression of freezing point and of 0.05 c.c. in the titrations. For most points it is actually less.

*Molecular Weights in Benzene, Ethyl and Methyl Alcohols by the  
Cottrell-Washburn Boiling-point Method.*

The apparatus used for the measurements with benzene and ethyl alcohol was an adaptation of that described by Cottrell (*J. Amer. Chem. Soc.*, 1919, 41, 721; see also Washburn, *ibid.*, p. 729) so designed

that the solutions could be kept dry. The dry solvent was distilled in a stream of dry air into a reservoir from which it could be elevated into a burette, as required, by suction, and it could be run out from this direct into the actual boiling-point apparatus. A side tube, from the outlet, was connected with this so that a positive pressure of dry air could be maintained within it, but no stream of air went through. The end space of the burette was calibrated in order that it could be completely emptied, and risk of solvent slowly leaking through the tap, which could not be greased, was thus avoided. The actual boiling-point apparatus is shown in Fig. 2. The outer Pyrex tube was 5 cm. in diameter at the top, but only 2.5 cm. at the

bottom, in order to use less liquid. The cork A carried a Beckmann thermometer, B, the end of the burette, C, the leads to the spiral composition-tubing condenser, D, and the pressure supply tube, E. There was also a hole through which solution could be withdrawn. An inner tube, F, 2.5 cm. in diameter, slightly constricted at the bottom, was held on to the thermometer by means of a cork, and the Y-tube G, through which the mixture of liquid and vapour rose, rested on this constriction and was held central by a loop of nickel wire encircling the thermometer. The dimensions are important, and the diagram is therefore drawn to scale. Radiation, etc., was prevented by the asbestos jacketing, and the burner was shielded from draughts by a mica chimney.

The results of two trial runs with ethyl alcohol as solvent and benzil as solute are in Table II. The readings were steady to  $0.001^\circ$  and it will be seen that the method is satisfactory for elevations down to  $0.02^\circ$ .

For the ethoxide, as in the freezing-point measurements, successive solutions were made up in the tube, their boiling points were determined, and they were then withdrawn and analysed. The more stable phenoxides could be weighed into measured volumes of benzene.

The ethyl alcohol was first dried with quick-lime and then with calcium; the benzene was treated as before.

FIG. 2.

Methyl alcohol rapidly attacked the corks in the above simple type of apparatus, so an all-glass apparatus, similar to that of

Washburn (*loc. cit.*), originally designed for use with pyridine, was adapted for use with this solvent. The dimensions were essentially the same as in the other apparatus, the inner tube fitted into the outer one by means of a large ground joint, the thermometer was fixed in it by a small piece of rubber tube, and the Y-tube rested on two pairs of indentations and was kept central by a loop of wire, as before. It had a side tube with a condenser jacket, and the end of this was connected with the dry air supply, so that a small pressure could be maintained within the apparatus.

The methyl alcohol was supplied by the Balliol and Trinity College Laboratories and was dried with aluminium methoxide (from aluminium amalgam); the thalious methoxide was freshly made, and not recrystallised from benzene. The general procedure was like that for the ethoxide, the solutions being poured out through a small side tube after the boiling point had been determined.

FIG. 3.

The degrees of association are tabulated below, and those for ethyl thalloacetoacetate are shown, plotted against simple molecular concentration, in Fig. 3.

(Ebullioscopic constant taken as 28.14, from calibration with benzil as solute.)

*Solubility Measurements.*

These were made by the usual analytical method, the two phases being stirred together for various periods, after which the solutions were withdrawn, filtered, and analysed. All outlets were protected

with sulphuric acid tubes, and a mercury-sealed stirrer was used, in order to prevent the ingress of moisture.

The observed solubilities at 25° were : thallous ethoxide in ethyl alcohol, 9.108 g. /100 g.; thallous methoxide in methyl alcohol, 1.703 g./100 g.; thallous methoxide in benzene, 3.16 g./100 g.

These are the mean values of sets of readings which each included one result obtained by saturating for at least 11 hours.

### *Discussion of Results.*

Both the aliphatic and the aromatic alcoholates of thallium behave in water as salts, and their differences in such properties as ease of hydrolysis can be explained by the differing acidities of the parent alcohols. They all dissolve in benzene, however, as much as covalent compounds could be expected to do, which shows that they are covalent in benzene and therefore, presumably, in the solid state. In these solutions they are highly associated, fourfold association being already complete when the *actual* concentrations (of the polymeride) are only about  $N/20$  in the case of the four aliphatic compounds examined and the *o*- and *m*-methoxyphenoxides. The phenoxide and the *o*-vanillin derivative, at actual concentrations of  $N/100$ — $N/50$ , are already associated about three times, but their sparing solubility prevents measurements at higher concentrations. The ethoxide (but not the benzyloxide) appears to undergo a slow further polymerisation in more concentrated solutions. Its complex is, moreover, stable in ethyl alcohol, but the methoxide is apparently unimolecular in methyl alcohol. Though both of these are more soluble in benzene than in their parent alcohols, the difference (at 25°) is less for the methoxide (benzene, 3.16 g./100 g.; methyl alcohol, 1.7 g./100 g.) than for the ethoxide (completely miscible with benzene; ethyl alcohol, 9.1 g./100 g.), which is probably connected with the difference of molecular states in the alcohols. From this it is evident that a fourfold polymeride exists which has a very considerable degree of stability and must, therefore, have a structure which explains why the alcoholates associate readily up to four times, and no further. One possibility is a cubic structure (I) and another is an eight-membered ring structure (II) :—

In the former structure the thallium, having gained one electron from the normal covalency and two from each co-ordinate link, has a complete octet 2, 3, 3, this including the two electrons which are inert in the normal thallos compounds. The oxygen atoms have each formed two co-ordinate links and so have completely shared octets as in basic beryllium acetate (Morgan and Bragg, *Proc. Roy. Soc.*, 1923, 104, 437; Sidgwick, *Nature*, 1923, 111, 808). The further polymerisation could be accounted for by assuming the formation of a co-ordinate link from a thallium atom in one molecule to one in another. In the ring structure each thallium atom has four shared electrons, having gained one by forming a covalency and two from the donor link, so it would probably have a shared quartet outside the core plus the "inert pair" (78) (2), 2, 2. Each oxygen has two ordinary covalencies and one co-ordinate link, as in the majority of its co-ordination compounds. Further polymerisation could occur either by the formation of a double bond between one or more pairs of thallium atoms in different molecules, or by the formation of a co-ordinate link from oxygen to thallium.

The main difficulty in the cubic structure is that it would certainly be highly strained, though a compound,

the existence of which was established by Werner (*Ber.*, 1907, 46, 4834), would have approximately the same degree of strain per atom, if the metallic atoms in each be assumed to have their valencies normally at right angles, as is certainly the case for the cobalt and possibly for the thallium. If not, the strain would be about twice as great as in this other compound. There is, on the other hand, a strong *a priori* objection to the ring structure inasmuch as no eight-membered chelate rings, in the strict sense of the word, are definitely known to exist (Sidgwick, "Electronic Theory of Valency," p. 251), whereas six-membered chelate rings are very common, and, therefore, if a ring compound were to be formed by polymerisation, we should expect it to be a three-fold and not a four-fold complex. In both formulæ we postulated that the thallium should accept co-ordinate links, but it is remarkable that it does not appear to do this from pyridine or acetone; the thallos phenoxides can be precipitated unchanged from pyridine solutions by ligroin, or recrystallised from acetone. Moreover, the one type of thallos ammine reported (Biltz and Stollenwerk, *Z. anorg. Chem.*, 1921, 119, 97) is only formed in liquid ammonia.

Ethyl thalloacetoacetate was found not to be a simple co-ordin-

ation compound, but to be completely polymerised to a two-molecular complex in a solution  $N/8$  in *actual* concentration. This polymeride could be formed in either of two ways. First, by the formation of a double bond between the two thallium atoms, which was suggested as a way in which the eight-membered ring might polymerise; this would be analogous to the readiness of the inert pair of electrons to partake in the formation of a completely shared octet, which is so marked in lead.

Secondly, co-ordinate links from oxygen to thallium could be formed, so that the thallium would be given a mixed octet, as in the suggested cubic structure. In fact, the whole similarity of the two structures may be taken to support both. Thallous acetylacetonate was reported by Kurowski (*Ber.*, 1910, **43**, 1078) to be unimolecular in ethyl alcohol, but we could not confirm this; we obtained irregular results suggestive, possibly, of alcoholysis. We should expect the thallous derivative of *o*-vanillin to behave in the same way, but actually, as previously stated, it appears to be associated largely to the four-fold polymeride.

These results are of interest in their bearing on Sugden's deductions from the parachors of thallium compounds (*J.*, 1929, 316). He there claims to have shown that the parachor of thallium in ethyl thalloacetoacetate is approximately the same as in dimethylthalliumbenzoylacetone, whether we assume singlet or duplet linkages, and the same as in thallous ethoxide, formate, and acetate, if we assume singlet linkages in the first two, and duplet linkages in the last three substances. If we assume that no allowance has to be made for the tervalency of the oxygen, the eight-membered ring structure gives parachor values for thallium practically identical with those derived from the unimolecular formula, on either the singlet or the duplet link hypothesis (*ca.* 62 for duplet links, and 85 for singlet links). The cubic structure involves parachors for thallium of about 48 for duplet links and less than 30 for singlet links. In order to derive a parachor value of about 62 from ethyl thalloacetoacetate, which we now know to be bimolecular, we must assume that all the thallium linkages (including those uniting the two

simple molecules) are singlet links; all other assumptions give lower values. Thus, the difficulty of reconciling the various data for  $P_m$  is that we have to assume that the polymerisation arises from the formation of duplet links in the case of the ethoxide and singlet links in the case of the acetoacetic ester derivative.

We should expect that, if the cubic structure were the correct one, crystals of the alcoholates would be cubic. From the previously mentioned crystallographic examination of the benzyloxide (the only derivative which gave suitably large crystals) this obviously was not so, but the cubic structure is not definitely ruled out as a consequence; carbon tetrabromide is cubic above  $46.68^\circ$ , but monoclinic below this temperature (Zirngiebl; compare Groth, "Chemische Krystallographie," Vol. I; [Leipzig, 1906], p. 229).

Though the structure of the four-molecular complex cannot be settled from the available evidence, its stable existence is interesting, since it shows that mono-covalent thallium, which could have a partially shared quartet (78), 2, 1, 1, or a shared pair outside the core plus the inert pair (78) (2), 1, 1 (compare the mercurous ion), although it can exist, is very unstable, and this may be correlated with the fact that no monoalkyl derivative of thallium has yet been isolated.

We should like to express our thanks to Dr. R. C. Menzies for his great kindness in supplying specimens of several thalloses compounds and for his helpful advice regarding the preparations; also to Imperial Chemical Industries Ltd. for a grant towards the expenses of the research.

## CLXXXIX.—*The Polysulphides of the Alkali Metals.* *Part I. Sodium (i).*

By THOMAS GIBSON PEARSON and PERCY LUCOCK  
ROBINSON.

IN spite of much research, little is definitely known of the polysulphides of the alkali metals, for none of the earlier work has escaped criticism, and, indeed, only the latest work, that of Rule and Thomas (J., 1914, 105, 177, 2819; 1917, 111, 1063), has remained unchallenged. Two anomalies, typical of many, are that one published equilibrium diagram shows *eight* and another *four* compounds; also, that the existence of a series of disodium compounds, described

either by Schöne or by Böttger, was contradicted by Bloxam, whose tetrasodium enneasulphide, in turn, Rule and Thomas were unable to prepare. Moreover, certain standard treatises in English appear to have been misled by several mistranslations in abstracts. In view of the great diversity of opinion, and as we were interested in the individual polysulphides as a possible source of pure persulphides of hydrogen (compare Mills and Robinson, J., 1928, 2326), we decided that an extensive re-examination of this field was essential.

The present paper describes a careful reinvestigation of all the previous work on the polysulphides of sodium, with the exception of that of Hugot (*Compt. rend.*, 1899, **129**, 388) in liquid ammonia, of Küster and Heberlein on the electrochemistry of aqueous polysulphide solutions, and of Sabatier (*Ann. Chim. Phys.*, 1881, **22**, 15) on thermochemical aspects. An endeavour to account for previous discrepancies has in great measure been successful. Moreover, certain other methods of attack have been applied to these problems for the first time, particularly (1) the amplification of thermal analysis of the system sodium monosulphide-sulphur by microscopic methods; (2) the confirmation of the existence of di-, tetra-, and penta-sulphides in melts by measurement of the loss of sulphur at various temperatures; and (3) the partial study of the system sodium monosulphide-sulphur-water-alcohol.

The conclusions reached are summarised on p. 1496. The peculiar stability of sodium tetrasulphide is significant. It appears to be readily obtained from solution in both anhydrous and hydrated forms and, furthermore, to be the only polysulphide obtainable from the hydrosulphide. Trisulphide, on the other hand, appears to be formed at 120° but to be completely decomposed into a mixture of di- and tetra-sulphides at temperatures far below its melting point. It would seem, however, that this stability is an inherent property of the molecular type  $\text{Na}_2\text{X}_4$ , rather than of the tetrasulphide itself, since dehydration of the highest hydrates at 100° produces  $\text{Na}_2\text{S}_3\text{H}_2\text{O}$ ,  $\text{Na}_2\text{S}_2\cdot 2\text{H}_2\text{O}$ ,  $\text{Na}_2\text{S}_3\cdot \text{H}_2\text{O}$ , and  $\text{Na}_2\text{S}_4$ , and leads to the hydrolysis of pentasulphide.

Further work, designed to elucidate the structure of these polysulphides, is in progress.

#### EXPERIMENTAL.

*Preparation of Materials Used.*—The sodium from Imperial Chemical Industries, Ltd., was kept under dry liquid paraffin containing 1% of amyl alcohol, which is known to preserve a fresh metallic surface. Experience enabled the metal to be cut to within 0.1 g. of the desired weight, thereby reducing oxidation to a minimum.

The sulphur was twice recrystallised from carbon disulphide and dried for several hours at  $100^{\circ}$ .

Absolute alcohol was dried by being twice refluxed for 3 hours over freshly burnt quick-lime and then distilled from the same material, with rejection of small head and tail fractions.

Toluene was dried by refluxing over metallic sodium, then over a polysulphide, and distillation from metallic sodium, small head and tail fractions being rejected.

*Analytical Methods.*—The total sulphur content was determined by adding a weighed amount of the polysulphide in aqueous solution to 50 c.c. of 10% sodium hydroxide containing 7 c.c. of bromine. The solution was gently heated until of a light straw colour, whereupon 30 c.c. of hydrochloric acid were added and the whole was boiled until colourless. The sulphate was then estimated in the usual way with barium chloride.

The polysulphide sulphur and the sodium were determined together on the same weighed sample: (1) a slight excess of 10% sulphuric acid was added, and the solution boiled to coagulate the precipitated sulphur, which was filtered, thoroughly washed, and dried in an electric oven at  $70-80^{\circ}$ ; (2) the filtrate was concentrated to a suitable volume, transferred to a platinum dish, evaporated to dryness, fused to the sulphate, and weighed.

Blanks were done on all the reagents used.

Experimental details are described under the relevant sections.

### I. The Preparation of Polysulphides from Solution.

(i) *The Action of Sulphur on Sodium Monosulphide in Aqueous Alcohol.*—Schöne (*Pogg. Ann.*, 1867, **131**, 380) dissolved excess of sulphur in aqueous sodium monosulphide, evaporated the solution to crystallisation in a vacuum, triturated it with alcohol, and cooled it in a freezing mixture, obtaining pale yellow plates of hydrated sodium tetrasulphide,  $\text{Na}_2\text{S}_4 \cdot 6\text{H}_2\text{O}$ . The mother-liquor on being chilled after further concentration gave orange-yellow crystalline pentasulphide,  $\text{Na}_2\text{S}_5 \cdot 6\text{H}_2\text{O}$ . Later, Filhol (*Ann. Chim. Phys.*, 1873, **28**, 529) failed to obtain any polysulphides from sulphur and aqueous monosulphide in sealed tubes, but Böttger (*Annalen*, 1884, **226**, 335) described the formation of four polysulphides,  $\text{Na}_2\text{S}_2 \cdot 5\text{H}_2\text{O}$ ,  $\text{Na}_2\text{S}_3 \cdot 3\text{H}_2\text{O}$ ,  $\text{Na}_2\text{S}_4 \cdot 8\text{H}_2\text{O}$ , and  $\text{Na}_2\text{S}_5 \cdot 8\text{H}_2\text{O}$ , by solution of the calculated amounts of sulphur in aqueous-alcoholic sodium monosulphide. These results were criticised by Bloxam (*J.*, 1900, **77**, 753) on the grounds that the alleged polysulphides could not have been formed since the sulphur added did not allow for the simultaneously formed thiosulphate (compare *Chem. News*, 1895, **72**, 63), or, alternatively, if formed, the polysulphides would have

been contaminated with this thiosulphate, which becomes soluble in alcohol in their presence; further, he criticised the absence of data as to yield or description of the product, and doubted whether any pure polysulphide had been obtained. In consequence, Bloxam attempted to prepare them by the action of sulphur on aqueous hydrosulphide in a stream of hydrogen sulphide, but obtained only an alleged tetrasodium enneasulphide,  $\text{Na}_4\text{S}_9 \cdot 14\text{H}_2\text{O}$  (compare p. 1483).

Küster and Heberlein (*Z. anorg. Chem.*, 1905, **43**, 53, 431) found that the solubility of sulphur in solutions of the monosulphide diminished only slightly with rise in temperature between  $0^\circ$  and  $50^\circ$  and depended mainly on the concentration of the monosulphide, being at a maximum at  $0.063N$ ; the elements were then present in the atomic ratio  $\text{Na} : \text{S} = 2 : 5.24$ . They advanced evidence that a complex equilibrium rather than definite compounds existed in the solutions. They also noted the unique stability of solutions of tetrasulphide composition and showed that the polysulphides undergo hydrolysis to an extent which diminishes regularly with increasing sulphur content.

It is evident that the formation of a number of polysulphides by Böttger's method was possible, and that the problem could be best solved by a phase-rule study of the system monosulphide-sulphur-water-alcohol. As a complete investigation was impracticable, however, we examined the solid phases separating from a series of solutions having a wide range of  $\text{S} : \text{Na}$  ratios at one temperature, viz.,  $-18^\circ \pm 2^\circ$  (compare Lash Miller and Kenrick, *J. Physical Chem.*, 1903, **7**, 259). These ratios for corresponding solid and liquid phases are plotted in Figs. 1a and 1b, and indicate unquestionably the formation of hydrated forms of di-, tri-, tetra-, and penta-sulphide, excluding the possibility of solid solutions. The work of Böttger and Schöne is therefore confirmed, although in several cases our hydrates differed from theirs; the new hydrates are:  $\text{Na}_2\text{S}_2 \cdot 6\text{H}_2\text{O}$ ;  $\text{Na}_2\text{S}_3 \cdot 8\text{H}_2\text{O}$ ;  $\text{Na}_2\text{S}_4 \cdot 9\text{H}_2\text{O}$ ; and  $\text{Na}_2\text{S}_4 \cdot 11\text{H}_2\text{O}$ ;  $\text{Na}_2\text{S}_5 \cdot 6\text{H}_2\text{O}$ . To these must be added a tetrasulphide which may be either a hepta- or a mixture of octa- and hexa-hydrates. Dehydration of these materials at  $100^\circ$  led to the formation of  $\text{Na}_2\text{S}_2 \cdot 2\text{H}_2\text{O}$  and  $\text{Na}_2\text{S}_3 \cdot \text{H}_2\text{O}$ . A more extensive study of these hydrates is being undertaken by means of vapour-pressure measurements.

We therefore dissent from Bloxam (*loc. cit.*), not only as to the formation of these compounds, but also as to their alleged serious contamination with thiosulphate and alcohol: with suitable precautions only traces of these substances are present. Further, it is significant that Biltz and Wilke-Dörfurt (*Ber.*, 1905, **38**, 123; *Z. anorg. Chem.*, 1906, **48**, 297) prepared rubidium and caesium poly-

sulphides by a similar method without observing the formation of thiosulphates.

FIG. 1a.

FIG. 1b.

*Experimental.* Solutions of the hydroxide for conversion to monosulphide were prepared by the action of clean metallic sodium on aqueous alcohol (Küster, *Z. anorg. Chem.*, 1904, **41**, 474) of

known composition. One-half of the solution was treated with hydrogen sulphide, giving pearly crystals which redissolved as saturation proceeded. The addition of the second half of the caustic soda immediately produced a nacreous crystalline precipitate which disappeared on warming. In this solution the requisite weight of sulphur was then dissolved by gentle heating on the water-bath for the minimum time. The resulting solutions varied in colour from light yellow at the disulphide composition to deep red at the pentasulphide. Within a specific range of composition, between di- and tetra-sulphide, a dark-coloured oil separated as a lower layer from the bulk of the solution on standing (see below).

The solutions—separated from the oils where necessary—were sampled for analysis and then crystallised in standard freezing mixtures of salt and ice (*i.e.*, at  $-18^{\circ} \pm 2^{\circ}$ ) except in runs 27 and 28, in which cooling was effected in ether and solid carbon dioxide at about  $-60^{\circ}$ . In the preliminary experiments, the solutions were crystallised completely in one cooling period of several hours, but the products generally had complex S : Na ratios and, as shown by subsequent fractional crystallisation, were mixtures formed by the successive crystallisation of individual polysulphides. In those exceptional cases, however, where large fractions of definite stoicheiometric composition were obtained, the first solid phase had obviously continued to be formed although metastable to the changed liquid, *e.g.*, runs 15, 16, 17. In general, therefore, fractions of crystals small enough to effect but little alteration in the composition of the solution were removed by filtration, washed first with ice-cold absolute alcohol and then with dry ether, exposed to phosphoric oxide and paraffin chips in a vacuum desiccator for 20 minutes, and analysed. Where large fractions were taken the resultant liquors were analysed (see footnote to runs 5, 15, 16, 17, 19, Table I). The results are shown in Table I and Fig. 1*a*, the S/Na ratios being, as elsewhere, atomic ratios. The "polysulphide" sulphur is denoted throughout by (S).

The red oily liquid separating when the ratio S : Na in the solution was between 1.09 and 1.94 proved to be an aqueous polysulphide of such high concentration as to suggest that it consisted of molten hydrates; moreover, it invariably approximated to the trisulphide in composition, *e.g.*, when the upper layer had S : Na = 1.879 : 1, the lower had the ratio 1.650 : 1. The oils were sampled for analysis, cooled to  $-7^{\circ}$ , and the smallest possible fraction of crystals was separated and dried as above. This was extremely difficult, for, once started, crystallisation tended to spread rapidly through the system. The mother-liquors after filtration were therefore frequently analysed to check changes due to the crystallisation

of too large a fraction. The results are given in Table II and Fig. 1b.

The products were tested for the presence of alcohol by distilling 5 g. samples in nitrogen until all volatile matter had been evolved, the water condenser finally being thoroughly rinsed into the ice-cooled receiver. The distillate was then submitted to Dupré's modification of Thresh's test [*Pharm. J.*, (3), 9, 408], and the quantity of alcohol shown to be less than 0.02% of the original crystals. Comparative experiments using the iodoform reaction indicated a quantity of the order of 0.01%. Thiosulphate, produced partly by aerial oxidation and partly by solution of sulphur in the hydrolysed monosulphide, was invariably present in small quantities in the crystals; that due to oxidation could be minimised by

avoiding access of air to the polysulphides or their solutions, and the remainder by dissolving the sulphur as quickly as possible in the monosulphide at the lowest convenient temperature, *viz.*, 60°. If the first precaution was not observed, 20 minutes' boiling gave in octahydrated tetrasulphide crystals a thiosulphate content of 2.6—3.0%; by careful exclusion of air, this was reduced to 1.6%, and the second precaution reduced this still further to 0.5—1%.

*Properties of the hydrated polysulphides.* The disulphide *hexahydrate* is a cream-coloured, acicularly crystalline compound; like the other hydrated sulphides, it is very soluble in water and less so in alcohol, giving clear, light yellow solutions. The mean of the analyses of twelve different samples gave: Na,  $21.11 \pm 0.23$ ; (S),  $14.51 \pm 0.33$ ; S,  $29.79 \pm 0.23$  [ $\text{Na}_2\text{S}_2 \cdot 6\text{H}_2\text{O}$  requires Na, 21.10; (S), 14.68; S, 29.36%]. Two samples when heated at 100° in a stream of pure hydrogen lost 34.20 and 34.80% of water, giving the *dihydrate* ( $\text{Na}_2\text{S}_2 \cdot 6\text{H}_2\text{O}$  requires  $4\text{H}_2\text{O}$ , 33.02%). The hexahydrate on heating to 200° could be almost completely dehydrated (Loss: 47.80, 48.50, 48.82. Calc.: 49.54%), but the removal of the last trace of water involved loss of hydrogen sulphide.

The hydrated trisulphide obtained from the oily layer consisted of dark yellow lamellæ melting at about 25° to a thick, oily, reddish-brown liquid. It appeared to be an *octahydrate* [Found (mean of 17 analyses on independent preparations): Na,  $16.21 \pm 0.14$ ; (S),  $23.08 \pm 0.40$ ; S,  $34.03 \pm 0.20$ .  $\text{Na}_2\text{S}_3 \cdot 8\text{H}_2\text{O}$  requires Na, 16.08; (S), 22.38; S, 33.57%]. On dehydration at 100° in a stream of hydrogen, three samples lost 43.96, 44.92, and 44.49% of water,

giving a *monohydrate* ( $\text{Na}_2\text{S}_3 \cdot 8\text{H}_2\text{O}$  requires  $7\text{H}_2\text{O}$ , 44.05%). The remaining water cannot be completely removed without considerable hydrolysis; e.g., at  $200^\circ$  three samples lost 47.94, 48.51, 49.20% (Calc. for  $8\text{H}_2\text{O}$  : 50.35%).

The hydrated tetrasulphides formed golden-yellow, glistening plates. The degree of hydration depended upon temperature and water concentration of the liquid from which they were crystallised. With high water content at low temperatures, two higher *hydrates* were obtained [Found in *A* : Na, 13.59; (S), 28.75; S, 38.05.  $\text{Na}_2\text{S}_4 \cdot 9\text{H}_2\text{O}$  requires Na, 13.69; (S), 28.58; S, 38.10%. Found in *B* : Na, 12.49; (S), 25.64; S, 34.10.  $\text{Na}_2\text{S}_4 \cdot 11\text{H}_2\text{O}$  requires Na, 12.37; (S), 25.81; S, 34.41%]. When the water content was reduced, an octahydrate separated [Found (mean of 8 analyses on 8 different samples) : Na,  $14.45 \pm 0.14$ ; (S),  $29.62 \pm 0.40$ ; S,  $40.78 \pm 0.32$ . Calc. : Na, 14.47; (S), 30.19; S, 40.26%]. By reducing the proportion of water or raising the temperature, a product which might be either a hepta- or mixture of hexa- and octa-hydrates was obtained [Found : Na, 15.76; (S), 31.58; S, 43.24. Calc. for heptahydrate : Na, 15.33; (S), 32.00; S, 42.66%].

Dehydration of any of these preparations at  $100^\circ$  gave no evidence of lower hydrates, and the whole of the water could be removed at  $140^\circ$  : thus three separate samples of octahydrate lost 46.35, 44.92, and 45.67% (Calc. : 45.27%).

The pentasulphide is an orange-coloured hexahydrate, crystallising in minute plates [Found : Na, 14.67; (S), 40.54; S, 51.18. Calc. : Na, 14.65; (S), 40.77; S, 50.96%]. This material obviously suffered decomposition by hydrolysis on dehydration even at  $100^\circ$ .

(ii) *The Action of Sulphur on Anhydrous Alcoholic Solutions of Sodium Monosulphide*.—Solutions of polysulphides have been prepared by dissolving sulphur in alcoholic solutions of sodium monosulphide. Through an examination of the solids crystallising from solutions varying considerably in the ratio S:Na, it has been established that, although unsuitable for preparation of pure polysulphides, the method yields di-, tri-, tetra-, and probably penta-sulphide. There is also some evidence of the existence of alcoholates, and this is being investigated by means of vapour-pressure measurements.

*Experimental*. A solution of sodium (4 g.) in anhydrous alcohol was converted to the monosulphide by dividing it into two equal portions, saturating one with hydrogen sulphide, gently boiling it in a stream of nitrogen to remove excess of gas, and adding it to the other. The requisite weight of sulphur was dissolved by boiling for the minimum time. The resulting liquids were, after analysis, partly crystallised by evaporation in a vacuum at  $15^\circ$ .

The small fraction of crystals deposited was quickly collected on a Buchner funnel, well pressed, washed with several small quantities of anhydrous alcohol, dried by exposure to calcium chloride in a vacuum desiccator, and analysed. The results are in Table III.

The solubility of the polysulphides increased with their sulphur content, so that with solutions above the tetrasulphide composition the separation of a primary fraction was prevented by crystallisation taking place in one stage with the removal of all but the last trace of alcohol. These products obviously had the composition of the mother-liquor and were therefore examined under the microscope without analysis. About the composition  $\text{Na}_2\text{S}_{4.5}$ , a large proportion of yellow crystals, typical of tetrasulphide, appeared, together with some brownish-yellow crystals, characteristic of pentasulphide. The light yellow constituent was largely replaced by the darker constituent at about the pentasulphide stage, whilst in the hexasulphide region this replacement was complete, but light yellow crystals of sulphur appeared. The products were in every case homogeneous microcrystalline polysulphides, uncontaminated by thiosulphate, but containing alcohol in such quantities as to indicate the presence of alcoholates (compare Rule and Thomas, J., 1914, 105, 177). The disulphide was golden-yellow, acicular, and microcrystalline; the trisulphide formed dull yellow, tabular crystals; the tetrasulphide, dull yellow cubes with an olive-green tinge; and the pentasulphide, deep, orange, tabular crystals.

(iii) *The Action of Sulphur on Sodium Hydrosulphide.*—Rule and Thomas (*ibid.*) dissolved various proportions of sulphur in a solution of sodium hydrosulphide in anhydrous alcohol and found pure tetrasulphide to be formed only with the elements present in the calculated ratio. With less sulphur the products were considered to be mixtures of tetrasulphide and unchanged hydrosulphide, with pentasulphide proportions a mixture of tetrasulphide and sulphur resulted, but with more sulphur still there was some indication of higher polysulphides in the mixture. These authors confirmed their conclusions by estimating the hydrogen sulphide evolved during the dissolution of the sulphur.

We have repeated and confirmed these results, and have extended

the experiments to aqueous-alcoholic solutions. This was done because the nearly equal solubility of hydrosulphide and tetrasulphide in anhydrous alcohol makes it impossible fractionally to separate them from this medium. In aqueous alcohol, however, the former appears to be definitely less soluble than the latter, and thus it has been possible to crystallise tetrasulphide as a late fraction even from solutions initially containing only sufficient sulphur to form trisulphide. Consequently, it would seem that sodium tetrasulphide is the only product from hydrosulphide over an extended range of sulphur concentration.

Bloxam (*loc. cit.*) stated that only one definite compound, *viz.*,  $\text{Na}_4\text{S}_9 \cdot 14\text{H}_2\text{O}$ , could be obtained from solutions of sulphur in aqueous hydrosulphide. In an endeavour to obtain such tetrasodium salts, we passed hydrogen sulphide through aqueous-alcoholic solutions of the hydrosulphide whilst the sulphur was dissolving. Products of extremely variable composition were obtained, and only a fortuitous choice would have given compounds apparently of the type described by Bloxam. If such compounds were actually produced, they would have to contain at least 14 molecules of water. This high state of hydration is unusual, and the cumulative evidence suggests that the materials were *mixtures* of disodium compounds.

*Experimental.* 6-G. portions of sodium, dissolved in 150-c.c. lots of pure dry alcohol, were converted to hydrosulphide by the usual process (p. 1478); in the gently boiling solutions the required weights of sulphur were dissolved, and the solutions were evaporated to crystallisation or precipitated with dry ether. In appearance, composition, and properties, the products so obtained were identical with those described by Rule and Thomas (*loc. cit.*, pp. 179—183), tetrasulphide being the only definite polysulphide. The formation of disulphide by the action of sodium on the tetrasulphide was also confirmed (*idem, ibid.*, pp. 187—188), and, by a modification of these authors' method, we obtained further support for our results by measuring the hydrogen sulphide evolved during the dissolution of the sulphur.

For work in aqueous alcohol, lots of 10.3 g. of sodium were converted to hydrosulphide in an alcohol-water mixture (120 and 65 c.c. respectively), and sufficient sulphur was subsequently added to give the trisulphide composition. In the first case, the solution, after being kept at  $-22^\circ$  for 7 hours, deposited a large mass of plate-like crystals [Found: Na, 15.51; (S), 26.59; S, 36.75%; Na:S = 1:1.703]. In a second preparation, the material was fractionally crystallised; the first fraction, produced by cooling to  $-15^\circ$  for one hour, was presumably a mixture of tetra- and hydro-sulphides

[Found: Na, 15.44; S, 41.82%; Na:S = 1:1.947], whilst a second fraction, obtained by cooling to  $-22^{\circ}$  for 2 hours, and a third, by evaporating the mother-liquor to half bulk in a vacuum at room temperature followed by cooling to  $-30^{\circ}$ , were pure tetrasulphide [Found: for (ii), Na, 15.62; S, 43.64; for (iii), Na, 14.68; S, 41.00%; Na:S = 1:2.009, 1:2.007].

These experiments were modified by passing hydrogen sulphide through the liquid during the dissolution of the sulphur, but the solids produced on cooling were of indefinite and variable composition.

## II. *Preparation of Polysulphides by Dry Methods.*

(i) *Reaction between Sulphur and Sodium Carbonate or Hydroxide.*—Polysulphides have been prepared by the action of sulphur on heated metallic oxides, hydroxides, or carbonates. Berthollet (*Ann. Chim.*, 1798, 25, 233) believed them to be pure, and ascribed the occurrence of sulphate in their solutions to a reaction with water, but Gay-Lussac (*ibid.*, 1811, 78, 87) and Vauquelin (*Ann. Chim. Phys.*, 1817, 6, 5) contended that it was a primary product, and this was confirmed by numerous subsequent workers. Fordos and Gelis (*Ann. Chim. Phys.*, 1846, 18, 86) found that a similar reaction took place in solution, producing thiosulphate and polysulphide, and Rose (*Annalen*, 1829, 17, 324; 1842, 45, 415, 533) confirmed this for potassium carbonate.

These results assume importance through Friederich's claim (*Met. Erz.*, 1914, 11, 80) to have obtained pure polysulphides by the reaction between sulphur and sodium carbonate in carbon dioxide, and through his having used them in the investigation of the sodium sulphide-sulphur equilibrium (see p. 1489).

*Experimental.* 8.21 G. of sulphur and 6.79 g. of anhydrous sodium carbonate were heated under nitrogen. Reaction commenced slowly at about  $200^{\circ}$ , giving thiosulphate and polysulphide. At  $350^{\circ}$  the product contained 11.25% of thiosulphate, less than 0.05% of sulphate, and some unchanged material; whilst at  $640^{\circ}$  a loss of 2.85 g., corresponding to the whole of the carbon dioxide in the carbonate, was found, and the residue contained 17.70% of sodium sulphate and 4.22% of sodium sulphite, but no thiosulphate.

Analogous reactions were observed with sodium hydroxide, but similar experiments in boiling aqueous solutions led only to thiosulphate and polysulphide.

(ii) *The Action of Sodium on Sulphur.*—The preparation of polysulphides by the action of metallic sodium on molten sulphur has been attempted by Jones (J., 1880, 37, 1461), Rosenfeld (*Ber.*, 1891, 24, 1658), and others. The method is unsatisfactory owing to the

violence of the combination and to contamination of the product either by silicates from the container or by oxidation. A more convenient process, due to Locke and Austell (*Amer. J. Sci.*, 1898, 20, 592), is to allow the elements to react under toluene. From purely qualitative observations of the presence of free sulphur in the toluene or of metallic sodium in the product according as the added sulphur sufficed for the formation of trisulphide or not, these authors concluded that no material is obtainable with less sulphur than a mixture of tri- with some tetra-sulphide. As these results have been generally held by subsequent writers to indicate that only trisulphide is produced under these conditions, we have

FIG. 2.

repeated this work quantitatively. Our findings (see Fig. 2) indicate that no compound higher than the trisulphide is produced. Free sodium in diminishing quantities is invariably present until this composition is reached, but not afterwards, provided that the reactants have been brought into intimate contact by crushing. The reaction is unique in that a polysulphide appears to be the first product, for even with a trace of sulphur no white film appears on the sodium surface such as might indicate monosulphide—under these conditions the metallic surface is partially coated with distinctly yellow patches, as though a polysulphide must be formed even at the cost of leaving available surface unattacked.

*Experimental.* The required weight of clean metallic sodium was melted under 250 c.c. of carefully dried toluene in a 500-c.c. flask

fitted with a reflux condenser through which was added a weighed quantity of sulphur in 0.5 g. portions. The sodium was immediately coated with a yellow coherent film, but the reaction did not become vigorous until 1.5 atomic proportions of sulphur had been added, whereupon the film burst. The escaping sodium reacted vigorously with the dissolved sulphur, and it became necessary to cool the flask in water. After each subsequent addition of sulphur, we ground the spongy, friable masses with a long glass pestle to free the imprisoned sodium. Finally, the toluene was boiled for 20 minutes to complete the operation.

The sulphide was quickly collected on a Buchner funnel, well pressed, washed with cold toluene, and heated at  $100^{\circ}$  for 2 hours

FIG. 3.

under a good vacuum applied through a drying train. With material below trisulphide composition, free sulphur was always present at this stage. When, however, sulphur equivalent to pentasulphide was used, there was a tendency for this element to crystallise on the cold filter pad; this was avoided by heating the funnel and washing with boiling toluene. The remainder of the toluene was removed by cautiously melting the sulphide. The products were homogeneous masses of pure sodium sulphides which gave clear solutions in water. If, however, insufficient care was taken to moderate the reaction in toluene by cooling, carbon to the extent of 0.05% might be present. Table IV compares the proportion of sulphur originally used with that found in the final product after melting.

(Calc. for  $\text{Na}_2\text{S}_3$ : S, 67.6%.)

(iii) *Desulphurisation of the Polysulphides*.—Rule and Thomas (J., 1917, 111, 1063) measured the loss in weight of sodium tetrasulphide when heated in a stream of hydrogen for consecutive  $\frac{1}{2}$ -hour periods, the temperature being raised by  $50^\circ$  between each period. The results, when plotted as time against composition, indicated that the disulphide is the most stable polysulphide at high temperatures. Their experiment was not designed to demonstrate the possible existence of lower polysulphides, and indeed, could not have done so, for the period of heating at each temperature was quite insufficient for equilibrium to be reached. In the experiments outlined below, rate of loss of sulphur with changing composition has been determined by weighing the sulphur evolved on heating a known quantity of polysulphide at various fixed temperatures in a stream of nitrogen of constant velocity. The results, shown graphically in Fig. 3, indicate the presence of di-, tetra-, and penta-sulphides by well-defined changes in the rate of loss of sulphur. The exceptional stability of the disulphide is here confirmed by the very low gradient.

*Experimental*. The apparatus (Fig. 4) consisted of an outer vessel, A, 28 cm. long and 32 mm. wide, fitted with a lining B provided with a gutter at the bottom which served for condensing and collecting the sulphur liberated. The annular space between the tubes was closed at the top by rubber through which the tube C delivered nitrogen in order to prevent sulphur vapour passing between the tubes. A little sulphur condensed on the thin glass stirrer (which could not be removed during the runs), but this was inappreciable compared with that deposited on B.

10 G. of the polysulphide were weighed into the tube and melted by heating the latter to a depth of 14 cm. in a suitable electric furnace, the temperature of which could be maintained to within  $10^\circ$  of a desired temperature. A weighed condensation tube was then pushed into position, and its upper portion cooled by a blast of

FIG. 4.

air. After 15 minutes, it was quickly removed, and replaced by a similar weighed tube. The process of weighing and replacing the tubes gave the information required. To observe the changes in rate of sulphur evolution, however, it was essential for the heating to be carefully adjusted. If the temperature was too high, the rapid decomposition prevented observation of the change in rate in materials of higher sulphur content, and if too low, the rate of evolution was impracticably slow. The results, being entirely

FIG. 5.

dependent upon the size and form of the apparatus, are only relative, but a few are given below as specimens (see Fig. 3).

### III. The System Sodium Monosulphide-Sulphur.

This system has been studied by Friederich (*loc. cit.*) and by Rule and Thomas (J., 1917, 111, 1063). Their results, shown graphically in Fig. 5, are obviously discordant: the former obtained indications of seven compounds from well-defined maxima on the

temperature-composition curve, together with an eighth,  $\text{Na}_2\text{S}_5$ , from a hidden maximum, whilst the latter workers had evidence of di-, tri-, tetra-, and penta-sulphides, but not of compounds of the type  $\text{Na}_4\text{S}_x$ .

Both these researches are open to criticism. Friederich prepared the higher polysulphides by heating sodium carbonate and sulphur in carbon dioxide, but the material so obtained is invariably contaminated with both sulphite and sulphate, even to the extent of 20% (see p. 1484). Furthermore, his lower polysulphides, produced by dehydrating hydrated monosulphide, must also have contained salts of the sulphur oxy-acids. Neither he nor Rule and Thomas brought forward any other evidence in support of their deductions from arrest temperatures. The extreme depression of some of the eutectic points of the latter authors suggests, in the absence of any statement as to cooling rates, that these were far too rapid in view of the type of material involved.

We have obtained definite indication of di-, tetra-, and penta-sulphides and, apart from its trisulphide region, are in general agreement with the diagram of Rule and Thomas; our melting points, however, are higher in every case but one, and by as much as  $30^\circ$ .

Certain difficulties encountered in our reinvestigation call for comment. (1) There was a pronounced tendency to supercooling, particularly at certain compositions; *e.g.*, with pure sodium tetra-sulphide, this sometimes reached  $87^\circ$ , even with vigorous stirring. Traces of moisture aggravated this difficulty, and the intensely hygroscopic nature of the material rendered seeding impracticable. The only way to overcome it was to take a cooling curve with the stirrer constantly scraping the bottom of the containing vessel, remelt the contents, allow the temperature to fall slightly below the maximum temperature reached in the previous solidification, and stir and scrape vigorously. By this means results might be repeated to within  $5^\circ$ . At the solidus, supercooling was somewhat reduced by causing the stirrer to vibrate rapidly, and when this failed, recourse was had to heating curves, since Tammann's more exact method (*Z. anorg. Chem.*, 1905, 45, 24) was inadmissible.

(2) Molten polysulphides are also characterised by very slow rates of crystallisation: a melt of sodium trisulphide composition required 7 days to reach even approximate equilibrium at  $50^\circ$  below the liquidus temperature. The rates of cooling had, therefore, to be kept as low as practicable.

(3) Again, rapid change in melting points with composition between mono- and di-sulphide and above the eutectic  $\text{Na}_2\text{S}_2$ - $\text{Na}_2\text{S}_4$  renders it imperative to have precisely known compositions and

accurately determined temperatures. The runs were therefore repeated several times on each melt, and the mean temperatures of commencement and completion of solidification taken as the correct ones.

*Experimental.* The materials used for these measurements were prepared under hot toluene (see p. 1485); for those of higher sulphur content than the trisulphide, this element was added to the compound, and for those below this composition sodium was added, the mixtures being carefully melted with thorough mixing. Although this method was useful down to disulphide composition, material with less sulphur than this was difficult to melt in the quantities required, owing to the violence of the combination of such quantities of free metal with the polysulphide when the reaction temperature was reached. In such cases, small quantities of sodium were cautiously added to molten disulphide; this procedure proved perfectly satisfactory, and it is of interest that monosulphide prepared by the method of Rule and Thomas was found to have precisely the same melting point. The total weight of material obtained from a known amount of sodium served as a useful check on the triplicate sulphur and sodium analyses made of the substances after solidification. This precaution was particularly useful in those cases where segregation occurred.

Melting, according to the temperature required, was done in test tubes of Pyrex glass (25 cm. by 28 mm., and 2 mm. thick) or of glazed porcelain (20 cm. by 26 mm., and 3 mm. thick) closed by a cork or asbestos stopper which carried a stirrer (3 mm. diameter) and a thin-walled thermocouple sheath of glass or porcelain, together with a tube for the delivery of nitrogen. The quantity of polysulphide used (50 g.) allowed the thermocouple sheath to be immersed to a depth of 5 cm.

The couple used up to 600° was the "chromel-eureka" 30 S.W.G. wire of the Foster Instrument Co., Letchworth, giving one millivolt for about 12.5°. This was frequently standardised during the course of the work, ice and the boiling points of water, naphthalene, and sulphur being the reference temperatures; it proved to be remarkably constant in use. For higher temperatures, the usual platinum-platinum-rhodium junction was used; it was calibrated as above and also at the freezing points of antimony, sodium chloride, and silver. In all experiments the cold junction was surrounded by melting ice. The potential measurements involved were made in a thermocouple potentiometer ("Laboratory Pattern," by the Cambridge Instrument Co.), reading to 1 microvolt, in conjunction with a 500-ohm A. and M. galvanometer which gave a scale deflexion of 11 mm. per 0.01 millivolt. So far as actual temperature

measurements were concerned, an accuracy of  $\pm 0.025^\circ$  and  $\pm 0.20^\circ$ , respectively, may be claimed for the base and noble-metal couples. Consideration of the concordance between successive remelts, however, indicates that the operation of other factors reduces these accuracies to  $\pm 0.5^\circ$  and  $\pm 5^\circ$  respectively. Over certain regions covering a large number of melts the actual curve certainly represents an accuracy of a much higher order than this in the arrest temperature.

To ensure suitable cooling conditions, a heavily lagged, nichrome-wound furnace was made for use over the lower temperature ranges, and for the upper ranges this was placed in a sheet-iron canister which acted as an air-jacket. The cooling rates employed were approximately as follows :

	Seconds per degree at				
	1000°.	800°.	600°.	400°.	200°.
Furnace jacketed .....	1.5	2	3	5	—
Furnace unjacketed .....	—	—	17	20	40

At the conclusion of each determination, the tube and its contents were allowed to reach room temperature in the furnace, the tube was broken, and a portion of the sulphide removed and immediately analysed, the remainder being stored in a sealed tube for microscopic examination.

The results are set out in Table V. The periods of arrest given in cols. 4 and 5 were obtained by plotting cooling curves in the manner described by Tammann (*Z. anorg. Chem.*, 1905, **47**, 289), but the values are only approximate since correction for supercooling cannot satisfactorily be applied. From these data, the temperature-composition diagram of the system sodium monosulphide-sulphur is plotted (Fig. 6).

The diagram begins at the melting point of sodium monosulphide ( $978^\circ$ ), which appears to be a stable compound under these conditions. From this point the curve descends steeply until disulphide proportions are reached, a break at  $473.9^\circ$  and at a composition slightly beyond that of  $\text{Na}_2\text{S}_2$  indicating that this compound is dissociated to some extent at its melting point. The almost flat portion between 58.9 and 60.2% supports this view. The break at 66.0% of sulphur, followed immediately by the flat portion to 67.0%, indicates the existence of two immiscible liquids. This is borne out by the steep descent to the eutectic which immediately follows. The liquidus curve thus gives no suggestion of sodium trisulphide. Following the  $\text{Na}_2\text{S}_2$ - $\text{Na}_2\text{S}_4$  eutectic ( $232.1^\circ$ ) at 68.77% of sulphur there is a steady rise to a maximum at tetrasulphide composition (compare Rule and Thomas), followed by the  $\text{Na}_2\text{S}_4$ - $\text{Na}_2\text{S}_5$  eutectic ( $249.2^\circ$ ) at 76.4% of sulphur, and finally

by a slight maximum at the pentasulphide composition. This is in agreement with the findings of Rule and Thomas, who suggest that the melting point of this compound is largely depressed by decomposition products. A saturated solid solution of sulphur in

FIG. 6.

pentasulphide appears at 78.5% of sulphur, as may be deduced from the constancy of the melting points ( $251.2^\circ$ ), from the gradual development of a free sulphur arrest point beyond this composition, and from the intersection of the composition-arrest period curve and the composition axis at this place. This agrees with the results

\* Temperature obtained from heating curve.

† Severe supercooling.

of Rule and Thomas and also with those of Küster and Heberlein (*loc. cit.*) and Jones (*loc. cit.*).

It is significant that we disagree entirely with Rule and Thomas on that portion of the curve where the upper arrest points are

particularly difficult to ascertain, *viz.*, between 64 and 69% of sulphur. The step-up in the liquidus line of their diagram between their alleged  $\text{Na}_2\text{S}_2$ - $\text{Na}_2\text{S}_3$  eutectic and trisulphide finds ready explanation in the prevalence of eutectic supercooling at these compositions. Indeed, by neglecting suitable precautions, we have been able to repeat very approximately the points recorded by these workers. Only by many repetitions, supplemented by careful heating curves, was it possible to establish the straightness of the eutectic line in this area. Nearer the disulphide it frequently failed to appear, or suffered supercooling by as much as  $45^\circ$ —an extent which makes it highly improbable that the true eutectic temperature could be reached even approximately with so little of that material present. It is noteworthy that Biltz and Wilke-Dörfurt (*Z. anorg. Chem.*, 1906, 48, 297) experienced so much difficulty in the trisulphide regions of the equilibria,  $\text{CsS-S}$  and  $\text{RbS-S}$ , that in the former case no points are given, and in the latter the curve is left discontinuous.

The appearance in certain melts in the region 65–69% sulphur of a small arrest at about  $190^\circ$  may have been due either to a transition or to the formation of another compound, possibly the trisulphide, only stable below about  $200^\circ$ . This phenomenon is being investigated.

*Micro-examination.* The ease with which much of the material was oxidised, and also its extremely hygroscopic nature, prevented the preparation of specimens for micro-examination by the usual means. Polishing, although difficult owing to softness and friability, was effected on various grades of emery paper under toluene or medicinal paraffin, but the polish-etch resulting was insufficient to characterise the structures present. Aqueous or ethyl-alcoholic reagents destroyed the surface, but a mixture of equal parts of amyl alcohol and carbon disulphide gave excellent results on certain specimens, notably those between disulphide and the  $\text{Na}_2\text{S}_2$ - $\text{Na}_2\text{S}_4$  eutectic and beyond pentasulphide (Plate 1, *b, d, e*). As, however, the materials were transparent, suitable sections were made by mounting them on glass slides with hot Canada balsam and rubbing them down under paraffin. Considerable patience was required, for only a very small proportion of the attempts were successful, and even these failed to realise single-crystal thicknesses or to transmit sufficient light for sharp photographic reproduction. They were, however, capable of giving a very good idea of the nature of the material, particularly if examined with the aid of oblique in addition to the normal direct illumination. The etched specimens were examined visually with oblique illumination, but here again the colour and the nature of the surfaces made successful

photography particularly difficult. In both cases, permanent records were made from typical regions by a drawing and painting directly from the microscope. These faithful reproductions were photographed and appear as Plate 1 with a magnification of 80.

The monosulphide, m. p.  $978^{\circ}$  (compare m. p.  $970^{\circ}$ , Steck, Slavin, and Ralston, *J. Amer. Chem. Soc.*, 1929, 51, 3241; m. p.  $920^{\circ}$ , Friederich, *loc. cit.*), is a reddish-chocolate substance, yellowish in section, and possesses the ordinary polygonal grained structure. Melts between mono- and di-sulphide showed no evidence of any eutectic material, and thus disagree with Friederich's diagram.

The disulphide consists of characteristic transparent, light yellow, needle-like crystals frequently twinned, with straight extinction. The dark lines at the crystal boundaries in the section (Plate 1, *a*) are due to emery powder embedded in the softer eutectic material. A similar structure in yellowish-brown appeared in etching with carbon disulphide and amyl alcohol. Materials of 64.12% sulphur content etched or in section showed needle-like crystals in a ground mass (Plate 1, *b*), which could barely be resolved under high magnification on account of the thickness of the sections, but showed evidence of pearlitic intergrowths typical of eutectic material. This structure was present in proportions increasing with the diminution of the acicular constituent in specimens up to the  $\text{Na}_2\text{S}_2$ - $\text{Na}_2\text{S}_4$  eutectic. Beyond this, polygonal grains began to appear until at tetrasulphide composition the structure revealed was that associated with a metal or other homogeneous crystalline substance (Plate 1, *c*).

As the pentasulphide region was approached, the material became increasingly brittle until, at the pure pentasulphide, it was so friable that it broke down to a powder of tiny crystals on the slightest mechanical shock. This rendered polishing impossible, but a surface obtained by letting the melt slowly cool in contact with a glass slide showed homogeneous polygonal grains quartered with two dark lines across the centre. One specimen of saturated solid solution containing 78.00% of sulphur was (after thirty attempts) successfully polished and etched (Plate 1, *d*), and showed the cored structure typical of such a constituent. A section (Plate 1, *e*) from more tractable material further along the diagram shows the same solid solution in the form of spherical masses embedded in a matrix of polygonal grains of sulphur.

Without exception, these results accord well with our reinvestigation of the thermal analysis, and provide further evidence invalidating previous conclusions respecting a trisulphide and polysulphides of the tetrasodium type.

*Summary.*

A critical reinvestigation of the formation and properties of sodium polysulphides, amplified by original work, has yielded the following results.

(1) The action of sulphur on aqueous-alcoholic solutions of sodium monosulphides gives polysulphide solutions from which may be crystallised:  $\text{Na}_2\text{S}_2, 6\text{H}_2\text{O}$ ;  $\text{Na}_2\text{S}_3, 8\text{H}_2\text{O}$ ;  $\text{Na}_2\text{S}_4, 8\text{H}_2\text{O}$ ;  $\text{Na}_2\text{S}_4, 9\text{H}_2\text{O}$ ;  $\text{Na}_2\text{S}_4, 11\text{H}_2\text{O}$ ;  $\text{Na}_2\text{S}_5, 6\text{H}_2\text{O}$ ; and a tetrasulphide which may be either  $\text{Na}_2\text{S}_4, 7\text{H}_2\text{O}$  or a mixture of  $\text{Na}_2\text{S}_4, 6\text{H}_2\text{O}$  and  $\text{Na}_2\text{S}_4, 8\text{H}_2\text{O}$ . Dehydration of the first two affords  $\text{Na}_2\text{S}_2, 2\text{H}_2\text{O}$  and  $\text{Na}_2\text{S}_3, \text{H}_2\text{O}$  respectively.

(2) The action of sulphur on anhydrous alcoholic solutions of sodium monosulphide, although unsuited for the preparation of pure compounds, gives anhydrous di-, tri-, tetra-, and penta-sulphide.

(3) By dissolution of various proportions of sulphur in alcoholic solutions of sodium hydrosulphide, only one pure compound,  $\text{Na}_2\text{S}_4$ , is obtained:  $2\text{NaHS} + 3\text{S} \rightarrow \text{Na}_2\text{S}_4 + \text{H}_2\text{S}$ . With less sulphur the products are mixtures of tetrasulphide and unchanged hydrosulphide, with pentasulphide proportions a mixture of tetrasulphide and sulphur, and with still more sulphur possibly a higher polysulphide.

(4) The action of metallic sodium on alcoholic solutions of sodium tetrasulphide gives only the disulphide.

(5) Sulphur reacts with sodium carbonate or hydroxide at low temperatures or in solution to produce polysulphides and thio-sulphate, and at higher temperatures to give polysulphides, sulphate, and a little sulphite.

(6) Sulphur reacts with molten sodium under toluene to produce only the trisulphide.

(7) By desulphurising the polysulphides of sodium in an atmosphere of nitrogen at carefully regulated temperatures, changes in decomposition velocity indicate the existence of penta-, tetra-, and di-sulphides.

(8) A phase-rule study of the system  $\text{Na}_2\text{S}-\text{S}$  indicates that monosulphide is stable at its melting point,  $978^\circ$ ; disulphide slightly decomposes, as indicated by a hidden maximum at  $473.9^\circ$ ; tetrasulphide is stable at its melting point,  $284.8^\circ$ ; a saturated solid solution of sulphur in the pentasulphide occurs with material containing 78.5% sulphur; and finally, that tetrasodium compounds are not formed.

The peculiar stability of the tetrasulphide and the marked instability of the trisulphide have been re-affirmed.

The authors wish to acknowledge the extended loan of a potentiometer from Engineer-Commander C. J. Hawkes, R.N. (Retd.),

and a grant from the Research Committee of this College for the purchase of a similar instrument for the completion of the work. They would also warmly thank Mr. J. H. Smith, who carried out a great number of preparations and analyses, and Mr. J. Bone to whose skill the illustrations in Plate I are due.

### CXC.—*Heterocyclic Systems Containing Selenium.* *Part III. cycloSelenopropane.*

By GILBERT T. MORGAN and FRANCIS HEReward BURSTALL.

WHEREAS the interaction of the requisite alkylene dibromide and sodium selenide leads readily to the production in good yields of cyclic selenohydrocarbons containing five- or six-membered rings (J., 1929, 1096, 2197), yet trimethylene dibromide and sodium selenide furnish only a small proportion of *cycloSelenopropane* (I), the main product being a six-fold *polymeride* (III) resulting by aggregations of simpler four-membered unsaturated radicals,  $-\text{CH}_2\cdot\text{CH}_2\cdot\text{CH}_2\cdot\text{Se}-$ .

*cycloSelenopropane* (I), a colourless liquid with a more pungent odour than those of *cycloSelenobutane* and *cycloSelenopentane*, resembles these selenohydrocarbons in yielding a characteristic deep purple *di-iodide* (II) and a white crystalline *mercurichloride*,

but differs from the two higher cyclic homologues in its tendency to give gummy ill-defined materials.

The amorphous saponaceous *polymeride* obtained from these gummy residues decomposes on heating, but without elimination of selenium, into propylene and the more stable *cyclotrimethylene diselenide* (V). This reaction suggests that at the higher temperature the *polymeride* has undergone partial depolymerisation with the intermediate formation of *cyclohexamethylene 1:5-diselenide* (IV). Dilute nitric acid does not rupture the polymeric complex but oxidises its selenium atoms with formation of a *nitrate* (VI), a water-soluble and readily decomposable compound which by double decomposition with hydrochloric acid gives rise to the corresponding *chloride* (VII): this is reduced by sodium metabisulphite to the original *polymeride*. Hot concentrated nitric acid attacks the *polymeride*, yielding *trimethylenediselenious acid dinitrate* (VIII), and oxalic acid, the latter compound being in all probability

maintained to ensure adequate agitation and to prevent aerial oxidation. The alcoholic solution, filtered from precipitated sodium bromide and yellow gum, was distilled under diminished pressure; the distillate was rectified until a colourless alcoholic solution was obtained. This solution was then poured into a large excess of water (1000 c.c. of water for each 100 c.c. of alcoholic solution), and the aqueous-alcoholic solution repeatedly extracted with petroleum (b. p. 40–60°). The petroleum extracts were dried over calcium chloride and the solvent distilled; the residue was distilled under diminished pressure and finally rectified in a stream of carbon dioxide under ordinary pressure. A considerable quantity of the oil polymerised to a yellow gum during these distillations. *cycloSelenopropane* was thus obtained as a colourless limpid oil of exceedingly powerful and penetrating odour. The vapour has an irritant effect on the mucous membrane of the nose. It boiled at 118–119°/779 mm.;  $n_D^{15}$  1.5612;  $d_4^{20}$  1.525;  $d_4^{25}$  1.510;  $d_4^{27.5}$  1.498;  $d_4^{27}$  1.484, whence  $d_4^t = 1.554 - 0.001493t$  (Found: C, 29.2; H, 5.0; Se, 65.0.  $C_3H_6Se$  requires C, 29.7; H, 4.95; Se, 65.3%). The selenohydrocarbon was insoluble in water but was miscible in all proportions with organic media. *cycloSelenopropane* was completely volatile in the vapours of alcohol or ether and to a small extent in the vapours of other volatile solvents. It remained unchanged when kept in a cool dark place. Mineral acids caused rapid polymerisation of this cyclic selenohydrocarbon.

*cycloSelenopropane* 1:1-Di-iodide (II).—Addition of alcoholic iodine to an alcoholic solution of *cycloselenopropane* caused the separation of two products. The less soluble *material*, present in larger quantity, a polymerised condition of the di-iodide, formed an amorphous purple deposit insoluble in all organic media; it softened at 87° and then remained liquid [Found: I, 67.4.  $(C_3H_6I_2Se)_x$  requires I, 67.7%].

The more soluble monomeric *di-iodide* separated in deep purple, hair-like needles, m. p. 98°. Although soluble in acetone, benzene or chloroform, this di-iodide dissolved only sparingly in alcohol and was insoluble in cold water. It decomposed slowly on exposure to light (Found: C, 9.8; H, 1.55; Se, 20.4; I, 67.9; *M*, in acetone, 369.  $C_3H_6I_2Se$  requires C, 9.6; H, 1.6; Se, 21.1; I, 67.7%; *M*, 375).

On grinding the foregoing monomeric di-iodide with water and silver oxide a colourless neutral solution of the dihydroxide resulted, but this soon decomposed with formation of a yellow solid, m. p. 73–74°. Aqueous sodium metabisulphite reduced the di-iodide with difficulty and the presence of *cycloselenopropane* was detected by its odour. A small quantity of yellow polymeride separated slowly from solution.

*cycloSelenopropane mercurichloride*,  $C_3H_6 > Se, HgCl_2$ , separated when alcoholic solutions of mercuric chloride and *cycloselenopropane* were mixed. The white crystalline precipitate, after being washed with alcohol and dried over sulphuric acid, decomposed at  $105^\circ$  after shrinking at  $80^\circ$  (Found: Hg, 50.8; Cl, 18.4.  $C_3H_6Cl_2SeHg$  requires Hg, 51.1; Cl, 18.1%). This mercurichloride was insoluble in water and organic solvents, but aqueous caustic alkalis decomposed it, liberating *cycloselenopropane*. When heated, the mercurichloride gave mercuric selenide and trimethylene dichloride. Addition of methyl iodide to an alcoholic solution of *cycloselenopropane* and cautious evaporation of the mixture led to the production of a brown oil, from which, however, no crystalline methiodide could be isolated.

*The Polymeride (III).*—The yellow gum separating from the original alcoholic solution of *cycloselenopropane* was washed with water to remove sodium bromide and dissolved in chloroform. Evaporation of the dried solution left a deep reddish gum, which was extracted with boiling acetone until the extracts were colourless. The residual gum then solidified to a pale yellow, soap-like substance, m. p.  $38-40^\circ$  [Found: C, 29.7; H, 4.9; Se, 65.0; *M*, ebullioscopic in benzene, 738, 836.  $C_{18}H_{36}Se_6$  requires C, 29.7; H, 4.95; Se, 65.3%; *M*, 727]. This complex substance was insoluble in water or alcohol and sparingly so in acetone, but dissolved readily in warm chloroform or benzene. From its solution in the last two solvents the halogens precipitated coloured unstable additive compounds whereas methyl iodide gave a dark gum. When this *polyselenide* was gently heated, selenium was not eliminated but a considerable amount of frothing took place and the evolved gas when passed through bromine water furnished propylene dibromide, b. p.  $140-141^\circ$  (Found: Br, 78.6. Calc.: Br, 79.15%). The residue consisted of *cyclotrimethylenediselenide*, identified by comparison with an authentic specimen made by the general method of preparation for these diselenides (*v. infra*).

*The Nitrate (VI).*—Warm 2*N*-nitric acid dissolved the polymeride and deposited on cooling a white microcrystalline *nitrate*, which was washed with 2*N*-nitric acid (Found: Se, 31.8.  $C_6H_{12}O_{12}N_4Se_2$  requires Se, 32.3%). This nitrate, which dissolved readily in water to a strongly acid solution, decomposed slowly with evolution of nitrous fumes, leaving a residue of yellow gum; it decomposed rapidly at  $87^\circ$ .

The corresponding *chloride* (VII) was precipitated when concentrated hydrochloric acid was added to a solution of the foregoing nitrate (Found: C, 18.3; H, 3.3; Cl, 36.2.  $C_6H_{12}Cl_4Se_2$  requires C, 18.7; H, 3.1; Cl, 36.9%). Although moderately easily soluble

in water, this white microcrystalline chloride dissolved only sparingly in hydrochloric acid and was insoluble in alcohol or acetone. On addition of aqueous sodium metabisulphite to its aqueous solution a yellow amorphous precipitate of the polymeride was deposited.

The gummy iodide was obtained when potassium iodide solution was added to a solution of the foregoing nitrate which had been neutralised with aqueous sodium acetate. It was sparingly soluble in most common organic solvents but could not be obtained in a state of purity. It decomposed indefinitely above 100°.

Hot concentrated nitric acid reacted violently with the polymeride and the resulting clear colourless solution after evaporation and cooling deposited oxalic acid, m. p. 100° (Found: C, 18·8; H, 4·9. Calc.: C, 19·0; H, 4·8%).

*Trimethylenediselenodi-iodide* (X).—After separation of the oxalic acid the viscid residue was freed from mineral acid by sodium acetate; addition of a concentrated solution of potassium iodide then precipitated the brick-red di-iodide arising from the reducing action of hydriodic acid on trimethylenediselenious acid. *Trimethylenediselenodi-iodide*, also obtained by treating a chloroform solution of *cyclotrimethylene* diselenide with iodine, dissolved in warm chloroform or benzene but very sparingly in acetone or alcohol; it melted to a red liquid at 124° (Found: C, 8·1; H, 1·2; Se, 34·5; I, 55·7.  $C_3H_6I_2Se_2$  requires C, 7·9; H, 1·3; Se, 34·9; I, 55·9%).

*Trimethylenediselenocyanate* (IX) was readily prepared by heating trimethylene dibromide (1 mol.) and potassium selenocyanate (2 mols.) in acetone. The dark filtrate from precipitated potassium bromide was obtained as an oil which subsequently solidified and was obtained in thin colourless prisms, m. p. 53°, by crystallisation from aqueous acetone. Hagelberg (*loc. cit.*) gave m. p. 51° (Found: Se, 62·5. Calc.: Se, 62·7%). This diselenocyanate, which remained undecomposed on keeping, possessed a faint and characteristic odour.

*cyclo*Trimethylene diselenide (V), obtained as a yellow amorphous precipitate when air was aspirated through an alcoholic soda solution of the foregoing diselenocyanate, was purified by crystallisation from acetone or chloroform; m. p. 59°. Hagelberg (*loc. cit.*) gave m. p. 54·5° (Found: Se, 78·9; *M*, ebullioscopic in benzene, 225. Calc. for  $C_3H_6Se_2$ : Se, 79·1%; *M*, 200). This diselenide distilled undecomposed when heated under diminished pressure. Its chloroform solution gave with iodine a red precipitate of trimethylenediselenodi-iodide, m. p. 124° (*vide supra*).

*Trimethylenediselenious Acid Dinitrate* (VIII).—The foregoing diselenocyanate and diselenide both dissolved readily in nitric

acid and the concentrated solution deposited a mass of white needles, which were recrystallised from nitric acid (Found: Se, 40.2.  $C_3H_{10}O_{10}N_2Se_2$  requires Se, 40.4%). The dinitrate decomposed at 112°; it dissolved easily in water and this solution when treated successively with sodium acetate and potassium iodide gave a brick-red precipitate of trimethylenediselenodi-iodide, m. p. 124°.

### CXCI.—*Pyrolysis of Diazoamino-p-toluene.*

By GILBERT T. MORGAN and LESLIE PERCY WALLS.

THE first researches on the pyrolysis of diazoamines were made by Heusler (*Annalen*, 1890, 260, 227), who heated these compounds either in sand or in liquid paraffin. Similar experiments on the heating of diazoaminobenzene in aniline were subsequently made by Hirsch (*Ber.*, 1892, 25, 1973), who recommended this process as a means of obtaining *o*- and *p*-aminodiphenyls (*o*- and *p*-xenyamines: D.R.-P. 62309; Friedländer's "Fortschritte," 3, 36; compare Aeschlimann, Lees, McClelland, and Nicklin, *J.*, 1925, 127, 66). Recent improvements in the technology of diphenyl and its derivatives have, however, afforded more direct means of preparing these two bases (Jenkins, McCullough, and Booth, *Ind. Eng. Chem.*, 1930, 22, 31; Morgan and Walls, *J. Soc. Chem. Ind.*, 1930, 49, 15r).

The foregoing researches showed that on pyrolysis diazoaminobenzene decomposed violently at 150°, evolving nitrogen and yielding *p*-aminoazobenzene, diphenylamine, *o*- and *p*-xenyamines, and small quantities of aniline, benzene, and diphenyl. To this list of pyrogenic products we would now add azobenzene, found in a repetition of Hirsch's experiment. In a comparative study of the pyrolysis of diazoamino-*p*-toluene and diazoamino-*p*-chlorobenzene Heusler found that both evolved nitrogen on heating, but he isolated only toluene and chlorobenzene respectively from the non-gaseous products of these decompositions, although the molecular configuration of the former diazoamine suggests that its pyrolysis should result in the production of a certain amount of *o*-aminoditolyl (I).

Pyrolysis of diazoamino-*p*-toluene in *p*-toluidine was attended by evolution of nitrogen at 150°, but in other respects the thermal changes differed considerably from those observed with diazoaminobenzene. Aminoazo-*p*-toluene and di-*p*-tolylamine were isolated only in small proportions and the total yield of aminoditolyls was

about 15% of the amount calculated. Quantitative estimations of the more volatile products of pyrolysis showed that toluene was the chief non-gaseous constituent and that nitrogen was always accompanied by ammonia.

Colouring matters such as indulines which arise in the pyrolysis of diazoaminobenzene were absent in this case. Azo-*p*-toluene was found in appreciable amount and, as this compound and toluene are both reduction products of diazoamino-*p*-toluene, the hydrogen required for their production must be sought in the resinification of a considerable proportion of the melt. The pitch left after extraction of the crystallisable products by petroleum consisted largely of acid-soluble resins similar to those obtained from low-temperature tar (*J. Soc. Chem. Ind.*, 1928, 47, 132r). The *p*-toluidine employed as solvent in the pyrolysis was recovered unchanged.

*Isomeric Aminoditolyls*.—The pyrolytic removal of nitrogen from diazoamino-*p*-toluene may be considered to yield two radicals, *p*-tolyl and *p*-iminotolyl, the union of which would result in the formation of di-*p*-tolylamine and of an aminoditolyl (I) in which the *p*-tolyl group enters the other ring in the ortho-position with respect to nitrogen.

The absence of any free para-position explains the small yield of aminoditolyl (compare Jacobsen, *Annalen*, 1922, 427, 148). The main basic product, which has been shown to have this constitution, is always accompanied by a small proportion of an isomeric amine which was first detected by its characteristic hydrochloride. Although the amount available of this by-product is too small for orientation experiments, it may be formulated provisionally as arising from the directive influence of the methyl group acting in opposition to that of the imino-residue (II). The constitution assigned to the main product, 2-amino-4' : 5-dimethyldiphenyl (4' : 5-dimethyl-2-zenylamine), was established by its pyrogenic conversion into 2 : 6-dimethylcarbazole (VI), a substance which would be a useful constitutional guide were it not for the confusion attaching to it in the literature.

2 : 6-Dimethylcarbazole.—Richter's "Lexicon" records 2 : 6-dimethylcarbazole, m. p. 208—209° (Borsche, Witte, and Bothe, *Annalen*, 1907, 359, 77), and 3 : 7-dimethylcarbazole, m. p. 224° (Ullmann, *Ber.*, 1898, 31, 1497). The alternative notation suggests

a structural identity, but as the disparity in melting points required elucidation, we have repeated the two preparations. Ullmann transformed hydrazo-*p*-toluene into the isomeric *o*-semidine (III), the triazole (IV) of which yielded 2:6-dimethylcarbazole (VI) on heating.

The *p*-tolylhydrazone (VII) of 3-methylcyclohexanone studied by Borsche, Witte, and Bothe loses ammonia to acid and becomes converted into a tetrahydrodimethylcarbazole (VIII). The constitution of this compound is not, however, defined completely by its mode of formation, since ring closure might have involved the carbon in position 2 of 3-methylcyclohexanone instead of carbon atom 6. Alternatively both condensations might have occurred concurrently with the formation of a mixture of two isomeric tetrahydrocarbazoles. However, oxidation of the product led solely to 2:6-dimethylcarbazole, m. p. 224°, identical with the two other preparations.

#### EXPERIMENTAL.

The diazoamino-*p*-toluene employed in the following experiments had been recrystallised from petroleum (b. p. 60–80°) and was in the form of yellow needles, m. p. 118°.

A preliminary heating of 10 g. of this diazoamine, which had been dried in a vacuum, with 25 g. of dry *p*-toluidine showed a slight evolution of nitrogen and ammonia at 120°, but with further rise of temperature the rate of gaseous evolution increased until at 150° the reaction became violent and exothermic, the temperature still rising without external application of heat. By operating under 5 mm. pressure, most of the *p*-toluidine present distilled away; the later fractions had a yellow tint due to azo-*p*-toluene, whereas the first runnings, when shaken with excess of 2*N*-hydrochloric acid to dissolve the base, left a light yellow, neutral oil which boiled at 110°, giving a colourless distillate identified as toluene.

**I. Quantitative Estimation of the more Volatile Products of Pyrolysis.**—(a) *Ammonia and toluene.* Quantities of diazoamino-*p*-toluene ranging from 5 to 8 g. were heated with three parts of

*p*-toluidine in a 50 c.c. distilling flask connected in series with a 10 c.c. graduated cylinder and a flask containing a measured quantity of *N*-hydrochloric acid. After the exothermic reaction had subsided, the temperature of the melt was raised until *p*-toluidine distilled. Heating was then stopped and air blown through the liquid to drive off all ammonia and toluene. The former was estimated alkalimetrically; the latter was measured directly in the graduated cylinder after the *p*-toluidine had been dissolved in 2*N*-hydrochloric acid. Calculated on a g.-mol. weight of diazoamino-*p*-toluene, the proportion of ammonia ranged from 0.31 to 0.35 g., whereas the amount of toluene varied from 40.2 to 44.1 g.

(b) *Nitrogen, ammonia and toluene.* The foregoing experimental details were modified so that the side tube of the graduated cylinder was connected with a Schiff nitrometer. One g. of the diazoamine in 4 g. of *p*-toluidine was pyrolysed in a stream of carbon dioxide and the evolved permanent gas, collected over aqueous caustic potash, was analysed and found to consist solely of nitrogen. Hydrogen either free or combined could not be detected. The weight of nitrogen from one molecular proportion of diazoamino-*p*-toluene (225 g.) was 25.8 g.

This experiment was repeated, a much larger amount (4.4 g.) of diazoamine being used. A 500 c.c. gas-holder was converted into a nitrometer, and a guard-tube, packed with dry paraffin wax to remove traces of *p*-toluidine, was inserted between the graduated receiver and the acid flask in which the ammonia was fixed as chloride. The toluene and nitrogen were measured directly, the ammonia was estimated as chloroplatinate: 225 g. of diazoamine furnished 46.5 g. of toluene, 0.31 g. of ammonia, and 26.6 g. of nitrogen, these numbers corresponding approximately with the molecular ratios of 0.5 C<sub>7</sub>H<sub>8</sub>, 0.02 NH<sub>3</sub> and 0.94 N<sub>2</sub>.

II. *Less Volatile Products of Pyrolysis.*—In earlier experiments the whole melt was distilled under reduced pressure, but experience showed that a preliminary extraction with petroleum was preferable. From two melts made by pyrolysis of 200 g. of diazoamine and 500 g. of *p*-toluidine, 482 g. of the base were recovered by distillation under reduced pressure, and when the black residue (142 g.) was extracted with excess of petroleum (b. p. 60–80°) approximately 30 g. of tarry matter remained undissolved. From this pitch a considerable amount of acid-soluble resinamine was obtained which when applied to wood surfaces from alcoholic solution gave a reddish-brown stain similar in appearance to that from the resinamines of low-temperature tar. After removal of the solvent a dark red residue (110 g.) was distilled under reduced pressure. A fraction, b. p. 74°/4 mm., consisted mainly of *p*-toluidine (22 g.), so the

whole of this base originally employed was accounted for in the distillates. The less volatile products were now distilled over a range 155—170°/4 mm., a bright red semi-solid product (57 g.) being obtained, mainly between 162° and 167°. This fraction was extracted with excess of warm 0.5*N*-hydrochloric acid; when the brownish-red residue (16 g.) was stirred with 50 c.c. of ether, 9 g. of red crystalline azo-*p*-toluene, m. p. 144° after one crystallisation from ligroin, remained undissolved. Removal of solvent from the ethereal extract yielded a semi-solid mass which gave from alcohol small characteristic red crystals of azo-*p*-toluene (1 g.) mixed with long silky needles. The less soluble azo-*p*-toluene was removed by warming the solution to 40° and filtering it rapidly; on cooling, silky yellowish-white needles (3 g.), m. p. 79°, separated from the filtrate. This product was identified as di-*p*-tolylamine and yielded a nitrosoamine crystallising from dilute alcohol in yellow needles, m. p. 101°.

6-*Amino*-3 : 4'-*dimethylazobenzene*. This substance, the chief product in the transformation of diazoamino-*p*-toluene by concentrated acid, is formed only in small quantity in the pyrolysis. Its presence could be detected in the alcoholic di-*p*-tolylamine-azo-*p*-toluene mother-liquor by a characteristic green coloration with concentrated hydrochloric acid.

In one experiment, however, a larger yield was obtained: the distillate from a melt made by pyrolysis of 267 g. of diazoamine in *p*-toluidine left after extraction with hydrochloric acid a dark brown residue (27 g.). When dry, this material was lixiviated with petroleum (b. p. 80—100°) to yield a red solution which on concentration furnished 6 g. of azo-*p*-toluene. The portion insoluble in petroleum dissolved in alcohol containing hydrochloric acid to a dark green solution, which deposited matted yellow needles (9 g.), darkening at 160° and melting at 174° (Found: Cl, 13.2, 13.5.  $C_{14}H_{15}N_3 \cdot HCl$  requires Cl, 13.5%). From this *hydrochloride*, which was hydrolysed even by water, *aminoazotoluene* was liberated by warm aqueous alkali; it crystallised from petroleum (b. p. 60—80°) in lustrous red needles, m. p. 118° (Found: N, 19.3.  $C_{14}H_{15}N_3$  requires N, 18.8%).

*Isomeric Aminoditolyls*.—The aqueous hydrochloric acid solution of primary bases (from 200 g. of diazoamino-*p*-toluene) deposited on cooling 10 g. of a hydrochloride (A) in small, thick, slightly yellow-tinted needles. Evaporation of the solution yielded a further 20 g. of these crystals. The filtrate on vigorous stirring gave a small precipitate of a hydrochloride (B) crystallising in characteristic silky needles, darkening on exposure, m. p. 175—177°, and the mother-liquor slowly furnished pale yellow, elongated plates (C), m. p. 172°.

The products B and C, which were only obtained in small amounts, yielded the same acetyl and azo- $\beta$ -naphthol derivatives. They were respectively the anhydrous and the hydrated form of the same hydrochloride (Found for B: C, 70.6; H, 7.2; N, 6.0; Cl, 14.7.  $C_{14}H_{15}N.HCl$  requires C, 71.9; H, 6.9; N, 6.0; Cl, 15.2. Found for C: C, 66.2; H, 7.6; N, 6.0; Cl, 13.9.  $C_{14}H_{15}N.HCl.H_2O$  requires C, 66.8; H, 7.2; N, 5.6; Cl, 14.1%).

The *acetyl* compound crystallised from petroleum (b. p. 80–100°) or alcohol in colourless lustrous needles, m. p. 169.5–170.5° (Found: C, 80.0; H, 7.3; N, 6.1.  $C_{16}H_{17}ON$  requires C, 80.3; H, 7.1; N, 5.9%).

The *azo- $\beta$ -naphthol* derivative crystallised from benzene, containing a little alcohol, in scarlet needles, m. p. 188–189.5° (Found: C, 81.25; H, 5.9; N, 8.2.  $C_{24}H_{20}ON_2$  requires C, 81.8; H, 5.7; N, 8.0%).

The small proportion of this aminoditolyl isolated did not permit of orientation experiments, but the more plentiful hydrochloride (A) yielded an isomeric base which was identified as follows:—

*2-Amino-4':5-dimethyldiphenyl (4':5-dimethyl-2-xenylamine)*. The hydrochloride (A), recrystallised from alcohol containing hydrochloric acid, separated in colourless needles, decomp. 216–226° (Found: N, 6.1; Cl, 15.0.  $C_{14}H_{15}N.HCl$  requires N, 6.0; Cl, 15.2%). This salt was readily diazotisable and treatment of the diazo-solution with sodium azide furnished an oily triazo-compound. The free base boiled at 165–167°/4 mm.

*2-Acetamido-4':5-dimethyldiphenyl (acetyl-4':5-dimethyl-2-xenylamine)*, prepared by the action of acetic anhydride and anhydrous sodium acetate on the foregoing hydrochloride, was only very sparingly soluble in water and crystallised from petroleum (b. p. 80–100°) in rosettes of brittle colourless needles, melting at 104° and dissolving readily in alcohol, benzene or chloroform (Found: N, 6.0.  $C_{16}H_{17}ON$  requires N, 5.9%).

*4':5-Dimethyldiphenyl-2-azo- $\beta$ -naphthol (4':5-dimethylxenyl-2-azo- $\beta$ -naphthol)* crystallised from benzene, containing a little alcohol, in lustrous red needles, m. p. 179.5° (Found: N, 7.95.  $C_{24}H_{20}ON_2$  requires N, 8.0%). This substance was almost insoluble in the alcohols, petroleum, chloroform or acetone, but dissolved readily in glacial acetic or concentrated sulphuric acid, developing with the latter a violet-red coloration.

III. *2:6-Dimethylcarbazole*.—(1) *From 4':5-dimethyl-2-xenylamine*. This oily base was heated in a hard glass tube in a current of air so that the gases passed over glowing quicklime (compare Blank, *Ber.*, 1891, 24, 306). An oily distillate (about 60%) was collected which rapidly solidified and was freed from a small amount of

unchanged primary base by crystallisation from benzene; 2 : 6-dimethylcarbazole then separated as a colourless solid, m. p. 224° (Found : C, 85.9; H, 6.55; N, 7.5.  $C_{14}H_{13}N$  requires C, 86.1; H, 6.65; N, 7.2%).

(2) *From azo-p-toluene.* This azo-compound was reduced with zinc and glacial acetic acid to hydrazo-*p*-toluene, which was transformed in alcoholic solution with stannous chloride and hydrochloric acid into the stannichloride of the *o*-semidine, 2-amino-4' : 5-dimethyldiphenylamine (Täuber, *Ber.*, 1892, 25, 1023). This readily oxidisable base was set free from the tin salt by alkali and extracted with ether, and the extract dried over anhydrous sodium sulphate. The base obtained after removal of ether crystallised from petroleum (b. p. 60—80°) in shining leaflets, m. p. 107°. Conversion into triazole was best effected by ethyl nitrite in alcoholic sulphuric acid; the product precipitated by dilution with water crystallised from petroleum in brownish-white plates, m. p. 93°. When maintained for some time at 360°, this triazole yielded 2 : 6-dimethylcarbazole (Ullmann, *loc. cit.*), which was purified by crystallisation from alcohol (with charcoal) and through its picrate (m. p. 162°).

(3) *From 3-methylcyclohexanone and p-tolylhydrazine.* In this synthesis both the racemoid 3-methylcyclohexanone and its dextrorotatory component were employed, the latter being obtained by hydrolysis of pulegone with sulphuric acid.

With *p*-tolylhydrazine the racemoid ketone gave a hydrazone liquid at the ordinary temperature, whereas the *d*-ketone gave a solid hydrazone (m. p. about 90°). On ring closure, both hydrazones gave a crystalline dimethyltetrahydrocarbazole of m. p. 147° (sintering at 135°), although this compound still retains the asymmetric carbon atom. In either case Perkin and Plant's method for tetrahydrocarbazole was employed (J., 1921, 119, 1831) in which the hydrazone was warmed with five parts of glacial acetic acid. A vigorous reaction ensued and the tetrahydro-compound separated; after recrystallisation from alcohol it was dehydrogenated by boiling with sulphur in quinoline (Perkin and Plant, J., 1923, 123, 694). The product was poured into hydrochloric acid, and the crude 2 : 6-dimethylcarbazole purified by sublimation with powdered iron at 225—240° under 15—20 mm. pressure and by crystallisation from benzene. The blue fluorescence in alcohol described by Borsche (*loc. cit.*) is not shown by solutions of the purified carbazole.

The three preparations of 2 : 6-dimethylcarbazole were shown to be identical by their consistent mixed melting points of 224°.

9-Nitroso-2 : 6-dimethylcarbazole was prepared by treating a solution of 0.8 g. of 2 : 6-dimethylcarbazole in 15 c.c. of glacial

acetic acid with a slight excess of sodium nitrite (0.6 g.) in water. The solution filled with yellow felted needles, m. p. 113° after recrystallisation from spirit.

The following table gives a comparison of the properties of carbazole (m. p. 238°), 2 : 6-dimethylcarbazole (m. p. 224°), and its 3 : 6-isomeride (m. p. 219°) (Täuber and Loewenherz, *Ber.*, 1891, 24, 1035, 2598).

## NOTES.

*The Mechanism of Cyanoacetamide and Cyanoacetic Ester Condensations. A Reply.* By JOGENDRA CHANDRA BARDHAN.

A SHORT time ago (J., 1929, 2225) the author discussed Ingold's view (J., 1921, 119, 330) that monoketonic compounds react with ethyl cyanoacetate in the enolic form, in the light of the contrary observations of Kohler and Corson (*J. Amer. Chem. Soc.*, 1923, 45, 1975) and of Lapworth and McRae (J., 1922, 121, 2741). In a recent communication (this vol., p. 184) Ingold states that the author's account of his work on the subject is misleading inasmuch as his subsequent modified views (J., 1926, 1868) have not been taken into consideration. In this later paper Ingold's references to aldol condensation are very brief. Indeed, no mention is made of

his earlier work or of the subsequent demonstrations of Kohler, Lapworth, and others which are definitely at variance with his hypothesis. In these circumstances the omission by the author of any reference to this paper was unavoidable.

The evidence which Ingold brings forward in support of the statement that in an enolised  $\beta$ -diketone carbon coupling consistently occurs at enolic carbon is not conclusive. There can be little doubt that in ethoxymethylene-ketones and other  $\alpha\beta$ -unsaturated ketones, *e.g.*, mesityl oxide, benzylideneacetone, etc., the ethylenic double bond takes part in additive reactions; but it is not clear to the author why similar considerations would hold in the case of enolised 1:3-dicarbonyl compounds where owing to prototropic changes the enolic double bond cannot always remain in the  $\alpha\beta$ -position. Furthermore, Ingold assumes that in hydroxymethylenecyclohexanone the direction of enolisation is beyond doubt and carbon coupling takes place at the enolic carbon, leading to the formation of a quinoline derivative. So far as the author is aware, scarcely any work appears to have been done on the constitution of hydroxymethylenecyclohexanone. On general grounds it is, however, quite conceivable that equilibrium exists between the hydroxymethylene form (I) and the aldo-enolic form (II), especially as the cyclohexane ring exhibits a marked tendency to acquire a double bond (compare, for instance, Dieckmann, *Annalen*, 1901, 317, 27; Birch, Kon, and Norris, J., 1923, 123, 1368). Consequently the view that in

hydroxymethylenecyclohexanone the direction of enolisation is fixed cannot be regarded as correct. According to the author's view, the preferential formation of the quinoline derivative is explicable by the superior activity of the aldehyde group in comparison with the carbonyl. The author's observations, however, are based on only a few instances and therefore it seems desirable to postpone discussion until further experiments have been performed. —UNIVERSITY COLLEGE OF SCIENCE, CALCUTTA. [Received, May 12th, 1930.]

*The Preparation of Anhydrous Oxalic Acid.* By ERIC IAN JOHNSON and JAMES RIDDICK PARTINGTON.

ANHYDROUS oxalic acid is readily prepared by the following method. A mixture of 5 g. of the hydrated acid with 100 c.c. of toluene, previously distilled over calcium chloride, is distilled in a wide-necked conical flask until about 15 c.c. of liquid remain. The contents of

the flask are submitted to filtration and the solid is washed with a little dry benzene. It is then kept in a vacuum desiccator over wax for 12 hours. The product is found by titration to be pure anhydrous oxalic acid. A conical flask is used since, during distillation, the anhydrous acid separates in small needles adhering to the side of the flask which are difficult to remove from an ordinary distilling flask. The method is probably capable of application, with suitable distilling liquids, in many other cases and an attempt is being made to obtain anhydrous periodic acid in this way. A similar method using carbon tetrachloride has been described (Adams, "Organic Syntheses," 1921, Vol. I, p. 67). Since toluene has a higher boiling point than carbon tetrachloride, its use will probably expedite the dehydration.—EAST LONDON COLLEGE, UNIVERSITY OF LONDON.

 condensation of, with *p*-aminoacetophenone (GRABOWSKA and WEIL), i, 260.  
 compounds of glycine with (BERGMANN and ENSSLIN), i, 1046.  
 action of, on methyluracils (SCHMIDT), i, 435.  
 action of, on proteins of serum (HENLEY), i, 716.  
 detection of (GHIGLIOTTO), ii, 445.  
 determination of (SCHULEK), ii, 606; (ROMEO), ii, 1009.

- Formazylbenzene, dibromo-** (CHATTAWAY and WALKER), i, 930.
- Formic acid, oxidation of, by hydrogen peroxide** (HATCHER and HOLDEN), ii, 684.
- action of, on sesquiterpenes (ROBERTSON, KERR, and HENDERSON), i, 1293.
- calcium salt, crystal structure of (YARDLEY), ii, 480.
- chromous salts (TRAUBE, BURMEISTER, and STAHN), ii, 990.
- sodium salt, reduction of mercuric bromide by (BOURION and PICARD), ii, 685.
- alkoxymethyl esters (FARREN, FIFE, CLARK, and GARLAND), i, 1230.
- isobornyl ester (PARISELLE), ii, 742.
- methyl ester, pyrogenic decomposition of (MULLER and PEYTRAL), i, 353; (PEYTRAL), i, 777.
- determination of, in blood and urine (DE EDS), i, 713.
- Formic acid, chloro-, esters of** (OESPER, BROKER, and COOK), i, 1408.
- cyano-, ethyl ester, action of magnesium ethyl bromide on (BRUYLANTS), i, 15.
- methyl ester, action of, on magnesium organic compounds (FINGER and GAUL), i, 1431.
- $\alpha$ -Formiminoacetoacetic acid, ethyl ester hydrochloride** (WIELAND and DORRER), i, 779.
- Formyltrimethylarsonium bromide, action of, on the nervous system** (HUNT and RENSHAW), i, 861.
- Fourmarierite, constitution of** (SCHOEP), ii, 236.
- Foyaita** (MOLENGRAFF and HALL), ii, 64.
- Fractionation apparatus, Fischer vacuum** (SATTLER), ii, 708.
- Free-space numbers** (LORENZ and HERZ), ii, 185.
- Freezing points of binary mixtures** (ANDREWS, KOHMAN, and JOHNSTON), ii, 852.
- of dilute solutions of electrolytes (HOVORKA and RODEBUSH), ii, 772.
- Friction, internal, of aqueous solutions, effect of temperature on** (WIEN), ii, 931.
- internal relative (HERZ and WEGNER), ii, 482.
- Friedel and Crafts reaction with aldehydes and ethylene oxide** (SCHAARSCHMIDT; HERMANN and SZEMZI), ii, 1278.
- Heart of. See Heart.
- Metabolism of. See Metabolism.
- Nerves of. See Nerves.
- Fruits, constituents of** (TUTIN), i, 1028.
- effect of storage on the anti-scurvy value of (DELF), i, 484.
- lead salts of acids from (AUERBACH and WEBER), i, 1130.
- Fruit juices, detection of lactic acid in** (BORNTRÄGER), ii, 1007.
- Fulgides, halochromism of** (DIETZEL and NATON), i, 1067.
- Fulminic acid** (WIELAND), i, 1048.
- Fumaric acid, formation of, from maleic acid** (TERRY and EICHELEBERGER), i, 780.
- crystal structure of (YARDLEY), ii, 1126.
- halogenation of (TERRY and EICHELEBERGER), i, 631.
- oxidation of, to tartaric acid (MILAS and TERRY), i, 780.
- sodium salt, surface tension of solutions of (RIBAS), ii, 647.
- Fungi, staling of cultures of** (PRATT), i, 106.
- calcium requirements of algæ and (LOEW), i, 1218.
- colouring matters of (KÖGL and POSTOWSKY), i, 50, 1083, 1439; (KÖGL and v. TAEUFFENBACH), i, 1440.
- ammonium acetate as source of nitrogen for (BACH), i, 216.
- oxidation of fats by (DERX), i, 1119.
- excretion of urea by (IVANOV), i, 344, 746.
- higher (GUTH), i, 1247.
- Furfuraldehyde, molecular association of** (GETMAN), ii, 511.
- condensation of, with aliphatic aldehydes (IVANOV), i, 421.
- Furfuraldoxime N-phenyl ether** (BAMBERGER), i, 142.
- Furfuroic acid, furfuryl ester** (ZANETTI), i, 953.
- Furfuryl alcohol, esters of** (ZANETTI), i, 567.
- Furfuryl bromide** (v. BRAUN, FUSSGÄNGER, and KUHN), i, 1403.
- Furfurylbenzylmethylamine, and its salts** (v. BRAUN, FUSSGÄNGER, and KUHN), i, 1403.
- $\alpha$ -Furfurylideneacetaldehyde, and its derivatives** (IVANOV), i, 421.
- Furfurylideneaminoacetic acid, barium salt** (BERGMANN, ENSSLIN, and ZERVAS), i, 891.
- $\alpha$ -Furfurylidenebutaldehyde, and its derivatives** (IVANOV), i, 421.
- $\alpha$ -Furfurylideneheptaldehyde, and its derivatives** (IVANOV), i, 421.
- 2-Furfurylidene-6-cyclohexylidenecyclohexanone** (GARLAND and REID), i, 1281.

- α*-Furfurylidenepropaldehyde, and its derivatives (IVANOV), i, 421.  
*α*-Furfurylidenevaleraldehyde, and its derivatives (IVANOV), i, 421.  
 Furnace, micro-, for high magnifications (ROBERTS and STADNICHENKO), ii, 707.  
 Furoxane, dicyano- (WIELAND), i, 1050.  
 Furyl-*n*-butylcarbinol (PIERCE and ADAMS), i, 824.  
 4-Furyl-1:6-dimethylmethylenedihydropyridine, and its salts and derivatives (MUMM), i, 965.  
 4-Furyl-1:6-dimethylpyridine-3:5-dicarboxylic acid, ethyl ester, methosulphate (MUMM), i, 964.  
 4-Furyl-1:6-dimethyl-*α*-pyridone (MUMM), i, 966.  
 Furyltrichloromethylcarbinol (HOWARD), i, 557.  
 4-Furyl-1:2:6-trimethylidihydropyridine-3:5-dicarboxylic acids, ethyl esters (MUMM), i, 966.  
 Fusain, oxidation of (TIDESWELL and WHEELER), i, 373.  
*Fusarium*, development of pigment in species of (SIDERIS), i, 1363.  
*Fusarium cromyophthoron*, effect of hydrogen-ion concentration on the pectinase in (SIDERIS), i, 1117.  
*Fusarium lini*, growth of (ANDERSON), i, 1522.

G.

- iso*Gadoleic acid, and its silver salt (HASHIMOTO), i, 1234.  
 Galactosamic acid, and its phenylhydrazide (FREUDENBERG and DOSER), i, 367.  
 Galactose, fermentation of, by yeast (v. EULER and NILSSON), i, 866; (v. EULER and LÖVGREN), i, 1214; (ABDERHALDEN), i, 1362.  
 metabolism of. See Metabolism.  
*isopropylidene* ether (LEVENE and MEYER), i, 1043.  
 Galactosemonodiphenylmethanedi-methylidihydrazone (v. BRAUN and BAYER), i, 1333.  
 Galactosidoglucose (SCHLUBACH and RAUCHENBERGER), i, 838.  
 Galanginidin chloride 3-methyl ether (MALKIN and ROBINSON), i, 827.  
 iodide (PRATT and ROBINSON), i, 826.  
 Galangin 3-methyl ether, and its di-acetyl derivative (KALFF and ROBINSON), i, 423.  
 trimethyl ether (TASAKI), i, 1444.  
 Galegine, and its salts (MÜLLER), i, 1520.  
 Gallium (FRICKE and BLENCKE), ii, 417.  
 spark spectrum of (WEINBERG), ii, 249; (CARROLL), ii, 1101.  
 hydroxide (FRICKE), ii, 578.  
 Gallium separation :—  
 separation of (SWIFT), ii, 71.  
 separation of, from aluminium and iron (FRICKE), ii, 717.  
 Gallotannin (NIERENSTEIN, SPIERS, and HATCHER), i, 692.  
 action of yeast on (NIERENSTEIN, SPIERS, and HADLEY), i, 951.  
 Gamboge suspensions, specific volume of (COUTTS), ii, 290.  
*Gardenia turgida*, *d*-mannitol from (FORSTER and RAO), i, 1295.  
 Gas, electrolytic, safety devices against explosions of (NORMANN), ii, 996.  
 Gases, electrical double refraction of (LYON), ii, 266.  
 reflection of electrons in (BAERWALD), ii, 731.  
 diamagnetism of (GLASER), ii, 82.  
 dispersion formula for (HEERZFELD and WOLF), ii, 182, 478.  
 electric discharge through (THOMSON), ii, 461; (BANERJI), ii, 921.  
 electrodeless discharge in (LASAREV), ii, 1107.  
 apparatus for studying passage of sparks through (JOLIBOIS), ii, 1194.  
 electrification by friction between solids and (PERUCCA), ii, 1028.  
 ionisation in (LANGMUIR and JONES), ii, 169.  
 by impacts (COMPTON and VAN VOOHRIS; TUYE; TATE; WALDIE), ii, 1106.  
 by slow-moving electrons (JESSE), ii, 919.  
 by *α*-particles (GURNEY), ii, 256.  
 ionisation and vapour pressure of (BECKER), ii, 342.  
 mobility of ions in (LORR), ii, 461; (WAHLIN), ii, 615.  
 liberation of ions in reactions between (BREWER), ii, 919.  
 critical potentials of (DYMOND), ii, 6, 253.  
 potential at interfaces of liquids with (FRUMKIN), ii, 873.  
 attachment of electrons to molecules of (BAILEY), ii, 1019.  
 molecular heats of, at low temperatures (GIACOMINI), ii, 757.  
 specific heat of (BRINKWORTH), ii, 373.  
 thermodynamic temperature of (WERTHEIMER), ii, 784.  
 thermal study of systems of (PICCARDI), ii, 540.

**Gases**, kinetic theory of (DE KOLOSOVSKI), ii, 531.  
 in relation to the quantum theory (SCHIDLOF), ii, 843.  
 equations for (LEDUC), ii, 376; (HERZ), ii, 496.  
 mass-action law for (GILLESPIE), ii, 532.  
 quantum methods applied to (PLANCK; EINSTEIN), ii, 495.  
 compressibility of (BATUECAS; BATUECAS, MAVERICK, and SCHLATTER), ii, 497.  
 apparatus for measuring (HOWARTH and BURT), ii, 818.  
 effect of molecular attraction on the pressure of (MAASS and MORRISON), ii, 500.  
 pressure and radiation in relation to intermolecular forces in (STEWART), ii, 1112.  
 equilibrium pressure of hydrates of (TAMMANN and KRIGE), ii, 869.  
 temperature and pressure variations in (MANDELL and WEST), ii, 99.  
 sudden cooling of, in a quartz tube (STAUDINGER and KREIS), ii, 316.  
 critical pressure of, under varying specific heat (WALKER), ii, 100.  
 cryoscopy of solutions of, in various solvents (GARELLI), ii, 1151.  
 density and diffusion of (BARUS), ii, 25.  
 viscosity of, at low temperatures (GÜNTHER), ii, 100.  
 interfacial properties of, in contact with liquids (GILBERT and SHAW), ii, 795.  
 movements of small bubbles of, in water (McTAGGART), ii, 509.  
 determination of solubility of, in liquids (MANCHOT), ii, 233.  
 supersaturation of, in liquids (KENRICK, WISMER, and WYATT), ii, 105; (WYATT), ii, 504.  
 absorption coefficients for electrons in (BRODE), ii, 617.  
 adsorption of (URBAIN; MUNRO and JOHNSON; RAY), ii, 191; (RUFF and HOHLFELD), ii, 192.  
 equation for (BANGHAM and SEVER), ii, 507.  
 influence of rate of flow on (LORENZ and WIEDBRAUCK), ii, 507.  
 by cellulose nitrate (COSTA), ii, 956.  
 by graphite (LOWRY and MORGAN), ii, 1051.  
 by liquids (LEWIS and WHITMAN), ii, 106.  
 by silica (BISCHOFF and ADKINS), ii, 533.  
 by water (WHITMAN and DAVIS; WHITMAN), ii, 106.

**Gases**, catalysis of, with metals of the platinum group (DUPARC, WENGER, and URFER), ii, 1177.  
 combustion of, with air (WHITE), ii, 48.  
 at high pressures (BONE, NEWITT, and TOWNEND), ii, 800.  
 electrification in (DICKINSON), ii, 740.  
 electrical ignition of (MORGAN), ii, 553.  
 influence of vapours on the inflammability of mixtures of air and (JORISSEN and MEUWISSEN), ii, 307; (JORISSEN and VAN DER VALK), ii, 374; (JORISSEN and ONGKIEHONG), ii, 875.  
 explosion of (BROWN, LESLIE, and HUNN), ii, 682.  
 apparatus for preparation of constant mixtures of air and (YANT and FREY), ii, 897.  
 circulation pump for (MENZIES, COLLINS, and TYSON), ii, 818.  
 complex, band spectra of crystals and of (KAHLER), ii, 626.  
 condensed, entropy of, at absolute zero (EVOKEN and FRIED), ii, 97.  
 degraded, theory of (BENNEWITZ), ii, 97.  
 diatomic, molecular heat and thermal conductivity of (SCHREINER), ii, 97.  
 heated, electrical conductivity of (GHOSH), ii, 461.  
 ideal, quantum theory of (EINSTEIN), ii, 624.  
 entropy of (v. HAUER), ii, 495; (DE KOLOSOVSKI), ii, 496.  
 inert, cathode fall, current density, and dark space in mixtures of (GÜNTHER-SCHULZE), ii, 341.  
 calculation of atomic frequencies of (NARBUTT), ii, 948.  
 rarity of (ASTON), ii, 18.  
 inflammable, propagation of flame in mixtures of air and (WHITE), ii, 408.  
 mixed, action of radiation on (SENFTLEBEN), ii, 883.  
 mobility of ions in (LOEB and ASHLEY), ii, 7.  
 adsorption and evolution of, from charcoal (LORENZ and WIEDBRAUCK), ii, 382.  
 effect of infra-red radiation on combustion of (DAVID), ii, 980.  
 ignition of (WHEELER), ii, 408; (WHITE), ii, 553.  
 explosion of (BERL and FISCHER), ii, 413; (WENDLANDT), ii, 136, 301.

- Gases**, mixed, separation of, by diffusion (LORENZ and MAGNUS), ii, 501.  
 thermal separation of (ELLIOTT and MASSON), ii, 763.  
 monatomic, chemical constants of (SIMON), ii, 98.  
 perfect, definition of (CLARK), ii, 495.  
 rare, in the atmosphere (JEFFREYS), ii, 83.  
 from volcanoes (PIUTTI and BOGGIO-LERA), ii, 1092.  
 excitation and ionisation potentials of (HERTZ and KLOPPERS), ii, 342.  
 ionisation and resonance potentials of (HERTZ and KLOPPERS), ii, 730.  
 relationship of pseudo- and non-electrolytes to (CARLSOHN), ii, 1044.  
 determination of, by combustion with cupric oxide (SVÉDA), ii, 432.  
**Gas absorption apparatus** (PATTERSON), ii, 151.  
 Geissler bulbs (ODDO), ii, 431.  
 pipette (JONES), ii, 431.  
**Gas analysis**, absorption of oxygen in (FIESER), ii, 238.  
 by combustion with copper oxide (SVÉDA), ii, 154.  
 automatic (LÖWENSTEIN), ii, 154.  
**Gas analysis apparatus** (MURRAY), ii, 593; (CHAMBERLAIN and NEWITT), ii, 710.  
 burette for electrochemical processes (JOFINOV), ii, 898.  
 burette for micro-analysis (CHRISTIANSEN), ii, 593.  
 multiple (DIRKEN), ii, 154.  
 for determining oxygen and carbon dioxide in respiratory exchange (HAGEDORN), i, 177.  
**Gas circulation apparatus** (PEARSON and THOMAS), ii, 1194.  
**Gas interferometer**, Haber-Löwe, calibration of (WERNER), ii, 1091.  
**Gastric juice**, action of, on chlorophyll (KORTSCHAGIN), i, 200.  
 determination of the free acid of (SAHLI), i, 458.  
 determination of pepsin in (ROSTOCK), i, 1009; (BOAS; HIRSCH-MAMROTH and RINDFLEISCH), i, 1213.  
**Gastropods**, intestines of. See Intestines.  
**Gaucher's disease**, kersin in (LIEB), i, 189.  
**Gay-Lussac's law** applied to liquid films (MARCELIN; DELAPLACE), ii, 772.  
**Gehlenite**, constitution of (GOSSNER), ii, 821.  
**Gelatin**, extraction and properties of (HÉRISSEY and CHEYMOL), i, 487.  
 sugars from (HÉRISSEY and CHEYMOL), i, 1383.  
**Gels**, character and electrical properties of (MICHAUD), ii, 292.  
 velocity of hydrogen ions in (ISGARISCHEV and POMERANZEVA), ii, 800.  
 kinetics of swelling and shrinking of (LIEPATOV), ii, 685, 968.  
 replacement of (LINDGREN), ii, 392.  
 adsorption and osmosis in (TOMITA), ii, 202.  
 effect of hydrogen-ion concentration on adsorption of colouring matters by (MARKER and GORDON), ii, 31.  
 rhythmic precipitation in (FISCHER), ii, 853.  
 microtome for cutting sections of (FRICKE), ii, 965.  
 deformed, effect of drying on (HATSCHEK), ii, 667.  
 dyed, birefringency and dichroism in (NEUBERT), ii, 201.  
**Gelatin** (KINGSTON and SCHRYVER), i, 89; (KNAGGS and SCHRYVER; MANNING), i, 90; (HOBNE), i, 91.  
 optical activity of (KRAEMER and FANSELOW), ii, 1057.  
 ultra-violet absorption spectrum of (BAKER and DAVIDSON), ii, 838.  
 rotatory power of (VLIES and VELINGER), ii, 292.  
 effect of hydrogen-ion concentration on (BOGUE and O'CONNELL), ii, 744.  
 photographically active (SHEPPARD), ii, 966.  
 second isoelectric point of (KRAEMER), ii, 519.  
 density and hydration of (SVEDBERG), ii, 202.  
 swelling of, in carbamide (CHODAT), ii, 521.  
 effect of hydrogen-ion concentration on (OSTWALD, KUHN, and BÖHME), ii, 777.  
 elasticity of (SCARTE), ii, 862.  
 electro-ultrafiltration of (BECHHOLD and ROSENBERG), ii, 668.  
 surface tension of (JOHLIN), ii, 388; (JOHNSTON and PEARD), ii, 659; (DE CARO), ii, 857.  
 distribution of hydrogen ions between water and (SHUKOV and STSCHOUAREV), ii, 386.  
 influence of, on transport numbers (SCATCHARD), ii, 41.  
 gels, elasticity of (POOLE; SAUER and KINKEL), ii, 519.

- Gelatin gels**, formation of Liesegang's rings in (SCOTT-BLAIR), ii, 519.  
 action of sodium aminoacetate and tungstate on, in test tubes (STUCKERT), ii, 1061.  
 solutions, plasticity and structure of (SHEPPARD; BOGUE), ii, 1058.  
 influence of neutral salts on (STIASNY and GUPTA), i, 707; ii, 392; (STIASNY, GUPTA, and TRESSER), ii, 393; (STIASNY), ii, 524; (CSAPÓ), ii, 1157.  
 action of bile salts on (STUCKERT), ii, 392.  
 protective action of, on gold sols (TARTAR and LORAH), ii, 864.  
 action of ferric hydroxide sols on aqueous solutions of (WINTGEN and MEYER), ii, 524.  
 precipitation of, by tannin (SMORODINOV and ADOVA), i, 847.  
 titration curve of (ATKIN and DOUGLAS), ii, 113.  
 sensitisation of Congo-red by (ETTISCH and RUNGE), ii, 864.
- Gelatinase**, formation of, by *Proteus* (CLARK and MERRILL), i, 1511.
- Geneserine hydriodide** (POLONOVSKI and POLONOVSKI), i, 960.
- $\psi$ -Geneserolimethine hydrochloride** (POLONOVSKI and POLONOVSKI), i, 293.
- $\psi$ -Geneseroline** (POLONOVSKI and POLONOVSKI), i, 293.
- Gentiacaolin**, hydrolysis of (BRIDEL), i, 336.
- Gentibiase** (KARRER and STAUB), i, 336.
- Geodia gigas***, constituents of (ACKERMANN, HOLTZ, and REINWEIN), i, 720.
- Geraniol**, hydrogenation of (GRIGNARD and ESCOURROU), i, 772.
- Germane**. See Germanium hydride.
- Germanibenzoic acid**. See Phenyl-germanic acid.
- Germanite**, analysis of (KRIESEL), ii, 153.
- Germanium** (DENNIS and HANCE), i, 798; (COREY, LAUBENGAYER, and DENNIS), ii, 493; (DENNIS and LAUBENGAYER), ii, 888.  
 spectrum of (LUNT), ii, 611.  
 ultra-violet spark spectrum of (IRETON), ii, 453.
- Germanium hydride**, physical properties of (COREY, LAUBENGAYER, and DENNIS), ii, 493.  
 vapour pressure of (SCHENCK and IMKER), ii, 279.  
 pharmacology of (PANETH and JOACHIMOGLU), i, 197.
- dioxide**, allotropy of (MÜLLER and BLANK), ii, 145.
- Germanium organic compounds**, aromatic (MORGAN and DREW), i, 1197.  
 tetra-alkyls and -aryls, and tetraethoxide (TABERN, ORNDORFF, and DENNIS), i, 1108.  
 tetraethyl (DENNIS and HANCE), i, 798.
- Germanium determination**:—  
 determination of (JOHNSON and DENNIS), ii, 442.
- Germicides**, properties of, in relation to structure (ISHIWARA), i, 750.  
 determination of power of (COOPER, WOODHOUSE, and FORSTNER), i, 749.
- Geum urbanum***, extraction of gein from (HÉRISSEY and CHEYMOL), i, 487.
- Gitogenin** in digitalis leaves (WINDAUS and BRUNKEN), i, 873.
- Gitonin**, and its degradation products (WINDAUS and LINSERT), i, 1438.
- Gitoxigenin**, and its derivatives (WINDAUS and SCHWARTZ), i, 1295.
- Gitoxin** from digitalis leaves (WINDAUS and SCHWARTZ), i, 1295.
- Glands**, physiology of (ASHER and TAKAHASHI), i, 331.  
 sexual, influence of, on metabolism (KORENOCHEVSKY and CARR), i, 1513.
- Glands**. See also Prostate, Salivary, Thymus, and Thyroid glands.
- Glass**, structure of (SELJAKOV, STRUTINSKI, and KRASNIKOV), ii, 849.  
 constitution and properties of (TURNER), ii, 1144; (ECKERT; TOOL and HILL; TAMMANN), ii, 1145.  
 physico-chemical composition of (BARY), ii, 380.  
 transparency of, in the infra-red (LIANA), ii, 357.
- allotropy** of (LE CHATELIER), ii, 190.
- viscosity** of (STOTT, IRVINE, and TURNER), ii, 503; (STOTT), ii, 1146.  
 influence of composition on (ENGLISH), ii, 954.
- viscosity and allotropy** of (LE CHATELIER), ii, 280.
- fusibility and viscosity** of (LACRENIER and GILARD), ii, 379.
- vapour pressure of the volatile constituents** of (BORN), ii, 785.
- sorption of ammonia and carbon dioxide** by (BANGHAM and BURT), ii, 284.
- adsorption of colouring matters** by (SCHELTE), ii, 286.
- adsorption of water** on (McHAFFIE and LENNER), ii, 854.
- adsorption of water and vapours** by (D'HUART; BANGHAM and BURT), ii, 657.

- Glass**, effect of chemicals on (KLAMER), ii, 427.  
 blue, substitute for (MEYER), ii, 601.  
 germanium (DENNIS and LAUBEN-GAYER), ii, 888.  
 molten, surface tension of (LACRENIER and GILARD), ii, 387.  
 silicate, physical properties of (TURNER), ii, 767.  
 soda-lime-silica, X-ray diffraction of (WYCKOFF and MOREY), ii, 1146.
- Gliadin** (TROENSEGAARD and FISCHER), i, 848.  
 isoelectric point of (TAGUE), ii, 391.  
 from wheat, preparation and properties of (DILL and ALSBERG), i, 1478.
- Globulins**, physical chemistry of (ADOLF), ii, 199.  
 heat changes of (ADOLF), ii, 520.  
 increase in, in blood, from decomposition of hæmoglobin (REYMANN), i, 1345.
- Glucal**, change of, to deoxyglucose, in rabbits (KONDO), i, 99.
- Gluconic acid**, formation of, by moulds (BUTKEWITSCH), i, 341.  
*p*-toluenesulphonylhydrazide (FREUDENBERG and BLÜMMEL), i, 52.
- Glucoproteins**, carbohydrate group in (IZUMI), i, 848.
- Glucosamine**, configuration of (KARBER, SCHNIDER, and SMIRNOV), i, 418.
- $\beta$ -Glucosan** from cellulose (VENN), i, 887.
- Glucosans** (KERB and KERB-ETZDORF), i, 233.
- d*-Glucose**. See Dextrose.
- $\beta$ -Glucose**, mutarotation of (LUNDSEGAARD and HOLBØLL), i, 1494.
- $\alpha$ - and  $\beta$ -Glucosephosphoric acids, barium salts (KOMATSU and NODZU), i, 515.
- Glucoside**,  $C_{21}H_{38}O_{12}$ , from *Helianthus annuus* (SANDO), i, 1026.
- Glucosides** (CRAIK and MACBETH), i, 1296.  
 enzymic hydrolysis of (JOSEPHSON), i, 1359, 1360.  
 synthesis of alkyl derivatives of (PACOT), i, 515.  
 standardisation of, affecting the heart (LENDLE), i, 1501.
- Glucosides**. See also:—  
 Acacin.  
 Amygdalin.  
 Arbutin.  
 Asperuloside.  
 Datiscin.  
 Diosmin.  
 Gein.  
 Gitogenin.  
 Gitonin.  
 Gitoxin.
- Glucosides**. See also:—  
 Helicin.  
 Irisin.  
 Loroglossin.  
 $\beta$ -Methylglucoside.  
 Rhamnucoside.  
 Salicin.
- 6(1)-[ $\beta$ -*d*-Glucosido]- $\alpha$ -methyl-*d*-glucoside** (HELPERICH and BECKER), i, 11.
- Glue**, velocity of swelling of (LIEPATOV), ii, 968.  
 electro-ultrafiltration of (BECHHOLD and ROSENBERG), ii, 668.
- Glutaconic acids** (GOSS, INGOLD, and THORPE), i, 549.
- Glutardialdoxime**, preparation of (SHAW), i, 299.
- Glutarylfluorescein** (DUTT and THORPE), i, 141.
- Glutarylrhodamine** (DUTT and THORPE), i, 142.
- Glutathione** (TUNNICLIFFE), i, 752; (HOPKINS), i, 1499.  
 synthesis of (STEWART and TUNNICLIFFE), i, 795.  
 effect of traces of iron on oxidation of (HARRISON), i, 13.  
 in mammalian blood (HOLDEN), i, 1484.  
 as an arsenic receptor in mammals (VOEGTLIN, DYER, and LEONARD), i, 861.
- Glutelin** from cotton seed (JONES and CSONKA), i, 1225.
- Gluten**, constituents of (DILL), i, 622.
- Gluten**, bromo- (VANDEVELDE), i, 91.
- Glutenin**, isoelectric point of (TAGUE), ii, 391.
- Glyceraldehyde**, oxidation of, in presence of phosphates (WIND), ii, 1174.
- l*-Glyceric acid**, effect of substitution on rotation of (GREENWALD), i, 712.
- Glycerol**, preparation of, by fermentation (TOMODA), i, 227.  
 heat of solution of (DE KOLOSOVSKI), ii, 540.  
 and its aqueous solutions, freezing points of (LANE), ii, 971.  
 dielectric constant and absorption coefficient of (BOCK), ii, 355.  
 vapour pressure of aqueous solutions of (LYER and USHER), ii, 501.  
 and its mixtures with sodium chloride (CARR, TOWNSEND, and BADGER), ii, 767.  
 purification of (KAILAN and ORIGH), i, 501.  
 assimilation of, by oxygenated yeast (MARIAN), i, 105.  
 acetylenic derivatives of (LESPIEAU), i, 1375.  
 metabolism of. See Metabolism.

- Glycerol**, detection of, colorimetrically (KOLTHOFF), ii, 161.
- Glycine**, possible synthesis of, in the body (SWANSON), i, 465.  
relation between taste and concentration of solutions of (HEIDUSCHKA and KOMM), i, 1389.  
compounds of formaldehyde with (BERGMANN and ENSSLIN), i, 1046.
- Glycine-*p*-allyloxyanilide** (KARRER, DIECHMANN, and HAEBLER), i, 243.
- Glycine anhydride**, oxidation of, by hydrogen peroxide (LÜDTKE), i, 837.  
diacetyl and dibenzoyl derivatives (ABDERHALDEN and KOMM), i, 175.
- Glycogen** (LING, NANJİ, and PATON), i, 1011.  
molecular weight of (FEARON), i, 12.  
heat of combustion of (MEIER and MEYERHOF), ii, 92.  
effect of sugar administration on formation of (GIGON), i, 192.  
hexose from fermentation of (v. EULER and NILSSON), i, 1496.  
hydrolysis of, by salivary diastase (PACHTNER), i, 738.  
content of, in liver (FRANK and FÖRSTER), i, 1503.  
decomposition of, in muscle (WEBER), i, 1004.  
determination of small quantities of (DE JONGH and PLANELLES), i, 325.
- Glycol**,  $C_2H_4O_2$ , and its derivatives, from American cotton wax (FARGHER and PROBERT), i, 879.
- Glycols**, synthesis of, from atrolactic acid (ROGER), i, 659.  
wandering of acyl groups in (BETTZICHE), i, 1147.  
reaction of, with acetone (HERMANS), ii, 50.
- Glycolysis** (NEGELEIN), i, 856.  
measurement of (WARBURG), i, 321.  
*in vitro* (MORGULIS and BARKUS; JOHN), i, 1344.  
effect of insulin on (NITZESCU and CADARIU), i, 1352.
- Glycosuria**. See Diabetes.
- Glycuronic acid** in plants (PALLADIN and LEVTSCHENKO), i, 1369.
- d*-Glycuronic acid** (EHRlich and REHORST), i, 1379.  
in vegetable fibres (SCHWALBE and FELDTMANN), i, 1238.
- d*-Glycuronolactone**, structure and rotation of (HUDSON), i, 515.
- Glycid-*dl*-serine**, hydrochloride and anhydrides of (BERGMANN and MIEKELEY), i, 235.
- Glycidtriphenylmethylaminoacetic acid**, and its sodium salt and ethyl ester (HELFERICH, MOOG, and JÜNGER), i, 792.
- Glycyrrhizin**, reactions of (BERTOLO), ii, 1212.
- Glyoxaline (*iminazole*)**, excretion of, in urine (HUNTER), i, 459.
- Glyoxalines**, methylation of (FORSYTH and PYMAN), i, 699.  
metabolism of. See Metabolism.  
determination of, colorimetrically (HUNTER), ii, 332.
- Glyoxaline compounds**, crystallography of (GREENWOOD), ii, 1037.
- Glyoxaline-4:5-dicarboxylic acid**, dissociation constants of (PAULY), i, 1327.  
salts of (LEHMSTEDT), i, 1103.
- l*-Glyoxalinelactic acid**, fate of, in the animal body (KONISHI and TANI), i, 731.
- Glyoxalinepropionic acid**, fate of, in the animal body (KONISHI and TANI), i, 731.
- Glyoxime dimethyl ether**, *diamino*-, and its tetra-acetyl derivative (AVOGADRO and TAVOLA), i, 1041.
- Glyoximes**, hydroxy- (PONZIO), i, 8.
- Glyoxylic acid**, isomeric hydrazones of (BUSCH and v. BEUST), i, 400.  
colour reaction of, with Schryver's reaction (FOSSE and HIEULLE), ii, 162.  
identification of, by its reaction with hydrazine and xanthhydrol (FOSSE and HIEULLE), i, 1130.
- Goats**, protein substitutes in diet of (PAASCH), i, 1498.  
bile of. See Bile.  
blood of. See Blood.  
thyroid of. See Thyroid.
- Goitre**, relation between iodine content of environment and (v. FELLEBERG), i, 329.
- Gold** obtained from mercury, atomic weight of (HÖNIGSCHMID and ZINTL), ii, 924.  
formation of, from mercury (KAUL), ii, 177; (NAGAOKA), ii, 835, 1111; (STAMMEICH), ii, 1208.  
arc spectrum of (LOWERY), ii, 4.  
series spectrum of (McLENNAN and McLAY), ii, 913.  
spark spectrum of (L. and E. BLOCH), ii, 829.  
ultra-violet absorption spectrum of (ZUMSTEIN), ii, 453.  
X-ray absorption coefficient of (WARBURTON and RICHMYER), ii, 1103.  
photo-electric sensitivity of (SUHRMANN), ii, 831.  
physical state and catalytic activity of (SMITH), ii, 1072.

**Gold**, catalysis of hydriodic acid on the surface of (HINSHELWOOD and PRICHARD), ii, 981.  
 anodic oxidation of (JIRSA and JELINEK), ii, 54, 141.  
 anodic solution of, in hydrochloric acid (ALLMAND and PURI), ii, 302.  
 behaviour of, with fused silicates (JANDER), ii, 416.  
 colloidal, preparation of (ZSIGMONDY and HÜCKEL), ii, 775; (HADEN), ii, 895.  
 effect of proteins on (ZSIGMONDY and JOEL), ii, 35; (KREBS), ii, 1155.  
 films, emission of electrons from, exposed to Röntgen rays (SIMONS), ii, 81.  
 sols (v. WEIMARN), ii, 196; (GALECKI), ii, 516.  
 mobility of particles in (THIESSEN), ii, 1157.  
 protective action of gelatin on (TARTAR and LORAH), ii, 864.  
 action of proteins on (REINDERS), ii, 1059.  
 action of salts on (KERMAK and VOGEL), ii, 523.  
 protective action of soaps on (PAPACONSTANTINOU), ii, 393, 526.  
 "explosive," nature of (RASCHIG), ii, 144.  
**Gold alloys** with cadmium (SALDAU), ii, 872.  
 with copper (SEDSTRÖM), ii, 104.  
 gold-copper compound in (STERNER-RAINER), ii, 651.  
 with palladium, structure of (HOLGERSSON and SEDSTRÖM), ii, 20.  
 with zinc (SALDAU), ii, 205.  
 Röntgen-ray analysis of (WESTGREN and PHRAGMÉN), ii, 746.  
**Gold salts**, toxic action of, on protoplasm (VORGTLIN, JOHNSON, and DYER), i, 1116.  
 trypanocidal action of (LEVADITI, GIRARD, and NICOLAU), i, 1117.  
**Gold** amidine and iminochloride (RASCHIG), ii, 144.  
 selenides (MOSER and ATYNSKI), ii, 584.  
**Auric chloride**, preparation of (PETIT), ii, 1089.  
 dissociation of (PETIT), ii, 668.  
 compound of carbon monoxide and (MANCHOT and GALL), ii, 1182.  
 compounds of, with mercaptans (RAY), ii, 184.  
 telluride (BRUKI), ii, 895.  
**Aurous halides**, ammoniates of (BILTZ and WEIN), ii, 1182.

**Gold**:—  
**Chloroauric acid**, compounds of acid amides with (FRICKE and RUSCHHAUPT), ii, 894.  
**Gold detection and determination**:—  
 detection of (STEIGMANN), ii, 719.  
 detection of, spectrographically (JOLIBOIS and BOSSUET), ii, 1208.  
 determination of, electrometrically (ZINTL and RAUCH), ii, 1005.  
*Gonepteryx rhamni*, dye from the wing of (WIELAND and SCHÖPF), i, 1464.  
 Goose, catalytic hydrolysis of proteins from the feathers of (SADIKOV), i, 175.  
 Goppelsroeder's reaction (SCHANTL), ii, 440.  
**Gossypic acid**, gossypyl ester (FARGHER and HIGGINBOTHAM), i, 880.  
**Granite**, weathering of, under peat (BLANCK and RIESEB), ii, 820.  
**Grapes**, American, effect of seasons on constituents of the juice of (CALDWELL), i, 1368.  
 Concord, non-volatile acids of (NELSON), i, 762.  
**Grape fruit**, insulin-like substances in (FISHER and MCKINLEY), i, 1016.  
**Graphite**, structure of (BERNAL), ii, 17.  
 crystal structure of wurtzite and (BECKENKAMP), ii, 271.  
 heats of combustion of (ROTH and NAESER), ii, 1140.  
 melting point and vaporisation of (RYSCHKEVITSCH), ii, 276, 374; (FAJANS), ii, 277.  
 adsorption of gases by (LOWRY and MORGAN), ii, 1053.  
 "activated," sorption of oxygen by (BANGHAM and STAFFORD), ii, 665.  
 "Graphites" (CIUSA), ii, 1083.  
**Grass**, Appa. See *Ageratum conyzoides*.  
 inchi. See *Cymbopogon caesiis*.  
**Grignard reaction**, mechanism of (RHEINOLDT and ROLEFF), i, 6.  
 in presence of water (SCHMALFUSS and WETZEL), i, 895.  
**Grignard reagents**, constitution of (MEISENHEIMER), i, 527.  
 luminescence spectra of (DUFFORD, NIGHTINGALE, and CALVERT), ii, 89, 474.  
 action of aldehydes on (MARSHALL), i, 1423.  
 action of, on amino-acids (THOMAS and BETTZIECHE), i, 250, 251, 257; (BETTZIECHE), i, 251, 1147.  
 detection of, colorimetrically (GILMAN and SCHULZE), ii, 1011.  
**Growth**, effect of ultra-violet light on, of rats (HUME and SMITH), i, 211.  
 effect of radium emanation on, of rats (CHICK and TAZELAAR), i, 211.

- Growth**, factors promoting (v. EULER, WIDELL, and ERIKSON; v. EULER and WIDELL), i, 869; (v. EULER and ERIKSON), i, 1220.  
 influence of fluorides and iodides on (MAZÉ), i, 870.  
 on a vitamin-rich diet, action of ions on (TSUKAMOTO), i, 210.
- Guaiacol**, melting point of (PUSHIN), ii, 277.
- Guaiacol**, 4-amino-, acetyl derivative, acetate, and benzoyl derivative (KEHRMANN and HOEHN), i, 561.
- Guanidine** (PELLIZZARI), i, 1047.  
 and its methyl derivatives, distinction between (MARSTON), i, 1047.  
 double carbonates of rare earth metals and (CANNERI), i, 524.
- Guanidine**, nitro-, isomeric forms of (DAVIS, ASHDOWN, and COUCH), i, 644.
- Guanidines**, alkylated (LECHER, GRAF, and GNÄDINGER), i, 1392.  
 methylated, pharmacological action of (v. GRAEVENITZ), i, 734.  
 determination of, in urine (SHARPE), i, 722.
- Guanidine bases**, detection of, colorimetrically (TREGS), i, 97.  
 determination of, colorimetrically (MARSTON), i, 97.
- Guanidoacetic acid**, cyano-, and its salts and derivatives (FROMM, BARRENSCHEEN, FRIEDER, PIRK, and KAPPELLER), i, 595.
- Guanylic acid**, salts of (IZUMI), i, 174.  
 brucine and strychnine salts (PEISER), i, 1477.
- d-Gulose**, preparation of, by oxidation of d-sorbitol (TALEN), i, 1382.
- Gums**, enzymes of (FOWLER and MALANDKAR), i, 1437.
- Gum arabic**, replacement of blood by solutions of (UEKI), i, 177.
- Gum benzoin** sols, action of salts on (KERMACK and VOGEL), ii, 523.
- Gypsum**, lattice constants of calcite and (HJALMAR and SIEGBAHN), ii, 92.  
 solubility of (COLSON), ii, 37.

## H.

- isoHamagglutinin**, physical chemistry of (WÖHLISCH and SCHÜTZ), i, 171.
- Hamatin**, natural pigments resembling (SCHUMM), i, 854.
- Hamatite**, crystal structure of (PAULING and HENDRICKS), ii, 368.  
 transformation of magnetite into (WATO and BAUDISCH), ii, 845.
- Hematoïdia**, identity of bilirubin and (RICH and BUMSTEAD), i, 1475.
- Hæmatoporphyrin**, fluorescence of (FABRE), ii, 1116.  
 metallic derivatives, absorption spectra of (HILL), i, 994.  
 fluorescence of (DHÉRE, SCHNEIDER, and VAN DER BOM), ii, 88.  
 detection of, in urine (POLICARD and LEULIER), i, 1351.
- Hæmin**, formation of porphyrin from (KÜSTER and HUTTENLOCHER), i, 845.  
 esterification of (ZALESKI and LINDENFELD), i, 89.  
 derivatives of (KÜSTER and HEES), i, 992.
- Hæmin**, hydroxy- (HANSIK), i, 1476.
- Hæmochromogen** (ANSON and MIRSKY), i, 1475.  
 carbon monoxide dissociation curve of (ANSON and MIRSKY), i, 456.
- Hæmocyanin** (STEDMAN and STEDMAN), i, 1199.
- Hæmoglobin**, osmotic pressure of (WILSON), ii, 292; (ADAIR), ii, 965.  
 ionic nature of (TAYLOR), i, 93.  
 surface tension of (JOHLIN), ii, 857.  
 kinetics of reactions of (HARTBRIDGE and ROUGHTON), ii, 557.  
 parent substance of (MARCHLEWSKI), i, 604.  
 oxidation-reduction of (NEILL), i, 868, 993.  
 influence of tension of oxygen on oxidation of (NEILL and HASTINGS), i, 709.  
 oxygen-combining capacity of (MASUDA), i, 604.  
 oxygen dissociation curve of (ADAIR), i, 851.  
 and its derivatives, hydrolysis of starch by (BIEDERMANN and JERNAKOFF), i, 11.  
 formation of bilirubin from (RICH), i, 711; (RICH and BUMSTEAD), i, 1482.  
 formation of porphyrin from (SCHUMM), i, 88.  
 action of digestive enzymes on the iron of (LINTZEL; BARKAN), i, 1482.  
 ultra-violet absorption spectra of derivatives of (FRIEDLI), ii, 179.  
 nitric oxide compound of (ANSON and MIRSKY), i, 1475.  
 non-protein component of (ANSON and MIRSKY), i, 1475, 1476.  
 storage and excretion of, in the organism (SHIMURA), i, 1342.  
 reactions of (ADAIR), i, 849, 850, 851.  
 determination of (NEWHAM, WILTSHIRE, and SCHARFF), i, 711.

- Hæmoglobin**, determination of, colorimetrically (KÄMMERER and SCHAULIN), i, 851.  
 use of acetylene in determination of (MILLER), i, 1112.
- Hæmoglobinometer**, new (BÜRKE), i, 177.
- Hæmoleucolysin** from the pancreas (BELFANTI), i, 326.
- Hæmolysis**, effect of blood serum and of sugars on (KENNEDY), i, 717.  
 specific (KLOPSTOCK), i, 1345.
- Hæmolysis**, colloidal theory of (HERRMANN and ROEHRER), i, 1202.  
 conductivity of red blood corpuscles during (PONDER and TAYLOR), i, 1202.
- Hæmometer**, Sahli's, standard solution for (KOUIMANS), i, 851.
- Hæmoporphyrin**, conversion of into mesoporphyrin and ætioporphyrin (FISCHER and MÜLLER), i, 845.
- Hafnium**, discovery and properties of (v. HEVESY), ii, 708.  
 atomic weight of (HÖNIGSCHMID and ZINTL), ii, 255, 347; (v. HEVESY), ii, 255.  
 preparation of (VAN ARKEL and DE BOER), ii, 1193.  
 content of, in zirconium ores (v. HEVESY and JANTZEN), ii, 430.
- Hafnium double fluorides**, solubility of (v. HEVESY, CHRISTIANSEN, and BERGLUND), ii, 505.  
 oxide, density of (v. HEVESY and BERGLUND), ii, 25.  
 in tungsten filaments (VAN LIEMPT), ii, 233.  
 phosphate (v. HEVESY and KIMURA), ii, 1085.  
 solubility of zirconium phosphate and (v. HEVESY and KIMURA), ii, 1147.
- Hafnium separation**:—  
 separation of, and its arc spectrum (BARDET and TOUSSAINT), ii, 826.  
 separation of, from cerium, thorium, and titanium (MOSER and LESSING), ii, 718.  
 separation of zirconium and (NAAM-LOOZE VENOOTSCHAP PHILIPS' GLOELAMPENTFABRIKEN), ii, 62, 63; (DE BOER and VAN ARKEL), ii, 243; (v. HEVESY and MADSEN), ii, 425; (MARQUIS, P. and G. URBAIN), ii, 699.
- Hair**, hydrolysis of (MERRILL), i, 92; (HOFFMAN), i, 1480.  
 substance giving the nitroprusside reaction in (KAYE), i, 180.
- Halides**, action of water on (SIDGWICK), ii, 102.
- Halides of elements of the fourth group**, melting points of (HANTZSCH and CARLSOHN), ii, 1043.  
 inorganic, reduction of (RUFF and THOMAS), ii, 1187.  
 organic, structure of, and their reactions with inorganic iodides (CONANT and HUSSEY), i, 493; (CONANT, KIRNER, and HUSSEY), i, 494.
- Hall coefficient**, relation of, to thermoelectric power (HEAPS), ii, 1135.
- Hall effect** in crystals (LENZ), ii, 920.
- Halochromic salts**, electrochemistry of, in relation to free radicals (CONANT, SMALL, and TAYLOR), ii, 874.
- Halogens**, photochemistry of (BERTHOUD and BELLENOT), ii, 141.  
 spectra of (STEBING), ii, 452.  
 ultra-violet emission spectra of (LUDLAM and WEST), ii, 350.  
 action of light on air saturated with vapour of (JONES), ii, 984.  
 electron affinity of (LUDLAM), ii, 1018; (v. ANGERER and MÜLLER), ii, 1025.  
 lability of, in organic compounds (MAOBETH and TRAILL), i, 628, 782.  
 reaction of saturated aliphatic ketones with (RICE and FRYLING), ii, 556.  
 reaction of potassium cyanide with (MÜLLER and SCHUCH), ii, 825.  
 determination of, in organic compounds (BUSCH), ii, 823.
- Halogens** (BROCKENBACH and KELLERMANN), ii, 568.
- Halogen compounds**, partial dehalogenation of (MEREJKOVSKI), i, 878.  
 reaction of siloxen with (KAUTSKY and THIELE), ii, 698.
- Halogen hydrides**, structure and nature of (HANTZSCH), ii, 359; (v. WISNIEWSKI), ii, 361.
- Halogen organic compounds**, action of alkali disulphides and of sodium tetrasulphide on (THOMAS and RIDING), i, 113.  
 reactions of sodium arsenite with (GUTMANN), ii, 238.
- Halogenation** (DATTA and CHATTERJEE), i, 891.
- Hamamelitannin**, and its derivatives (FREUDENBERG and BLÜMMEL), i, 51.
- Hay fever**, analysis of blood in (RAMIREZ, St. GEORGE, and MOSES), i, 999.
- Heart**, frog's, action of calcium and sodium ions on (HOLZLÖHNER), i, 1500.  
 action of potassium cyanide and copper on (FUJIMAKI), i, 338.

- Heat, atomic, of solid aliphatic crystals** (SALANT), ii, 1042.
- latent, determination of** (SMITH), ii, 756.
- molecular, of gases, at low temperatures** (GIACOMINI), ii, 757.
- of diatomic gases at low temperatures** (SCHREINER), ii, 97.
- specific** (WIESNER), ii, 275, 737.
- at low temperatures** (LANGE), ii, 96.
- and viscosity** (DE KOLOSOVSKI), ii, 870.
- of electrolytes** (ZWICKY), ii, 1138.
- of gases** (BRINKWORTH), ii, 373.
- of liquids** (GHOSH), ii, 275; (SCHULZE), ii, 491; (FOA), ii, 1138.
- of binary mixed liquids** (WILLIAMS and DANIELS), ii, 765.
- of organic liquids** (BUSSE), ii, 373.
- of metals** (BEHRENS and DRUCKER), ii, 24.
- of solutions** (DE KOLOSOVSKI), ii, 653, 791.
- of aqueous solutions** (RICHARDS and GUCKER), ii, 848.
- Heat of combustion** (JAEGER and v. STEINWEHR), ii, 126.
- standard values for** (VERKADE), ii, 871.
- of members of homologous series** (VERKADE, HARTMAN, and COOPS), ii, 364.
- of organic compounds** (VERKADE, COOPS, and HARTMAN), ii, 490.
- in relation to valency of organic compounds** (KHARASCH and SHER), ii, 636.
- Heat of dilution and solution of salts** (WÜST and LANGE), ii, 791, 796.
- Heat of evaporation of electrons** (WEIGLE), ii, 253.
- Heat of formation of alloys** (BILTZ and HOLVERSCHUIT), ii, 268.
- of onium compounds** (TSCHELINCSEV), ii, 480.
- Heat of fusion, latent** (STRATTON and PARTINGTON), ii, 25.
- Heat of hydration of alkali halides** (LANGE), ii, 847.
- Heat of mixture of condensed systems** (VAN LAAR and LORENZ), ii, 870.
- Heat of oxidation of pure metals** (MOORE and PARR), ii, 208.
- Heat of reaction, incomplete** (BÉRENGER and TIAN), ii, 791.
- dissipation of** (BOHN and FRANCK), ii, 365.
- Heat of solution** (BÉRENGER and TIAN), ii, 790; (WÜST and LANGE), ii, 791.
- Heat of solution, determination of** (COHEN, MOESVELD, and HELDERMAN), ii, 402.
- calorimeter for** (COHEN, MOESVELD, and HELDERMAN), ii, 151.
- solubility and lattice energy of salts** (BUTLER), ii, 39.
- of alkali halides** (LANGE), ii, 847.
- partial, relation between, and the deviation from Raoult's law** (BUTLER), ii, 539.
- Heat of vaporisation** (BYK), ii, 97.
- molecular** (PRUD'HOMME), ii, 188; (NARBUTT), ii, 1140.
- relation between surface tension and** (PLACINTEANU), ii, 39.
- of liquids in relation to the velocity of sound** (IONESCU), ii, 644.
- Hederagic acid, and its methyl esters** (JACOBS), i, 948.
- Hederagenic acid, methyl ester, and its derivatives** (JACOBS), i, 948.
- Hederagenin, structure of** (VAN DER HAAR), i, 946.
